The best choices for treatment depend on the biologic mechanisms causing excess uric acid. The many causes of hyperuricemia may be divided into two groups. The first group involves renal underexcretion, where hyperuricemia can be treated with uricosuric drugs or XOR inhibitors. The second group involves renal overload, which includes disorders where uric acid is overproduced in the body or underexcreted by the gut. Hyperuricemia associated with renal overload should be treated with XOR inhibitors, not with uricosuric drugs that further increase the burden of uric acid handled by the kidneys. Rasburicase is usually reserved for the transient marked increases in serum uric acid associated with tumor lysis syndrome. Pegloticase is usually reserved for the treatment of gout resistant to other medications.

These medications are usually combined with generous hydration to provide a constant flow of associated purine metabolites from the body. A low-purine diet is sometimes recommended as well. Some foods contain large amounts of purines, such as dried or cured meats (sardines, anchovies) and organ meats (thymus, kidney, liver). Fructose and alcohol also should be avoided because they stimulate purine turnover and result in increased uric acid production.

THE HEREDITARY XANTHINURIAS

The hereditary xanthinurias are a group of autosomal recessive disorders defined by high levels of xanthine in the urine, along with low or nondetectable serum uric acid. The estimated incidence is 0.5-1 per 100,000 live births. The metabolic abnormalities result from deficiency of XOR, the enzyme that converts hypoxanthine and xanthine into uric acid (see Fig. 110.2). XOR exists in two forms, sometimes called *xanthine oxidase* or *xanthine reductase,* both with a molybdenum-containing cofactor at the active site. These two forms are encoded by the same gene. Xanthine oxidase is derived from posttranslational modification of xanthine reductase.

Although the hereditary xanthinurias all result from XOR deficiency, distinct molecular mechanisms define three different groups. **Hereditary xanthinuria type I** is caused by pathogenic variants in the *XOR* gene. **Hereditary xanthinuria type II** is caused by pathogenic variants in the *MOCOS* gene, which encodes molybdenum cofactor sulfurase, an enzyme that sulfurates the molybdenum cofactor required for XOR as well as the enzyme aldehyde oxidase. As a result, hereditary xanthinuria type II is characterized by combined deficiency of XOR and aldehyde oxidase. The **third type of hereditary xanthinuria** is caused by defects in the synthesis of the molybdenum cofactor. Molybdenum cofactor deficiency has been linked with four genes: *MOCS1* (molybdenum cofactor synthase 1), *MOCS2* (molybdenum cofactor synthase 2), *MOCS3* (molybdenum cofactor synthase 3), and *GPHN* (gephyrin). *MOCS1* accounts for two thirds of all cases. All are required for the synthesis of the molybdenum cofactor, which is used by four enzymes including XOR, aldehyde oxidase, sulfite oxidase, and mitochondrial amidoxime reducing component. As a result, the molybdenum cofactor deficiencies are characterized by the combined defects of all four enzymes.

Clinical Features

The clinical features of hereditary xanthinuria type I caused by isolated XOR deficiency may be benign. Many individuals are asymptomatic. The increased excretion of xanthine leads to kidney stones in approximately one third of individuals. These stones may develop any time from early childhood through later adulthood. Clinical signs may be acute with dysuria, hematuria, renal colic, or a history of recurrent urinary tract infections. Alternatively, affected individuals may present with acute or chronic renal failure. Xanthine stones, like other purine stones, are radiolucent; they are detectable with ultrasound but may be missed on abdominal plain films or CT unless they calcify. Some individuals may develop myopathy after strenuous exercise with xanthine crystals in muscle because of the rapid turnover of purines associated with exercise.

The clinical features of combined deficiency of XOR and aldehyde oxidase in hereditary xanthinuria type II are similar to those of type I. There appears to be no obvious clinical impact of the added deficiency of aldehyde oxidase.

Table 110.2 Disorders Influencing Uric Acid

DISORDER	GENE SYMBOL	SERUM URIC ACID	URINARY URIC ACID
Hereditary xanthinurias			
Type I	*XOR*	↓↓	↓↓
Type II	*MOCOS*		
Molybdenum cofactor deficiencies	*MOCS1-3, GPHN*		
HPRT1-associated disorders	*HPRT1*	↑	↑↑
PRPP dysregulation disorders	*PRPS1*	↑	↑
Excretion disorders			
Renal hypouricemia	*SLC22A12, SLC2A9*	↓↓	↑↑
Reduced gut excretion	*ABCG2*	↑	↑
Carbohydrate disorders			
Fructosemia	*ALDOB*	↑ (chronic or exercise-induced)	↑ (chronic or exercise-induced)

The clinical features of the **molybdenum cofactor deficiencies** are more severe. Individuals often present with failure to thrive during infancy, difficulties feeding, intractable seizures, psychomotor delay, and microcephaly. Brain MRI may show diffuse atrophy or cerebellar hypoplasia, multicystic encephalomalacia, and signal abnormalities of the globus pallidus. Eye findings may include ectopic lens, spherophakia, and nystagmus. Most die in early childhood.

Because uric acid is included in many routine blood chemistry screening panels, the diagnosis of the hereditary xanthinurias often starts with serendipitous identification of low or absent uric acid. Instead, urinary xanthine and hypoxanthine are elevated. However, xanthine is elevated more than hypoxanthine, because the latter can be recycled by HGprt or cleared by the kidneys. In individuals with hereditary xanthinuria type II with combined deficiency of XOR and aldehyde oxidase, urinary methyl-2-pyridone-carboxamide also is low or absent. The characteristic pattern observed among individuals with the molybdenum cofactor deficiencies includes low uric acid in serum and urine along with high urinary xanthine, hypoxanthine, sulfite, and S-sulfocysteine. Enzymatic tests for XOR are feasible but not commonly used for clinical diagnosis. They require biopsy of the liver or small bowel where the amounts of this enzyme reach high enough levels for measurement. A convenient test for aldehyde oxidase involves assessing its ability to oxidize a test dose of allopurinol to oxypurinol. Sulfite oxidase and molybdenum cofactor can be measured in liver or fibroblasts. A molecular diagnosis can be made by finding pathogenic variants in one of the relevant genes.

Treatment and Prognosis

The treatment of all hereditary xanthinurias involves generous hydration to constantly flush xanthine from the renal collecting system to avoid stone formation. Hydration is sometimes combined with a low-purine diet.

Aside from palliative care, minimal success has been achieved with numerous approaches to the treatment of the molybdenum cofactor deficiencies. However, cyclic pyranopterin monophosphate (fosdenopterin) can have a life-changing impact on the normally serious consequences of molybdenum cofactor deficiency associated with *MOCS1*. Treatment has been reported to normalize metabolic measures and allow near-normal development among individuals who start it at a very early age before there is significant brain damage. It is approved for use in individuals with *MOCS1* defects by the U.S. Food and Drug Administration (FDA).

HPRT1-ASSOCIATED DISORDERS

Disorders associated with the *HPRT1* gene are rare, with an overall prevalence of approximately three cases per million. Inheritance is X-linked and recessive, although sporadic cases are not uncommon. The gene encodes hypoxanthine-guanine phosphoribosyl transferase (HGprt), an enzyme responsible for two different reactions (see Fig. 110.2). In one reaction, the cosubstrate phosphoribosyl pyrophosphate (PRPP) is combined with the purine base hypoxanthine to produce IMP. In the other reaction, PRPP is combined with guanine to produce GMP. IMP and GMP are then recirculated into the nucleotide pools. When HGprt activity is impaired, its substrates accumulate. Accumulation of PRPP leads to excessive drive of purine synthesis, because PRPP is also used in the first and rate-limiting reaction of the de novo synthetic pathway. The substrates hypoxanthine and guanine also accumulate, and they are ultimately catabolized to uric acid. The combination of accelerated purine synthesis and increased catabolism of hypoxanthine and guanine results in a marked overproduction of uric acid. This overproduction of uric acid is responsible for several clinical features of *HPRT1*-associated disorders, including hyperuricemia, nephrolithiasis, gout, and tophi.

Overproduction of uric acid *is not* responsible for all the clinical features of HGprt deficiency. Reduced HGprt activity also leads to impaired recycling of hypoxanthine and guanine, with purine wasting. This loss of purines may lead to purine deficiency, especially in tissues where the synthetic pathway cannot compensate for purines lost due to the failure of recycling. Erythrocytes lack a fully operational synthetic pathway, so they are dependent on recycling purines taken up from the blood to maintain purines. These observations may account for *macrocytic anemia,* which is common in *HPRT1*-associated disorders.

A similar mechanism may occur in the brain, where purine recycling is important because purine synthesis is relatively low. In individuals

with HGprt deficiency, overt structural malformations are not usually found when performing routine clinical CT or MRI of the brain. Such studies are usually normal or they show only mild diffuse atrophy. However, advanced imaging methods have revealed several abnormalities. Quantitative MRI-based, voxel-based morphometry has revealed subjects with *HPRT1*-associated disorders to have volume loss in several brain regions. Similar studies, along with diffusion tensor imaging MRI, have revealed diffuse loss of white matter. The basal ganglia appear to be more affected than most other regions. In fact, PET scans have revealed a significant reduction in markers associated with basal ganglia dopamine systems.

Autopsy studies of the brains of individuals with *HPRT1*-associated disorders do not show signs of maldevelopment or neurodegeneration. Dopamine neurons are present, but they do not express normal levels of dopamine-related markers. Dysfunction of the basal ganglia is thought to be responsible for several of the neurologic features of *HPRT1*-associated disorders, including dystonia and self-injurious behavior. Dysfunction of corticospinal pathways may be responsible for cognitive impairment, spasticity, and seizures.

Clinical Features

Pathologic genetic variants in *HPRT1* are associated with a spectrum of clinical phenotypes (Fig. 110.4). Most cases are males, although rare females with defects in both *HPRT1* alleles have been described. More than 600 different gene variants are known. A complete loss of HGprt function is associated with most of these variants, such as deletions, insertions, nonsense substitutions, and some single amino acid substitutions. A partial loss of HGprt function is associated with other variants, usually conservative single amino acid substitutions and some splice variants.

The severity of the clinical phenotypes is related to the degree of associated enzyme impairment. The spectrum of clinical phenotypes is usually subdivided into three overlapping groups. *HPRT1* variants associated with a mean value of 12% of normal HGprt activity are associated with the mildest clinical phenotype. This phenotype is known as **HGprt-related hyperuricemia**. These individuals experience overproduction of uric acid, along with associated problems of hyperuricemia, nephrolithiasis, gout, and tophi. These individuals do not have overt neurologic or behavioral problems, although mild clumsiness or mild cognitive impairments may be disclosed with careful testing. The age at presentation ranges from infancy to adulthood, usually with renal problems or gout.

HPRT1 variants associated with a mean of 7% of normal HGprt activity are associated with an intermediate phenotype with overproduction of uric acid along with clinically overt neurologic impairments. This phenotype is known as **HGprt-related neurologic dysfunction**. Motor impairments vary widely and may range from minor clumsiness to a phenotype that resembles severe dyskinetic cerebral palsy. Cognitive deficits may range from attention-deficit disorder to moderate intellectual disability. These individuals typically present with delayed motor development, although some present with renal problems or gout.

HPRT1 variants associated with a mean value of 1% normal HGprt activity are associated with the most severe phenotype, known as **Lesch-Nyhan disease**. These individuals have overproduction of uric acid, disabling motor impairments, moderate intellectual disability, and an unusual behavioral syndrome. The motor problems begin with delayed development in infancy and evolve similar to severe dyskinetic cerebral palsy. Epilepsy is common. The most characteristic aspect of the behavioral syndrome is severe recurrent self-injury, with self-biting, self-hitting, recurrent scratching or poking, and others. Self-injury typically begins between 2 and 4 years of age but may be delayed until the teenage years. Other difficult behaviors are also common, such as impaired attention and impulsivity. Difficult behaviors may be also directed toward others. They include use of language that is foul, sexually inappropriate, or racially charged. Also frequent are hitting, grabbing, or spitting.

The diagnosis of any *HPRT1*-associated disorder should be suspected in a child or young adult with evidence for overproduction of uric acid such as hyperuricemia, uric acid nephrolithiasis, or gout. Uric acid (pink) crystals in diapers during infancy are frequently the first clue. Suspicion for an *HPRT1*-associated disorder increases when there is evidence for overproduction of uric acid along with a history of delayed motor development. The emergence of self-injurious behavior between 2 and 4 years of age often provides a more specific clue for Lesch-Nyhan disease. A definitive diagnosis requires demonstration of a pathogenic variant in the *HPRT1* gene and/or enzymatic evidence for reduced HGprt function.

Treatment and Prognosis

For all *HPRT1*-associated disorders, excessive production of uric acid must be treated to avoid renal complications and gouty arthritis. Treatment requires a lifelong combination of an inhibitor of XOR to reduce production of uric acid and generous hydration. The commonly used XOR inhibitor is allopurinol, although others can also be used. Doses are titrated to maintain serum uric acid within normal limits. Stones may continue to form despite treatment, and lithotripsy or surgical removal is sometimes required. High doses of XOR inhibitors that reduce serum uric acid to very low levels are discouraged, because this approach increases the risk of stones composed of the precursors xanthine and hypoxanthine. Some specialists advocate alkalinization of the urine to promote solubility of uric acid or a low-purine diet to reduce intake of purines that are metabolized to uric acid.

The motor disorder is dominated by dystonia, sometimes with spasticity. The increased muscle tone associated with these problems is most often treated with muscle relaxants such as benzodiazepines or baclofen. Anticholinergics and dopamine-related drugs are not generally successful. Several case reports describe great success with deep brain stimulation surgery, but the rate of surgical complications is unusually high, and the overall risk-benefit ratio does not favor universal recommendation of this approach.

The behavioral problems require a combination of physical protective devices, specific behavioral modification techniques, and sometimes pharmacotherapy. Most individuals with Lesch-Nyhan disease require regular restraints of the hands and arms to prevent self-hitting and biting of the fingers. Approximately half of all individuals require tooth removal to prevent biting of the lips and tongue. A custom-designed wheelchair with dangerous regions shielded is often needed. The most useful behavioral techniques involve extinction (ignoring) and redirection (distraction). Methods that use positive reinforcement are useful, but methods that use negative reinforcement amplify negative behaviors.

Individuals with the mildest clinical phenotypes may have a normal life span, provided uric acid is well-managed. Those with more severe phenotypes have a shorter life span, with death occurring in the teens through the fifth decade. Most frequent causes of death include aspiration pneumonia or complications from renal dysfunction. Cases of sudden unexplained death have also been reported.

APRT-ASSOCIATED DISORDERS

Disorders associated with the *APRT* gene are rare, with fewer than 1,000 individuals reported. More than 200 pathogenic variants have been described. Inheritance is autosomal recessive. The disorder has been reported worldwide, but there are clusters of individuals with the same genetic variants originating in Japan, France, and Iceland.

The *APRT* gene encodes adenine phosphoribosyl transferase (APRT), an enzyme that is responsible for catalyzing a reaction in which PRPP is combined with the purine base adenine to produce AMP (see Fig. 110.2). Deficiency of APRT leads to accumulation of adenine, which is metabolized by XOR into 2,8-dihydroxyadenine (DHA). DHA does not accumulate in serum because it is rapidly cleared by the kidneys. Because solubility of DHA is poor, it precipitates in the urinary collecting system as either small crystals or larger stones. Small crystals cause chronic renal insufficiency because they provoke tubulointerstitial nephritis, inflammation, and fibrosis. Larger stones may cause acute obstructive renal failure.

Clinical Features

Clinical manifestations are attributable to the kidneys, and they may develop in a wide age range from infancy through adulthood.

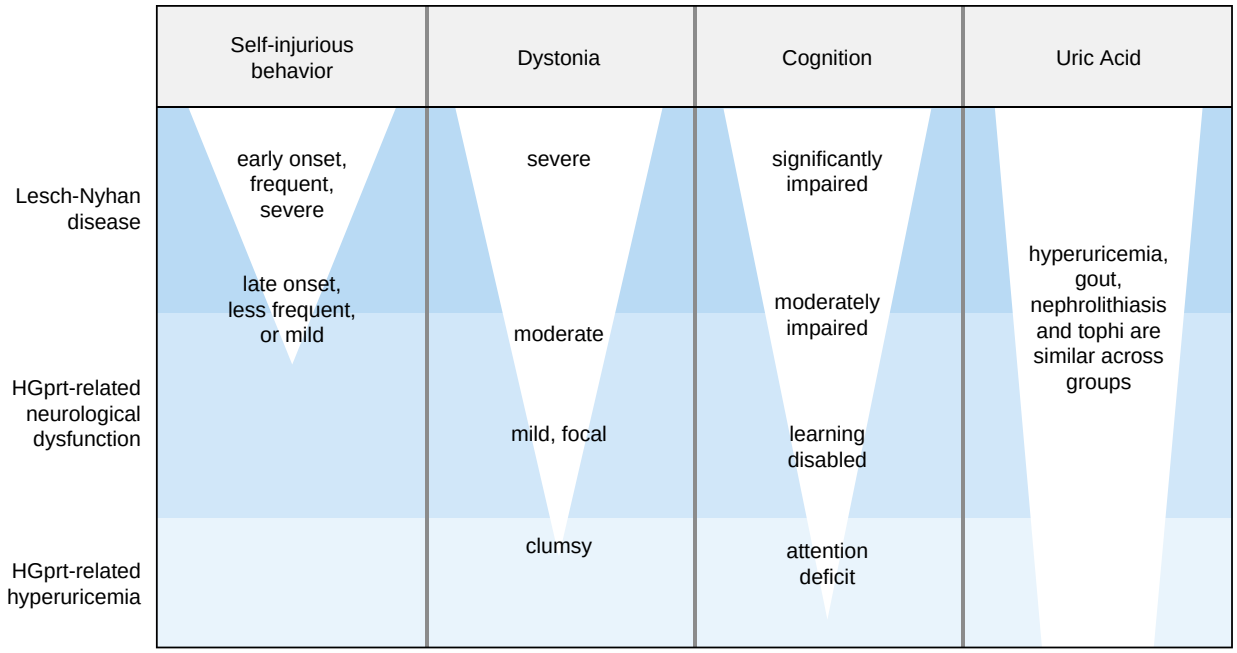

Fig. 110.4 *HPRT1*-associated disorders. This schematic provides a graphical representation of the overlapping spectrum of *HPRT1*-associated disorders. The three disorders are listed on the left side of the panel. The most common clinical features are shown in the top row. The *white triangles* depict the severity of individual clinical features for each of the disorders. For example, problems related to overproduction of uric acid occur in all phenotypes, but self-injurious behavior is limited to the most severe phenotype. Dystonia and cognition both show a wide range of severity across all groups, but severity correlates with overall phenotypic subgroup. This schematic provides only a general guide, as some exceptions may occur. (*Copyright H.A. Jinnah.*)

Approximately half of individuals with APRT deficiency have no symptoms, or symptoms may develop only in old age. The initial presentations fall into two groups which may overlap: nephrolithiasis and DHA nephropathy. Individuals with nephrolithiasis may present acutely with dysuria, hematuria, renal colic, or recurrent urinary tract infections. They may describe accompanying crystals, larger stones, or gravel in the urine. The precipitates are often reddish-brown in color and easily crushed. Alternatively, DHA nephropathy may result in a more slowly evolving renal insufficiency, with approximately 15% first presenting with end-stage renal failure.

The diagnosis should be suspected when there is evidence for crystalluria or nephrolithiasis, especially in a child. DHA stones, like other purine stones, are radiolucent. Unless they calcify, they may be detected via ultrasound but not with abdominal plain films or CT. The diagnosis may also be suspected in individuals with unexplained renal failure who undergo renal biopsy revealing a crystallopathy with tubulointerstitial nephritis, inflammation, and/or fibrosis. APRT deficiency must be distinguished from other disorders that involve nephrolithiasis and/or renal failure.

Commonly used clinical biochemical methods may not be able to distinguish DHA stones from other purine stones, but more specific methods have been developed at some specialized centers. DHA crystals in the urine can also be identified by light and polarizing microscopy, along with infrared spectrophotometry. Crystals in renal biopsy specimens can be identified by polarizing microscopy with infrared microscopy. Definitive diagnosis can also be achieved by measuring APRT enzyme activity in erythrocytes or by documenting pathogenic variants in the *APRT* gene.

Treatment and Prognosis

Treatment requires an inhibitor of XOR to reduce production of DHA. The commonly used XOR inhibitors include allopurinol or febuxostat, and they must be continued lifelong. Generous hydration is useful to flush purine metabolites through the renal collecting system. A low-purine diet is sometimes recommended. Large stones may require lithotripsy or surgical removal. Individuals who are diagnosed early in life and adhere to therapy may have a normal life span. Individuals who are diagnosed late may have chronic renal insufficiency or even renal failure that requires dialysis or kidney transplantation.

DISORDERS ASSOCIATED WITH AMP-DEAMINASE

The enzyme AMP-deaminase catalyzes the deamination of AMP to IMP with simultaneous production of NH_3. The IMP can then be recirculated either to AMP or GMP (see Fig. 110.2). The enzyme is encoded by three homologous genes. *AMPD1* is expressed predominantly in muscle, *AMPD2* is broadly expressed with high levels in the brain, and *AMPD3* is broadly expressed at high levels in bone marrow cells. Each gene has been associated with genetic variants producing null enzyme activity.

Clinical Features

For *AMPD1,* approximately 20% of White and Black individuals have a c.34C>T variant producing an early termination codon (p.Q12>X) in exon 2. In these populations, 1–2% are homozygotes with null enzyme activity in muscle. Most homozygotes have no symptoms, but **myopathic features** have been reported for some. These features include exercise intolerance with fatigue or myalgia, sometimes with muscle cramping or increased serum creatine kinase. Symptoms may begin at any age from early childhood to later adulthood. Histochemical stains for AMP-deaminase are negative in muscle biopsy specimens, but frank myopathic features are usually lacking. Because of the large numbers of nonsymptomatic individuals, the role of the genetic variant in causing symptoms is not clear. The variant may be benign, or it may combine with other genes or factors to cause symptoms. A diagnosis can be made via the forearm exercise test with measures of lactate and NH_3 production, histochemical staining of the enzyme in a muscle biopsy, or finding a variant in the *AMPD1* gene.

For *AMPD2,* pathogenic variants have been linked with **pontocerebellar hypoplasia** (PCH9). This neurologic disorder is rare, with fewer than 50 cases reported worldwide. Pontocerebellar hypoplasia is a group of disorders described by dysgenesis of the pons and cerebellum. Individuals with the PCH9 subtype also have dysgenesis of the

corpus callosum and microcephaly. Clinical symptoms include severe psychomotor delay, central visual impairment, and seizures.

ADSL-ASSOCIATED DISORDERS

Disorders associated with the *ADSL* gene are rare, with fewer than 100 individuals reported. The disorder is autosomal recessive. Pathogenic gene variants with complete loss of enzyme activity are likely incompatible with life. The pathogenic variants associated with disease produce a partial loss of enzyme function. The enzyme is bifunctional, and it mediates two distinct reactions in purine synthesis (see Fig. 110.2). Reduced enzyme function leads to accumulation of succinylpurines (succinyl-aminoimidazole carboxamide riboside and succinyl-adenosine), which are eliminated in the urine. Historically, this disorder was therefore called succinyl-purinuria. The clinical manifestations are thought to result predominantly from pathologic effects of succinyl purines in the brain. Brain MRI reveals varied findings from nearly normal to global or regional atrophy with delayed myelination.

Clinical Features

The clinical manifestations are often described in three distinct groups, but the groups overlap with a graded spectrum of severity. The most severely affected group is described as a **fatal neonatal encephalopathy**. These individuals have a severe paucity of spontaneous movement from birth, intractable seizures, and respiratory failure. They die within the first weeks of birth. Individuals in the **intermediate group** (type I) present with hypotonia and motor delay. They survive for longer periods, with moderate to severe psychomotor delay and seizures. Abnormal behaviors have been described as autistic with poor eye contact, repetitive stereotyped movements or sounds, and frequent agitation. The least severely affected group is referred to as **type II**. They present within the first years of life with evidence for psychomotor delay, sometimes with seizures and behavioral problems. The diagnosis is made by finding elevated succinyl purines in urine or cerebrospinal fluid (CSF) or by finding pathogenic variants in the *ADSL* gene.

Treatment and Prognosis

Treatment is palliative. Seizures may be refractory to conventional anticonvulsants, but some success has been reported with the ketogenic diet.

OTHER INHERITED PURINE DISORDERS

Adenosine Deaminase

Deficiency of adenosine deaminase results in **severe combined immunodeficiency syndrome (SCID)**, with defects in both humoral (B cells) and cellular (T cells) immunity. Individuals with severe SCID present shortly after birth with life-threatening infections. Individuals with milder disease may present at 2-4 years of age, or even older (see Chapter 165.1). In contrast with adenosine deaminase deficiency, superactivity of the same enzyme causes hemolytic anemia.

Adenosine kinase. Adenosine kinase is sometimes considered among the purine salvage enzymes because it recycles adenosine into adenosine monophosphate (AMP). Pathogenic variants of the associated *ADK* gene in multiple cases from independent families have been linked with hypermethioninemia, psychomotor delay, seizures, and multiple dysmorphic features. The disorder is autosomal recessive.

Adenylate kinase. There are four isoforms of adenylate kinase encoded by genes *AK1-4*. The enzyme phosphorylates AMP to ADP (see Fig. 110.2). The *AK1* gene is highly expressed in erythrocytes. Pathogenic variants in *AK1* in multiple cases from independent families have been linked with nonspherocytic hemolytic anemia, sometimes with cognitive disability.

The *AK2* gene is more broadly expressed but localizes to mitochondria. Pathogenic variants in *AK2* in multiple cases from independent families have been linked with reticular dysgenesis, a type of SCID, often with sensorineural hearing loss. Disorders associated with *AK1* and *AK2* are autosomal recessive.

Adenylosuccinate synthase. The *ADSS* gene encodes adenylosuccinate synthase, an enzyme involved in the conversion of IMP to AMP (see Fig. 110.2). There are multiple isoforms, and pathogenic variants in *ADSSL1* have been linked with a form of **myopathy**, **MPD5**. The disorder is autosomal recessive, usually begins in adolescence, and is slowly progressive. One study of affected individuals indicated that distal leg weakness was the most common feature, often with weakness of the hands. Approximately one third had weakness of the face or jaw muscles leading to difficulty with mastication. Some had left ventricular hypertrophy. Involvement of the diaphragm may lead to respiratory insufficiency in later stages of the illness.

ATIC-associated disorders. Disorders associated with the *ATIC* gene are very rare. Only four cases from three families have been reported. The disorder is autosomal recessive. The enzyme is bifunctional and mediates two distinct reactions (see Fig. 110.2). Complete loss of the enzyme is probably incompatible with life. Reduced enzyme function leads to accumulation of ZMP along with its phosphorylated derivatives. ZMP and its derivatives can be detected with the Bratton-Marshall test, a routinely used neonatal screen in some countries. All reported cases had prenatal and postnatal growth restriction, severe to profound psychomotor delay, chorioretinal atrophy with severe visual impairment, and dysmorphic facial features. Some had epilepsy. Treatment is palliative.

Deoxyguanosine kinase. The *DGK* gene encodes deoxyguanosine kinase, an enzyme that phosphorylates deoxypurine nucleosides into their respective deoxynucleotides for DNA synthesis (see Fig. 110.2). The gene is encoded by the nucleus, but the enzyme functions in mitochondria. Gene defects lead to an impairment of mitochondrial DNA synthesis, so the disorder is classified among the mitochondrial DNA depletion disorders. The disorder is rare and inherited in an autosomal recessive fashion. The clinical features reflect an early-onset multiorgan disorder, most notably liver failure, and psychomotor delay.

IMPDH-associated disorders. IMP-dehydrogenase is an enzyme that stands at a branchpoint in purine metabolism, directing the synthesis of purines toward guanine-based nucleotides rather than adenine-based nucleotides (see Fig. 110.2). This enzyme has two isoforms encoded by distinct but homologous genes. The *IMPDH1* gene is expressed primarily in the retina, whereas the *IMPDH2* gene is expressed in most other tissues. Disorders associated with these genes are rare, with only a handful of families reported.

Pathogenic variants in *IMPDH1* have been linked with **autosomal dominant retinopathy**. Affected individuals may have severe congenital retinal dysfunction with vision loss and pendular nystagmus **(Leber congenital amaurosis, LCA11)**. Others have childhood-onset retinitis pigmentosa with progressive visual impairment **(retinitis pigmentosa, RP10)**. There are no known treatments for either *IMPDH*-associated disorder.

Pathogenic variants in *IMPDH2* have been linked with an autosomal dominant neurologic disorder. Affected individuals may present with developmental delay, infantile dystonia, and seizures. Others present with a milder phenotype of dystonia that emerges in childhood or adolescence. There are no known treatments.

Phosphoribosylaminoimidazole carboxylase. The *PAICS* gene encodes a bifunctional enzyme that mediates two steps in the synthesis of purines (see Fig. 110.2). Pathogenic variants associated with *PAICS* are very rare, with only two individuals from a single family identified by exome sequencing. Both had multiple craniocervical malformations, and one had additional limb malformations. Both died within a few days of birth from respiratory failure.

Purine nucleoside phosphorylase. Deficiency of purine nucleoside phosphorylase results in selective dysfunction of T cells with susceptibility to viral illnesses. Two thirds have neurologic abnormalities, and one third have anemia. This disorder is covered in more detail in Chapter 165.2.

DISORDERS OF PYRIMIDINE METABOLISM

CAD Deficiency

The *CAD* gene encodes a trifunctional enzyme that mediates three of the initial six steps in pyrimidine synthesis (see Fig. 110.3). The disorder takes its name from the three relevant enzymatic activities, which include carbamoyl-phosphate synthetase, aspartate transcarbamylase,

and dihydroorotase. The associated clinical disorder is autosomal recessive.

Clinical Features

Fewer than 10 cases have been reported. Most presented in infancy with developmental delay, anisocytosis, and poikilocytosis. Most had medication-refractory seizures by 2 years of age, although epilepsy may start later. Many cases had global or cerebellar brain atrophy on MRI. The disorder cannot be identified by any of the metabolic tests routinely used for clinical diagnosis, but the activity of the enzyme can be measured. The disorder can also be identified by finding pathogenic variants in the *CAD* gene.

Treatment and Prognosis

Although it is quite rare, early diagnosis is important because treatment with uridine produces remarkably positive outcomes. Most of the subjects who were treated experienced a significant reduction in seizures, correction of hematologic abnormalities, and partial reversal of neurodevelopmental impairments. The disorder is therefore sometimes called **uridine-responsive epileptic encephalopathy**. It is likely that the degree of improvement depends on instituting treatments before significant brain damage occurs.

Dihydroorotate Dehydrogenase Deficiency

The *DHODH* gene encodes an enzyme that mediates the fourth of six steps in pyrimidine synthesis. The enzyme is localized in mitochondria, where electrons from the dehydrogenase are transferred to ubiquinone in the electron transport chain. A complete loss of the enzyme is not compatible with life, so all affected cases have had some residual enzyme function. The disorder is autosomal recessive.

Clinical Features

Fewer than 100 cases have been reported. Affected individuals have **Miller syndrome**, one of the acrofacial dysostosis syndromes where dysmorphic facial features are combined with abnormalities of the distal limbs. The facial anomalies include malar hypoplasia (underdeveloped cheekbones), micrognathia (small jaw), orofacial clefts (incomplete fusion of the roof of the mouth or lips), hypoplastic lower eyelids, and cup-shaped ears. The limb anomalies include abnormalities of the fifth and/or fourth fingers and toes (webbing, fusion, or hypoplasia), short forearms (ulnar hypoplasia sometimes with fusions to the radius), and hypoplasia of the fibula. Some cases also have other structural abnormalities such as pectus excavatum, rib defects, accessory nipples, or involvement of internal organs.

Treatment and Prognosis

There are no specific treatments for this disorder.

Hereditary Orotic Aciduria

The *UMPS* gene encodes a bifunctional enzyme that mediates two of the last six steps in pyrimidine synthesis (see Fig. 110.3). The relevant enzymatic activities are carried out by a single protein and include orotate phosphoribosyltransferase and orotidine 5′-monophosphate decarboxylase. These activities are sometimes combined under the term *UMP synthase,* and the disorder is sometimes known as *UMP synthase deficiency*. Affected individuals cannot convert orotic acid into UMP, so they excrete large amounts of orotic acid in the urine. Levels may be so high that orotic acid crystals may precipitate in the renal collecting system. Inheritance is autosomal recessive.

Clinical Features

The disorder is rare, with fewer than 50 reported cases. Most present in the first few weeks or months of age with failure to thrive and developmental delay. The majority have megaloblastic anemia, hypochromia, anisocytosis, and poikilocytosis. A few have had strabismus, congenital malformations, or seizures. Heterozygous carriers may excrete high levels of orotic acid without any additional symptoms.

The diagnosis is often first suspected by finding high levels of orotic acid in the urine. UMP synthase deficiency is not the only condition associated with high urinary orotic acid. Other disorders include urea cycle defects (e.g., ornithine transcarbamylase deficiency), some mitochondrial disorders, Reye syndrome, or treatment with medications (allopurinol and 6-azauridine). A definitive diagnosis of hereditary orotic aciduria comes from genetic testing that reveals pathogenic variants in the *UMPS* gene, and the enzyme can be measured in blood cells or fibroblasts.

Treatment and Prognosis

Although rare, early diagnosis is important because it is treatable with uridine. In general, supplements with uridine can reverse hematologic abnormalities and stimulate normal growth and development. Long-term treatments are associated with good results. Uridine triacetate is approved for treatment by the FDA.

Thymidine Phosphorylase Deficiency

The *TYMP* gene encodes thymidine phosphorylase, an enzyme responsible for converting thymidine to thymine (see Fig. 110.3). Deficiency of the enzyme results in marked elevations in blood thymidine. The disorder is autosomal recessive. Accumulation of phosphorylated derivatives of thymidine and deoxyuridine result in abnormal DNA replication in mitochondria and depletion of mitochondrial DNA. The enzyme has had two additional names used in the literature prior to its isolation and molecular identification. It is known as *platelet-derived endothelial cell growth factor* because of its angiogenic properties. It also is known as *gliostatin* because of a suppressive effect on the growth of glia.

Clinical Features

The disorder is rare and responsible for **mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)**. Symptoms begin in adolescents or young adults. Initial symptoms are often attributable to the gastrointestinal system and include diarrhea, vomiting, malabsorption, weight loss, and episodes of pseudoobstruction. Neurologic features include progressive external ophthalmoparesis, ptosis, myopathy, neuropathy, and hearing loss.

Treatment and Prognosis

There is no specific treatment for the early-onset severe phenotype. Treatment with 5-fluorouracil and related drugs is contraindicated.

DIHYDROPYRIMIDINE DEHYDROGENASE DEFICIENCY

The *DPD* gene encodes dihydropyrimidine dehydrogenase, the first enzyme involved in the catabolism of thymine and uracil (see Fig. 110.3). Genetic variants are common. Screening studies have suggested a prevalence of 3–5% for partial deficiency and 0.1–0.5% for severe deficiency. Severe enzyme deficiency is inherited in an autosomal recessive manner, and it is associated with marked elevations of thymine and uracil in urine, blood, and CSF. The associated disorder is therefore sometimes called **thiamine-uraciluria**.

Clinical Features

The clinical manifestations are quite varied, even among individuals who carry the same genetic variant. Some individuals with severe enzyme deficiency have no symptoms, and they are identified in adulthood because of severe toxicity after treatment with 5-flurouracil or related drugs. Others are identified in childhood, although fewer than 50 cases have been reported. Approximately half of these cases have had psychomotor delay, often with seizures. A few have presented with growth restriction, microcephaly, ocular abnormalities, or autistic behaviors.

Treatment and Prognosis

There is no specific treatment for the early-onset severe phenotype. For individuals with partial deficiency, treatment with 5-fluorouracil and related drugs is contraindicated.

Dihydropyrimidinase Deficiency

The *DPYS* gene encodes dihydropyrimidinase, the second enzyme involved in the catabolism of thymine and uracil (see Fig. 110.3).

Approximately 9% of individuals of European ancestry have genetic variants that substantially reduce enzyme activity, and 0.5% have almost no activity. Associated disorders are autosomal recessive. Severe enzyme deficiency is associated with marked elevations of dihydrothymine and dihydrouracil and in urine, blood, and CSF. The associated disorder is therefore sometimes called **dihydropyrimidinuria**.

Clinical Features

Genetic variants in *DPYS* are associated with very different clinical manifestations, even among individuals who carry the same genetic variant. The severe form of the disorder is rare, with fewer than 50 reported individuals. Some individuals with severe enzyme deficiency have no symptoms. Others are identified in childhood, with approximately half having psychomotor delay and a third having seizures. Gastrointestinal problems are common and include feeding difficulties with recurrent vomiting, malabsorption, and gastroesophageal reflux. A few have presented with growth restriction, microcephaly, or autistic behaviors.

Treatment and Prognosis

There is no specific treatment for the early-onset severe phenotype. Testing for common genetic variants before the use of 5-fluorouracil and related drugs has been recommended.

β-Ureidopropionase Deficiency

The *UPB1* gene encodes β-ureidopropionase, also known as *β-alanine synthase*. It is responsible for the last step of pyrimidine catabolism (see Fig. 110.3). Deficiency of the enzyme leads to accumulation of *N*-carbamoyl-β-alanine and *N*-carbamyl-β-aminoisobutyric acid in urine, blood, and CSF. As a result, the disorder is sometimes called ***N*-carbamoyl-β-amino aciduria**. The mechanism by which the enzyme defect leads to clinical disease is not well known.

Clinical Features

The disorder is autosomal recessive and rare, with fewer than 50 reported individuals. Affected individuals have psychomotor delay, seizures, microcephaly, and autistic behaviors. However, enzyme screening has revealed some individuals with no apparent symptoms. Diagnosis can be made by measuring accumulation of the associated metabolites, enzyme testing from liver biopsy, or finding pathogenic variants in the gene.

Treatment and Prognosis

There is no specific treatment for this disorder.

DISORDERS ASSOCIATED WITH THYMIDINE KINASE

Dividing cells rely on de novo synthesis of pyrimidines to make most of their nucleotides, but these pathways are downregulated in postmitotic cells, which primarily maintain pyrimidine nucleotides instead via salvage (see Fig. 110.3). Salvage enzymes include cytosolic thymidine kinase (*TK1* gene) and mitochondrial thymidine kinase (*TK2* gene). The *TK1* gene is often overexpressed in rapidly dividing cells and used as a marker for early detection or recurrence of cancer.

Pathogenic variants in the *TK2* gene impair the phosphorylation of thymidine and deoxycytosine, leading to reductions in associated nucleotides needed for DNA synthesis. The result is abnormalities in the rate and/or accuracy of mitochondrial DNA synthesis, with mitochondrial DNA depletion. Disorders associated with *TK2* are autosomal recessive, with three overlapping groups delineated by age at onset. Individuals with **infantile onset** (<1 year) have severe myopathy with proximal muscle weakness, facial diplegia, dysphagia, and respiratory compromise. Some may also have encephalopathy and seizures. Death usually occurs within 1-4 years. Individuals with the **childhood-onset** form (up to 12 years of age) have a more slowly progressive myopathy with weakness and longer survival periods. Those with **late onset** (>12 years of age) may have limited areas of weakness such as chronic progressive ophthalmoplegia, facial diplegia, or oropharyngeal weakness. There is no known treatment, but trials with relevant pyrimidine derivatives have been initiated.

COMBINED DISORDERS OF BOTH PURINES AND PYRIMIDINES

PRPS1-Associated Disorders

The *PRPS1* gene encodes the enzyme PRPP synthase type 1. Two additional isoforms of this enzyme are encoded by separate genes: *PRPS1L1* and *PRPS2*. *PRPS1* and *PRPS2* reside on opposite arms of the X chromosome, and *PRPS1L1* is on chromosome 7. *PRPS1* is ubiquitously expressed. *PRPS1L1* is expressed only in testis, and *PRPS2* is expressed in the gastrointestinal system, endocrine tissues, and reproductive organs. Only *PRPS1* has been linked with human disease. *PRPS1*-associated disorders are rare, with fewer than 1,000 individuals reported.

All three isoforms of PRPP-synthase transfer high-energy phosphate bonds from ATP to ribose-5-phosphate to generate PRPP. The PRPP can then use the high-energy phosphate bonds to drive certain energy-requiring reactions. PRPP is a cosubstrate for the first and rate-limiting reaction in purine synthesis (see Fig. 110.2). PRPP also serves as a cosubstrate for the main purine salvage enzymes HGprt and APRT. PRPP affects pyrimidine synthesis as well, because it is a cosubstrate for the first step in pyrimidine synthesis (see Fig. 110.3). PRPP is also a cosubstrate for two additional enzymes involved in the synthesis of the pyridine nucleotides: NAD and NADP (Table 110.4). PRPP-synthase plays a key role in regulating the synthesis of both purines and pyrimidines, and overexpression of *PRPS1* is common in certain cancer cells, which need large quantities of purines and pyrimidines for DNA replication during cell division.

Because of its integral involvement in many vital biochemical pathways, complete loss of PRPP-synthase is not compatible with life. Instead, clinical disease results from abnormally high enzyme activity or partial loss of enzyme activity. High levels of the enzyme produce excessive quantities of PRPP, and elevations in PRPP accelerate purine production, with resultant overproduction of uric acid. It is likely that increases in PRPP accelerate pyrimidine metabolism, but measures of this pathway are not widely used in clinical medicine. Conversely, impaired enzyme activity results in reduced metabolism of both purines and pyrimidines.

Clinical Features

The clinical phenotypes of *PRPS1*-associated disorders are remarkably diverse. Phenotypic variation is caused by varied changes in enzyme function. The phenotypes associated with *reduced enzyme activity* historically have been described as distinct entities, although clinical features overlap, and the reality is a continuous spectrum of severity (Fig. 110.5). The mildest phenotype is **X-linked nonsyndromic hearing loss (DFN2)**. Hearing impairments in males may range from a slowly progressive postlingual hearing loss to profound congenital deafness. A more severe phenotype associated with impaired enzyme activity has been called **Rosenberg-Chutorian syndrome or X-linked Charcot-Marie-Tooth disease (CMTX5)**. This phenotype in males combines prelingual hearing loss, progressive optic neuropathy, and peripheral neuropathy beginning at 5-10 years of age and sometimes gait impairments. An even more severe phenotype has been called **Arts syndrome**. It also is X-linked, and males have profound congenital deafness, early-onset optic neuropathy, peripheral neuropathy, psychomotor delay, and recurrent respiratory infections that may cause early death. In addition to these three phenotypes classically associated with reduced enzyme activity, there are reports that suggest a fourth and even more severe phenotype. Males have intrauterine growth restriction and failure to thrive after birth, congenital retinopathy and deafness, diabetes insipidus, and a more severe neurologic condition that includes severe psychomotor delay, spastic tetraparesis, seizures, and evidence for delayed white matter development on brain MRI.

The *PRPS1* gene is X-linked, so variants associated with reduced PRPP-synthase affect males, often from an early age. However, female carriers may express milder or adult-onset phenotypes. In families where males are affected only with early-onset hearing loss, female carriers may develop progressive hearing loss as young adults. In

families where males have a more severe early childhood phenotype that includes additional neurologic signs, female carriers may have progressive hearing loss, retinopathy, optic neuropathy, peripheral neuropathy, and sometimes additional signs attributable to the central nervous system. For the most severe phenotype, female carriers may also have short stature. In some families, only females are clinically affected, with evidence for embryonic lethality of males. These families suggest the existence of a fifth phenotype of embryonic lethality in males. Because hearing loss is the most consistent feature associated with reduced PRPP-synthase, the diagnosis of a *PRPS1*-associated disorder should be considered in males or females with sensorineural hearing loss, especially when combined with other neurologic signs.

There are also two different phenotypes associated with *abnormally high levels* of PRPP-synthase activity. The milder phenotype is associated with overexpression of a normal *PRPS1* mRNA transcript. Males present with signs of uric acid overproduction, including hyperuricemia and gout. Female carriers may also be affected. A more severe phenotype is associated with a point pathogenic variant in *PRPS1*, which renders the protein less durable but insensitive to feedback inhibition. The lack of feedback inhibition results in excessive PRPP production, with acceleration of purine synthesis and overproduction of uric acid. However, tissues with normally low levels of *PRPS1* may experience PRPP shortage because the enzyme is unstable. Erythrocytes lack a nucleus, so there is no ongoing mRNA transcription to provide a constant supply of new enzyme. In individuals with an unstable enzyme, erythrocyte PRPP-synthase is absent. A similar mechanism may explain the neurologic consequences, which overlap with those of PRPP-synthase deficiency syndromes. Affected individuals show signs of overproduction of uric acid combined with sensorineural hearing impairments, neuropathy, and/or psychomotor delay. The diagnosis of a disorder associated with excessive activity of PRPP-synthase should be suspected in any individual with evidence for overproduction of uric acid, especially when combined with the typical neurologic signs.

Treatment and Prognosis

The overproduction of uric acid in disorders associated with increased activity of PRPP-synthase is treated with inhibitors of XOR (allopurinol or febuxostat) combined with generous hydration. No treatments have proven effective in the treatment of disorders associated with reduced activity of the enzyme.

Disorders Associated with Nucleotidases

There are numerous enzymes that function as nucleotidases to remove phosphate groups from nucleotides (see Figs. 110.1 and 110.3). Many act nonselectively on multiple nucleotides and other small molecules, but they are often described according to their most prominent (or first discovered) enzymatic activity. At least five of these nucleotidases are cytosolic, one is bound to the plasma membrane, and another is localized to mitochondria. Early studies based on enzymatic activity did not always identify the exact isoform involved, but more recent studies have more precisely delineated the precise enzyme involved.

Nucleotidase-associated pervasive developmental delay. A marked increase in nucleotidase activity was found in cells of nine individuals with motor and cognitive delay, hyperactivity and impulsivity, delayed or absent language, seizures, awkward movements, and other abnormal behaviors. Some had immunologic impairments too. Although the exact enzyme and gene were not delineated, individuals had chronic hypouricemia, indicating reduced purine metabolism. Biochemical studies suggested the disorder was associated with depletion of pyrimidine nucleotides, and the behavioral abnormalities responded to uridine supplements.

Pyrimidine 5′-nucleotidase deficiency. The *NT5C3A* gene encodes an erythrocyte-specific 5′-nucleotidase isoform (P5N-1) with preferential activity toward the pyrimidines CMP and UMP (see Fig. 110. 3). Enzyme deficiency is inherited in an autosomal recessive manner and associated with accumulation of pyrimidine nucleotides in erythrocytes.

The clinical manifestations include chronic nonspherocytic hemolytic anemia; marked basophilic stippling and reticulocytosis; and accompanying splenomegaly, hemoglobinuria, and jaundice resulting from overproduction of bilirubin. The diagnosis is suspected when there is prominent basophilic stippling of erythrocytes, a phenomenon also associated with lead intoxication. Erythrocytes have an overabundance of pyrimidines, and the enzyme can be measured in red cells. The anemia is generally moderate and does not usually require transfusion.

Spastic paraplegia (SPG45). The *NT5C2* gene encodes a cytosolic 5′-nucleotidase with preferential activity toward IMP and other purine nucleotides. Pathogenic variants in this gene leading to reduced enzyme function have been linked with spastic paraplegia (SPG45). The disorder is rare and described for fewer than 20 individuals in a few different families. Affected individuals have early-onset gait impairment with leg weakness, spasticity, hyperreflexia, clonus, and extensor plantar reflexes. Many also have cognitive impairments. MRI may show white matter brain changes with dysgenesis of the corpus callosum.

Desbuqois dysplasia type 1 (DBQB1). The *CANT1* gene encodes a secreted calcium-dependent enzyme that functions as a triphosphatase or diphosphatase with activity toward ATP, ADP, UTP, and UDP. Pathogenic variants in this gene have been linked with a rare form of osteochondrodysplasia. Affected individuals have short stature with short limbs, joint laxity with frequent joint dislocations, pectus carinatum, osteopenia, dysmorphic facies, and intellectual disability.

Table 110.4 Enzymes Dependent on Phosphoribosylpyrophosphate

ENZYME	GENE	PATHWAY
Amido phosphoribosyl transferase	*PPAT*	Purine synthesis
Hypoxanthine-guanine phosphoribosyl transferase	*HPRT1*	Purine recycling
Adenine phosphoribosyl transferase	*APRT*	Purine recycling
Orotate phosphoribosyl transferase Uridine monophosphate synthetase	*UMPS*	Pyrimidine synthesis
Nicotinate phosphoribosyl transferase	*NAPRT*	NAD synthesis
Nicotinamide phosphoribosyl transferase	*NAMPT*	NADP synthesis

NAD, Nicotinamide adenine dinucleotide; NADP, nicotinamide-adenine dinucleotide phosphate.

DISORDERS ASSOCIATED WITH RIBONUCLEOTIDE REDUCTASE

Ribonucleotide reductase is the enzyme responsible for generating the deoxynucleotides dADP, dCDP, dGDP, and dUDP (see Figs. 110.1 and 110.3). These deoxynucleotides are used to synthesize DNA, so the enzyme plays a key role in regulating DNA replication for cell division. The enzyme is the target for hydroxyurea used for sickle cell anemia and certain malignancies. The human enzyme has three subunits, but only the subunit encoded by the *RRM2B* gene has been linked with human disease.

Clinical Features

Pathogenic variants in *RRM2B* are responsible for a **mitochondrial DNA depletion syndrome** with severe encephalomyopathy. The disorder is inherited in an autosomal recessive manner. Only a handful of cases from a few families have been reported. Pathogenic variants in the same gene have also been linked with an autosomal dominant **progressive external ophthalmoplegia (PEOA5)**. Only a few cases have been reported. There is no specific treatment for either disorder.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

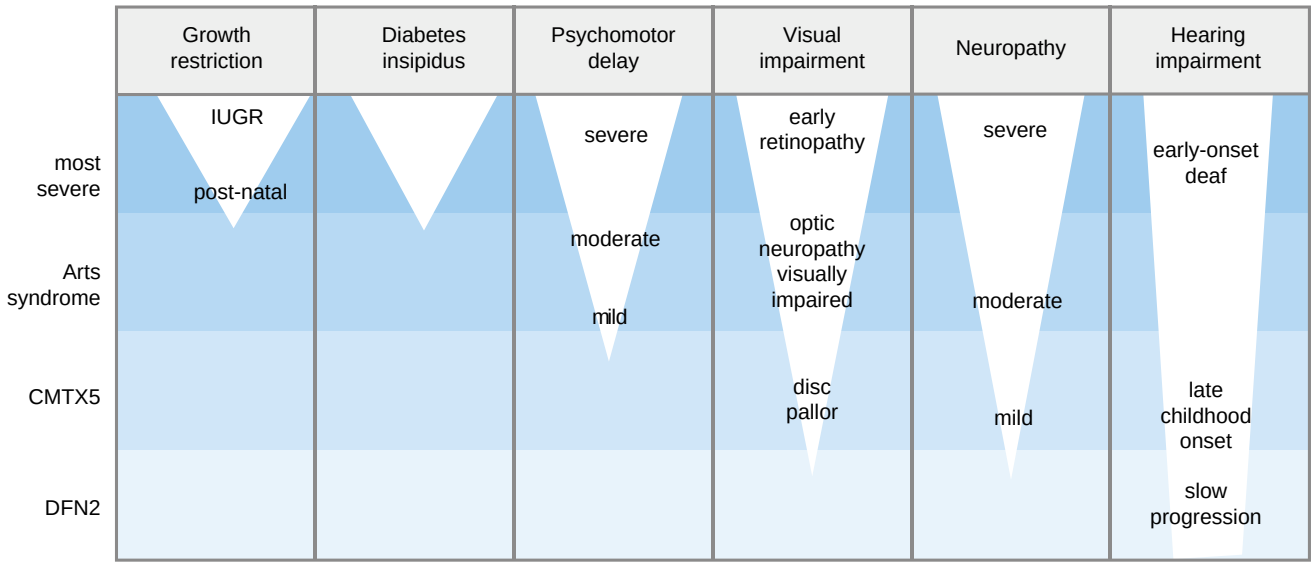

Fig. 110.5 *PRPS1*-associated disorders. This schematic provides a graphical representation of the overlapping spectrum of *PRPS1*-associated disorders. The four disorders are listed on the left side of the panel. The most common clinical features are shown in the top row. The *white triangles* depict the severity of individual clinical features for each of the disorders. For example, hearing loss may begin in adulthood with slow progression in the milder phenotypes (DFN2), whereas it may be reflected as earlier or more complete deafness in the more severe phenotypes. Conversely, growth retardation and diabetes insipidus have been reported only for the most severe phenotype. This schematic provides only a general guide, as some exceptions may occur. Chapter 111

Hutchinson-Gilford Progeria Syndrome (Progeria)

Timothy R. O'Toole and Leslie B. Gordon

Hutchinson-Gilford progeria syndrome (HGPS, or progeria) is a rare, fatal, autosomal dominant segmental premature aging disease. With an estimated incidence of 1 in 4 million live births and prevalence of 1 in 20 million living individuals, there are an estimated total of 400 children living with progeria in 2023 worldwide. There is no gender, ethnic, or regional bias.

Progeria is caused by a single-base pathogenic variant in the *LMNA* gene, which results in the production of an abnormal lamin A protein called **progerin**. Lamin A is an intermediate-filament inner nuclear membrane protein found in most differentiated cells of the body. Without progerin-directed treatment, children with progeria develop **premature progressive atherosclerosis** and die of heart failure, usually between ages 5 and 20 years. Progerin is found in increased concentration in the skin and vascular wall of normal older individuals compared with younger individuals, suggesting a role in normal aging.

CLINICAL MANIFESTATIONS

Children are born looking normal and begin to develop clinical signs of disease during year one. Physical appearance and clinical findings change dramatically each year that they age (Figs. 111.1 and 111.2). Both clinical and biologic overlaps with aging are segmental, or partial. The disease features discussed next are roughly in order of clinical appearance.

Dermatologic Changes in Skin, Hair, and Nails

Skin findings are often apparent as initial signs of progeria—at birth in about 25% of cases and by age 2 months in 80% of cases. These are variable in severity and include areas of discoloration, stippled dyspigmentation, tightened areas that can restrict movement, and areas of the trunk or legs where small (1-2 cm), soft, bulging skin is present.

Although usually born with normal appearance, cranial hair is lost within the first few years. Initial hair loss occurs in the temporal and occipital areas, with preservation of hair on the mid-scalp and vertex for the longest period. Eventually total alopecia occurs, leaving soft, downy, sparse, immature hair on the scalp, no eyebrows, and scant eyelashes.

Nails on hands and feet are usually normal at birth but become dystrophic later in life.

Failure to Thrive

Children with progeria experience apparently normal fetal and early postnatal development. Between several months and 1 year of age, abnormalities in growth and body composition are readily apparent. Severe failure to thrive ensues, heralding generalized lipoatrophy, with apparent wasting of limbs, circumoral cyanosis, and prominent veins around the scalp, neck, and trunk resulting from a paucity of subcutaneous fat. The weight percentile is usually normal at birth but decreases to below the third percentile despite adequate caloric intake for normal growth and normal resting energy expenditure. A review of 35 children showed an average weight increase

Fig. 111.1 Distinguishing clinical features in Hutchinson-Gilford progeria syndrome. **A,** Alopecia, prominent scalp veins, narrowed nasal bridge, retrognathia. **B,** Generalized lipoatrophy leaves muscular prominence. **C,** Skin tightening and mottling. **D,** Skin bulging. **E,** Digital joint contractures. **F,** Nail dystrophy with spooning. **G,** Knee joint contractures, lipodystrophy. **H,** Corneal scarring secondary to exposure keratopathy. **I,** Flat umbilicus with scarred-over appearance; **J,** Calcinosis cutis in a digit. (*Photos courtesy The Progeria Research Foundation and Boston Children's Hospital.*)

of only 0.44 kg/year, beginning at 24 months of age and persisting through life. Weight gain over time is linear, which contrasts with the pulsatile acceleration in growth velocity for normal age- and gender-matched children. Children reach an average final height of approximately 1 meter and weight of approximately 15-20 kg. Head circumference is normal. The weight deficit is more pronounced than the height deficit and, associated with the loss of subcutaneous fat, results in the emaciated appearance with muscular prominence. Clinical problems caused by the lack of subcutaneous fat include sensitivity to cold temperatures and foot discomfort caused by lack of fat cushioning. Overt diabetes is unusual in progeria, but at least 75% of children eventually develop insulin resistance, usually starting at around age 8 years.

Musculoskeletal Impairments

Both upper and lower extremity range-of-motion impairments (e.g., fingers, elbows, hips, knees, ankles) may be present at birth and may progress with age. Joint contractures are caused by both bony and cartilaginous disease, along with tightened skin. Along with irregularities in the congruency of articulating joint surfaces, these changes serve to limit joint motion and affect both upper and lower extremity gross and fine motor function. *Physical therapy is recommended routinely and throughout life to maximize joint function.*

Ocular Abnormalities

Ophthalmic signs and symptoms are caused in part by shallow orbits, tight skin, and a paucity of subcutaneous fat around the eyes. Eyes are prominent and often experience ocular surface disease secondary to nocturnal lagophthalmos and exposure keratopathy, which produce photophobia, tearing, ocular irritation, corneal scarring, and corneal ulceration that can lead to vison loss. Most patients have relatively good acuity; however, advanced ophthalmic disease can be associated with reduced acuity. *Children with progeria should have an ophthalmic evaluation at diagnosis and at least yearly thereafter.* Aggressive ocular surface lubrication is recommended, including the use of tape tarsorrhaphy at night.

Craniofacial and Dental Phenotypes

Children develop craniofacial disproportion, with micrognathia and retrognathia caused by mandibular hypoplasia. Typical oral and dental manifestations include hypodontia, delayed tooth eruption, severe dental crowding caused by hypoplastic maxilla and mandible, ogival palatal arch, ankyloglossia, presence of median sagittal palatal fissure, and generalized gingival recession. Eruption may be delayed for many months, and primary teeth may persist for the duration of life. Secondary teeth are present but may or may not erupt. They sometimes erupt on the lingual and palatal surfaces of the mandibular and maxillary alveolar ridges, rather than in place of the primary incisors. In some, but not all cases, extracting primary teeth promotes movement of secondary teeth into place.

Skeletal Abnormalities

Development of bone structure and bone density represents a unique skeletal dysplasia that is not based in malnutrition. Acroosteolysis of the distal phalanges, distal clavicular resorption, and thin, tapered ribs are early signs of progeria (as early as 3 months

Fig. 111.2 Pathologic skeletal and cardiovascular findings in Hutchinson-Gilford progeria. **A,** Coxa valga of the hip. **B,** Clavicular osteolysis. **C,** Acroosteolysis in a thumb. **D,** H&E staining of mid-right coronary artery characterized by an enlarged and highly fibrotic adventitia *(arrow).* The media is markedly thinned in the area with adventitial fibrosis and plaque showing clinically significant stenosis (90%) and a necrotic core with calcification (staining not shown). **E,** Near-complete loss of the distal vertebral artery *(circle)* and prominent anterior spinal artery collateral *(arrow).* **F,** Acute gyral infarcts *(black arrow).* Bright signal in the sulci indicates slow cortical collateral flow *(white arrows).* **G,** M1 *(single black arrow)* and A1 stenoses *(double black arrows),* internal maxillary artery collaterals *(wavy black arrows),* subfrontal collaterals *(single white arrow),* and enlarged anterior and posterior spinal arteries *(double white arrows).*

of age). *Facial disproportion, a narrowed nasal bridge, and retrognathia make intubation extremely difficult, and fiberoptic intubation is recommended.* A pyriform chest structure and small clavicles can lead to reducible glenohumeral joint instability. Growth of the spine and bony pelvis is normal. Hip disease is pervasive and results in repeated dislocations in about 20% of cases that are not amenable to splinting. Dysplastic growth of the femoral head and neck axis results in coxa valgus (straightening of the femoral head-neck axis >125 degrees) and coxa magna, where the diameter of the femoral head is disproportionately large for the acetabulum, resulting in hip instability. The resulting hip dysplasia can be progressive and may result in osteoarthritis, avascular necrosis, hip dislocation, and inability to bear weight.

In response to repeated hip dislocations, five instances of either unilateral or bilateral surgical correction of hip dysplasia using periacetabular and femoral osteotomy have been conducted, each at different hospitals. Follow-up after 4-8 years has yielded mixed results. Other than in a single instance, hip dislocations have not recurred. In two cases, postsurgical healing occurred normally, resulting in ability to bear weight and walk short-to-long distances. In two cases, hardware failure with nonunion of femoral bone necessitated hardware removal and new hardware insertion; skin breakdown and need for additional bone grafting complicated one of these cases. These two cases yielded limited weight-bearing with no assistance when walking short distances, but the patients required wheelchair use for longer distances. Finally, one case healed well with no adverse events, but mobility was not restored because of postsurgery progression of joint contractures, resulting in inability to bear weight or walk and subsequent wheelchair use. Adequate vitamin D levels are likely important for bone healing in all cases.

Other changes to the appendicular skeleton include flaring of the humeral and femoral metaphyses and constriction of the radial neck. Growth plate morphology is generally normal but can be variable within a single radiograph. The appearance of ossification

centers used to define bone age is normal. Bone structure assessed by peripheral quantitative computed tomography (pQCT) of the radius demonstrates distinct and severe abnormalities in bone structural geometry, consistent with progeria representing a *skeletal dysplasia*. Areal bone mineral density (aBMD) *z* scores measured by dual-energy x-ray absorptiometry (DXA) adjusted for height and age and true (volumetric) BMD assessed by pQCT are normal to mildly reduced, refuting the assumption that patients with progeria are osteoporotic. Fracture rates in progeria are normal and not associated with fragility fractures observed in other pediatric metabolic bone diseases, such as osteogenesis imperfecta.

Hearing

Low-tone conductive hearing loss is pervasive in progeria and likely indicative of a stiff tympanic membrane and/or deficits in the middle ear bony and ligamentous structures. Overall, this does not affect the ability to hear the usual spoken tones, but preferential classroom seating is recommended, along with annual hearing examinations.

Cardiovascular Disease

Approximately 80% of deaths in progeria are caused by cardiovascular failure, with end-stage events sometimes precipitated by superimposed respiratory infection or stressors surrounding surgical intervention. Progeria is a **primary vasculopathy** characterized by pervasive accelerated vascular stiffening, followed by large- and medium-vessel occlusive disease from atherosclerotic plaque formation, with valvular and cardiac calcification and insufficiency at advanced stages of disease. Some evidence of vascular dysfunction is apparent in all ages tested. ECG abnormalities are generally nonspecific, but indications of left ventricular hypertrophy and nonspecific ST-T wave abnormalities can occur later in disease progression. Hypertension, angina, cardiomegaly, metabolic syndrome, and congestive heart failure are common end-stage events.

Transthoracic echocardiography reveals early-onset diastolic left ventricular dysfunction associated with age-related decline in lateral and septal early (E′) diastolic tissue Doppler velocity *z* scores and an increase in the ratio of mitral inflow (E) to lateral and septal E′ velocity *z* scores. Other echocardiographic findings include left ventricular hypertrophy, left ventricular systolic dysfunction, and mitral or aortic valve disease with calcification, which tend to appear later in life.

Vascular stiffening assessed using carotid and femoral ultrasound reveals elevated carotid-femoral pulse wave velocity (PWV_{cf}) and wall echodensity with medial and adventitial thickening. These are considered early and important indicators of cardiovascular decline. In the general population, increased PWV_{cf} is associated with increased risk of cardiac death. Intima-media thickness is normal. In addition, elevated carotid artery mean flow velocities appear early in life, and underscore the presence of arterial occlusive disease.

Routine blood pressure (BP) monitoring with special attention to proper cuff size is recommended. When normalized for patient size using height and age correction, both systolic and diastolic BP are increased in about half of patients with HGPS. These elevated BP trends would be expected in the setting of significant vascular stiffness. *Antihypertensive medications have been used in the setting of elevated BP, with special attention to maintaining adequate BP to avoid strokes.*

BP monitoring, ECG, echocardiography, carotid ultrasound for plaque evaluation, and PWV_{cf} measures for vascular stiffening are recommended.

End-stage cardiovascular disease (CVD) in progeria is often characterized by atherosclerotic plaques in large and medium-sized arteries, severe aortic stenosis, and cardiac failure. Critical aortic stenosis with heart failure is amenable to transapical transcatheter aortic valve implantation and apico-aortic conduit surgeries to alleviate severe aortic stenosis. These carry high risk of death but have yielded significant symptomatic improvement and prolongation of life in several cases (see treatment section).

Cerebrovascular Arteriopathy and Stroke

The earliest incidence of stroke occurred at age 0.4 years. More often, strokes occur in the later years. Over the life span, MRI evidence of infarction can be found in as many as 60% of patients with progeria, with half of these clinically silent. Both extracranial and intracranial occlusive disease is present in the neurovascular axis, with resulting extensive collateral vessel formation that pseudonormalizes intracranial flow. Carotid artery blockages are well documented, but infarction can occur even in their absence. Both large- and small-vessel disease is found; collateral vessel formation is extensive. A propensity for strokes and an underlying stiff vasculature make maintaining adequate blood pressure through oral hydration a priority in patients with progeria; special care should be taken when considering maintenance of consistent BP during general anesthesia, airplane trips, and hot weather. In addition, 15% of deaths in children with progeria occur from head injury or trauma, including subdural hematoma. This implies an underlying susceptibility to subdural hematoma, though known risk of stroke is much higher and frequently warrants low-dose aspirin therapy.

Sexual Development

Females with progeria can develop Tanner stage II secondary sexual characteristics, including signs of early breast development and sparse pubic hair. Progression to Tanner stage III has not been observed. Despite minimal to absent physical signs of pubertal development and markedly reduced body fat, over half of females experience spontaneous menarche at a median age of 14 years. Menarche is not preceded by gain in body mass or increase in body fat. Timing of menarche is variable; some adolescents start menstruation at Tanner stage I without progression to Tanner II, while others start at Tanner stage II. Those experiencing menarche vs nonmenstruating females have similar body mass indices, percentage body fat, and serum leptin levels, all of which are vastly below the healthy adolescent population. Menorrhagia has been observed and can result in symptomatic anemia. *In addition to iron supplementation, oral contraceptives may be indicated to regulate menses.* Progestin-only or minimal estrogen-content products are preferred because of elevated cardiovascular risks associated with estrogen-based medication in the face of HGPS-associated atherosclerosis. There are no documented cases of reproductive capacity in females or males with progeria; however, the data suggest there is potential for further sexual development and the possibility of fertility in these females. Secondary sexual characteristics in males have not been reported.

Normally Functioning Systems

Liver, kidney, thyroid, immune, gastrointestinal, and neurologic function (other than stroke related) remain intact. Intellect is normal for age, possibly in part from downregulation of progerin expression in the brain by a brain-specific micro-RNA, miR-9.

LABORATORY FINDINGS

The most consistent laboratory findings are low serum leptin below detectable levels (>90%) and insulin resistance (75%, usually starting over age 8 years). Platelet count is often moderately high. High-density lipoprotein (HDL) cholesterol and adiponectin concentrations decrease with increasing age to values significantly below normal. Otherwise, lipid panels, high-sensitivity C-reactive protein, blood chemistries, liver and kidney function tests, endocrine test, and coagulation tests are generally normal.

MOLECULAR PATHOGENESIS

Pathogenic variants in the *LMNA* gene cause progeria. The normal *LMNA/C* gene encodes the proteins lamins A and C, of which only lamin

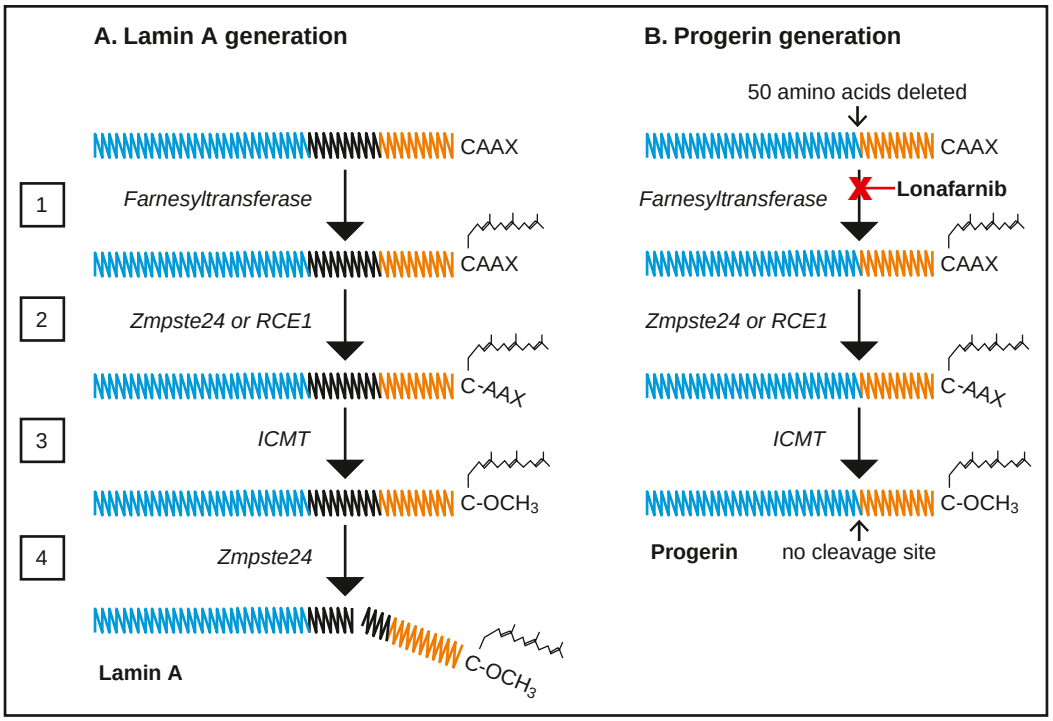

Fig. 111.3 Posttranslational processing pathways producing lamin A and progerin, including the target site for lonafarnib. **A,** Prelamin A polypeptide chain, showing its central α-helical rod domain and C-terminal–CAAX box, representing cysteine (C), aliphatic amino acids (AA), and any amino acid (X). The α-helical rod domain is divided into segments that assist in displaying the progerin defect. Posttranslational processing consists of four steps: (1) a farnesyl group is attached to the cysteine residue of the −CAAX box by farnesyltransferase; (2) the last three residues are proteolytically cleaved by the zinc metalloprotease Zmpste24 or Ras-converting enzyme (RCE1); (3) carboxy-methylation by isoprenyl-cysteine carboxyl methyltransferase (ICMT); and (4) the terminal 15 C-terminal residues, including the farnesylated and carboxymethylated cysteine, are cleaved off by Zmpste24. **B,** A 50–amino acid deletion in prelamin A (represented by the black segment of the lamin A rod) is the result of a pathogenic variant that activates a cryptic splice site within exon 11 of the *LMNA* gene. This deletion leaves progerin without an attachment site for the last processing step—cleavage of the farnesylation and carboxymethylated terminal 15 amino acid residues. Thus progerin remains farnesylated and intercalated within the inner nuclear membrane, where it causes much of its cellular damage.

A is associated with human diseases. The lamin proteins are the principal proteins of the nuclear lamina, a complex molecular interface located between the inner membrane of the nuclear envelope and chromatin. The integrity of the lamina is central to many cellular functions, creating and maintaining structural integrity of the nuclear scaffold, DNA replication, RNA transcription, organization of the nucleus, nuclear pore assembly, chromatin function, cell cycling, senescence, and apoptosis.

Progeria is a sporadic autosomal dominant disease in about 98% of cases. Two percent of cases presumably arise from parental mosaicism; The Progeria Research Foundation reports five identified sibling occurrences of genetically confirmed HGPS. HGPS is caused by the accelerated use of an alternative, internal splice site that results in the deletion of 150 base pairs in the 3′ portion of exon 11 of the *LMNA* gene. In about 90% of cases, this results from a single C to T transition at nucleotide 1824 that is silent (Gly608Gly) but optimizes an internal splice site within exon 11. The remaining 10% of cases possess one of several single-base pathogenic variants within the intron 11 splice donor site, thus reducing specificity for this site and altering the splicing balance in favor of the internal splice. Subsequent to all these pathogenic variants, translation followed by posttranslational processing of the altered mRNA produces progerin, a shortened abnormal lamin A protein with a 50–amino acid deletion near its C-terminal end. An understanding of the posttranslational processing pathway and how it is altered to create progerin has led to a number of treatment prospects for the disease (Fig. 111.3).

Both prelamin A and preprogerin possess a methylated farnesyl side group attached during posttranslational processing. This is a lipophilic moiety that facilitates intercalation of proteins into the inner nuclear membrane, where most of the lamin and progerin functions are performed. During posttranslational processing of normal lamin A, loss of the methylated farnesyl anchor releases prelamin from the nuclear membrane, rendering it soluble for autophagic degradation. However, preprogerin and, subsequently, progerin retain the farnesyl moiety. Progerin remains anchored to the membrane, binding other proteins, causing blebbing of the nucleus, disrupting mitosis, and altering gene expression. Progerin also retains a methyl moiety.

Disease in progeria is produced by a dominant negative mechanism; *the action of progerin,* not the diminution of lamin A, causes the disease phenotype. The severity of disease is determined in part by progerin levels, which are regulated by the particular pathogenic variant, tissue type, or other factors influencing use of the internal splice site.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Overall, the constellation of small body habitus, bone, hair, subcutaneous fat, and skin changes results in the marked physical resemblance among patients with progeria (Fig. 111.4). For this reason, if disease signs are present, clinical diagnosis can often be achieved or excluded with relative confidence even at young ages. There are rare

Fig. 111.4 Unrelated 7-yr-old female and 10-yr-old male with progeria. The appearance is remarkably similar between patients. (*Photograph courtesy The Progeria Research Foundation.*)

cases of mosaicism or relatively low-progerin-expressing patients with extremely mild clinical signs of disease. Thus lack of early disease manifestation should not be considered exclusionary. Clinical suspicion should be followed by *LMNA* genetic sequence testing. In addition, a number of premature aging disorders have features that overlap with HGPS but are not progerin-producing (Table 111.1). Patients may fall under none of these diagnoses and represent ultrarare, unnamed progeroid diseases that carry either non–progerin-producing pathogenic variants in *LMNA* or the lamin-associated enzyme (ZMPSTE24), or progeroid syndromes without lamin-associated pathogenic variants.

TREATMENT

Lonafarnib (Zokinvy) is a farnesyltransferase inhibitor that blocks the addition of a farnesyl lipid moiety onto preprogerin, thus preventing progerin from associating with the inner nuclear membrane where it effects much of its damage (see Fig. 111.3). Lonafarnib is approved by the US FDA and European Medicines Agency for use in patients with HGPS and processing-deficient progeroid laminopathies ages 12 months and older. It is the first and only approved indication for either disease. It is initiated at a dose of 115 mg/m^2 orally twice daily. After four months, the dose is increased to 150 mg/m^2 twice daily. The most common side effects are diarrhea, nausea, and loss of appetite, which can be mitigated with loperamide, ondansetron HCl, and cyproheptadine, respectively.

Overall, children with HGPS treated with long-term lonafarnib therapy demonstrated an increase in mean estimated survival of 4.3 years (30%) over untreated children. Treatment decreased plasma progerin levels by an average of 38% starting at 4-6 months and persisting for up to 10 years on therapy. In a single-arm clinical trial with lonafarnib (NCT00425607), subgroups of patients experienced increased rate of weight gain, decreased vascular stiffness measured by decreased PWV_{cf} and carotid artery echodensity, improved left ventricular diastolic function, increased radial bone structural rigidity, improved sensorineural hearing, and early evidence of decreased headache, TIA, and stroke rates. Dermatologic, dental, joint contracture, insulin resistance, lipodystrophy, BMD, and joint contractures were unaffected by drug treatment.

Dosing: In general, medications should be dosed according to weight or body surface area instead of age because of the small size and decreased weight for height.

Hydration is important for maintaining adequate blood flow in the face of generalized vascular stiffness and collateral vascular formation in the brain.

Low-dose aspirin therapy is recommended at 2 mg/kg/day, as an extension of what is known about decreasing cardiovascular risk in the general at-risk adult population. It is not known whether low-dose aspirin therapy has any effect on morbidity or mortality in HGPS.

Antihypertensive medications have been used with elevated BP, with special attention to maintaining adequate BP to avoid strokes. Due to small, thin body habitus, appropriately sized blood pressure cuff and height-age adjustments when evaluating hypertension (>95th percentile) should be employed.

Extraskeletal calcifications have been observed in patients with progeria radiographically and cutaneously, both at a baseline off therapy (around 30% of patients) and with increasing frequency during a clinical trial when the patients were treated with oral calcium carbonate supplementation, and/or zoledronic acid, pravastatin, and lonafarnib (around 45% of patients). Oral calcium carbonate supplementation may therefore aggravate calcium dysfunction in children with progeria. Given this potential concern, calcium intake via dietary means, along with vitamin D supplementation, is likely the safest intake strategy.

Physical and occupational therapy initiation are recommended as young as possible to preserve joint mobility and optimize capacity for activities of daily living.

Cardiac intervention. A primary cause of mortality in HGPS is critical aortic stenosis caused by premature atherosclerosis. At end stage, high-risk intervention has been performed using transcatheter aortic valve implantation (TAVI) for patients large enough to receive the smallest valve available, using a transapical approach because the femoral artery is small and calcified, precluding a transfemoral approach. The majority of patients' aortic valves are too small to implement TAVI. In these cases, apico-aortic conduit (aortic valve bypass) surgery has been achieved. Both procedures have resulted in postoperative symptomatic relief and lifespan extension when successful. The procedures carry high risk for perisurgical morbidity and mortality.

Clinical trials. One currently ongoing clinical trial adding *everolimus* (an FDA-approved mTOR inhibitor) to a lonafarnib regimen is aimed at accelerating autophagy of progerin, thus theoretically reducing its accumulation and cellular damage (NCT02579044). Patient treatment phase is complete and results are pending.

PROGNOSIS

Children with progeria develop a severe premature form of atherosclerosis. Before death, cardiac decline with left-sided hypertrophy, valvular insufficiency, and pulmonary edema develop; neurovascular decline with TIAs, strokes, and occasionally seizures can result in significant morbidity.

Without lonafarnib drug treatment, death occurs generally between ages 5 and 20 years, with a median life span of 14.5 years, resulting from heart failure, sometimes with superimposed respiratory infection (approximately 80%); from head injury or trauma, including subdural hematoma (approximately 15%); and, rarely, from stroke (1–3%) or complications from anesthesia during surgery (1–3%). With lonafarnib therapy, long-term use has been associated with up to 4.3 years' (30%) lifespan extension. Surgical intervention for critical aortic stenosis can decrease cardiovascular morbidity and extend lifespan by an indeterminate duration.

PATIENT RESOURCES

The Progeria Research Foundation (www.progeriaresearch.org) maintains an international progeria patient registry, provides a diagnostics program and complete patient care manual, and coordinates clinical treatment trials. It funds preclinical and clinical research to define the underpinnings of the disorder and to discover

Table 111.1 Features of Hutchinson-Gilford Progeria Syndrome and Other Premature Aging Disorders with Overlapping Features

DISEASE	CAUSATIVE GENE	ONSET	MAIN CLINICAL FEATURES
Hutchinson-Gilford progeria syndrome (HGPS)	*LMNA*: de novo dominant point pathogenic variant (c.1824C>T; p.G608G or pathogenic variants in first five intronic bases of intron 11)	Early childhood	Severe failure to thrive in infancy, progressive alopecia leading to total alopecia, skin lesions, characteristic facies, loss of subcutaneous fat, bone changes, skeletal anomalies, musculoskeletal degeneration, hearing loss, high-pitched voice, delayed and crowded dentition, atherosclerosis, cerebrovascular disease, average death in mid-teens from myocardial infarction or stroke (from cardiovascular disease).
Restrictive dermopathy (RD)	*ZMPSTE24*: recessive null pathogenic variants	Neonatal	Intrauterine growth restriction, reduced fetal movements, and preterm delivery, tight and translucent skin with erosions, facial dysmorphism, skeletal malformations, generalized arthrogryposis; lethal within the first weeks of life
Mandibuloacral dysplasia type B (MADB)	*ZMPSTE24*: recessive pathogenic variants: often compound heterozygous pathogenic variants with a null allele and one maintaining some residual activity	Early childhood	Generalized lipodystrophy, altered skin pigmentation, alopecia, severe bone and growth defects
Mandibuloacral dysplasia type A (MADA)	*LMNA*: recessive missense pathogenic variants	Early childhood	Partial lipodystrophy at torso and limbs, bone abnormalities, altered skin pigmentation, lipodystrophic signs and mildly accelerated aging
Nestor-Guillermo progeria syndrome (NGPS)	*BANF1*: recessive pathogenic variant (c.34G>A; p.Ala12Thr)	Early childhood	Failure to thrive, aged appearance, growth restriction, decreased subcutaneous fat, thin limbs, stiff joints, severe osteolysis, absence of early cardiovascular impairment
Mandibular hypoplasia, deafness, progeroid features, and lipodystrophy syndrome (MDPL)	*POLD1*: dominant pathogenic variants, including the common de novo pathogenic variant (c.1812_1814delCTC. P.Ser605del) observed in 80% of the patients	Early childhood	Mandibular hypoplasia, prominent loss of subcutaneous fat, progeroid appearance, skin abnormalities, metabolic abnormalities including insulin resistance and diabetes mellitus, sensorineural deafness, hypogonadism in males
Mandibuloacral dysplasia associated with *MTX2* (MADaM)	*MTX2*: recessive pathogenic variants	Early childhood	Small viscerocranium with mandibular underdevelopment, growth restriction, lipodystrophy, altered skin pigmentation, distal acroosteolyses, renal focal glomerulosclerosis, severe cardiovascular disease
Atypical progeroid laminopathies	*LMNA* and *ZMPSTE24*	Variable from early life to adulthood	Several *LMNA* pathogenic variants, including dominant and recessive ones, result in a spectrum of progeroid laminopathies ranging in severity from severe RD-like forms to adult-onset atypical WS; atypical (severe) MADB forms can result from recessive *ZMPSTE24* pathogenic variants
Werner syndrome (WS)	*WRN*: recessive pathogenic variants	Adulthood	Lack of the pubertal growth spurt during early teen years, graying or loss of hair, scleroderma-like skin lesions, characteristic facies, bilateral cataracts, type 2 diabetes mellitus, hypogonadism, skin ulcers, osteoporosis, arteriosclerosis, increased risk of cancer
Wiedemann-Rautenstrauch syndrome	*POLR3A*	Neonatal	Severe prenatal and postnatal growth restriction, facial dysmorphism, generalized lipodystrophy with local fatty tissue accumulations
Cockayne syndrome	CSA *(ERCC8)* CSB *(ERCC6)*	Neonatal/ infancy	Skin and dental abnormalities, subcutaneous fat loss, short stature, vasculopathy, hypogonadism, hearing loss, cataracts, intellectual disability, neurologic disorders
Rothmund-Thompson syndrome	*RECQL4*	Infancy	Diffuse hair loss, skin and dental abnormalities, short stature, osteopenia, hypogonadism, hyperkeratosis, cataracts, tumor predisposition

Chapter 112

The Porphyrias

Manisha Balwani, Robert J. Desnick, and Karl E. Anderson

Porphyrias are metabolic diseases resulting from altered activities of specific enzymes of the heme biosynthetic pathway. These enzymes are most active in bone marrow and liver. **Erythropoietic porphyrias**, in which overproduction of heme pathway intermediates occurs primarily in bone marrow erythroid cells, usually present at birth or in early childhood with *cutaneous photosensitivity,* or in the case of congenital erythropoietic porphyria, even in utero as *nonimmune hydrops*. Erythropoietic protoporphyria is the most common porphyria in children. Most porphyrias are hepatic, with overproduction and initial accumulation of porphyrin precursors or porphyrins in the liver. Activation of hepatic porphyrias is very rare during childhood, reflecting the distinct hepatic regulatory mechanisms for heme biosynthesis that are influenced by pubertal development. Homozygous forms of the hepatic porphyrias may manifest clinically before puberty. Children who are heterozygous for inherited hepatic porphyrias may present with nonspecific and unrelated symptoms, and parents often request advice about long-term prognosis and express concerns about drugs that may exacerbate these conditions.

THE HEME BIOSYNTHETIC PATHWAY

Heme is required for a variety of hemoproteins, such as hemoglobin, myoglobin, respiratory cytochromes, and cytochrome P450 enzymes (CYPs). It is believed that the eight enzymes in the pathway for heme biosynthesis are active in all tissues. Hemoglobin synthesis in erythroid precursor cells accounts for approximately 85% of daily heme synthesis in humans. Hepatocytes account for most of the rest, primarily for synthesis of CYPs, which are especially abundant in the liver endoplasmic reticulum and turn over more rapidly than many other hemoproteins, such as the mitochondrial respiratory cytochromes. Pathway intermediates are the porphyrin precursors δ-**aminolevulinic acid** (ALA, also known as *5-aminolevulinic acid*) and **porphobilinogen (PBG)**, as well as porphyrins (mostly in their reduced forms, known as **porphyrinogens**) (Fig. 112.1). These intermediates do not accumulate in significant amounts or have important physiologic functions under normal conditions.

Altered activity of each enzyme in the pathway has been associated with a specific type of porphyria (Table 112.1). The first enzyme, ALA synthase (ALAS), occurs in two forms. An erythroid-specific form, ALAS2, is deficient in X-linked sideroblastic anemia as a result of pathogenic variants of the *ALAS2* gene on chromosome Xp11.2. Gain-of-function pathogenic variants of *ALAS2* caused by deletions in the last exon cause **X-linked protoporphyria (XLP)**, which is phenotypically identical to erythropoietic protoporphyria.

Regulation of heme synthesis differs in the two major heme-forming tissues. Liver heme biosynthesis is primary controlled by the ubiquitous form of ALAS (ALAS1). Synthesis of ALAS1 in liver is regulated by a "free" heme pool (see Fig. 112.1), which can be augmented by newly synthesized heme or by existing heme released from hemoproteins and destined for breakdown to biliverdin by heme oxygenase.

In comparison, in the hematopoietic system, novel regulatory mechanisms allow the production of the very large amounts of heme needed for hemoglobin synthesis. The response to stimuli for hemoglobin synthesis occurs during cell differentiation, leading to an increase in cell number. Also, unlike the liver, heme has a stimulatory role in hemoglobin formation, and the stimulation of heme synthesis in erythroid cells is accompanied not only by increases in ALAS2 but also by sequential induction of other heme biosynthetic enzymes. Separate

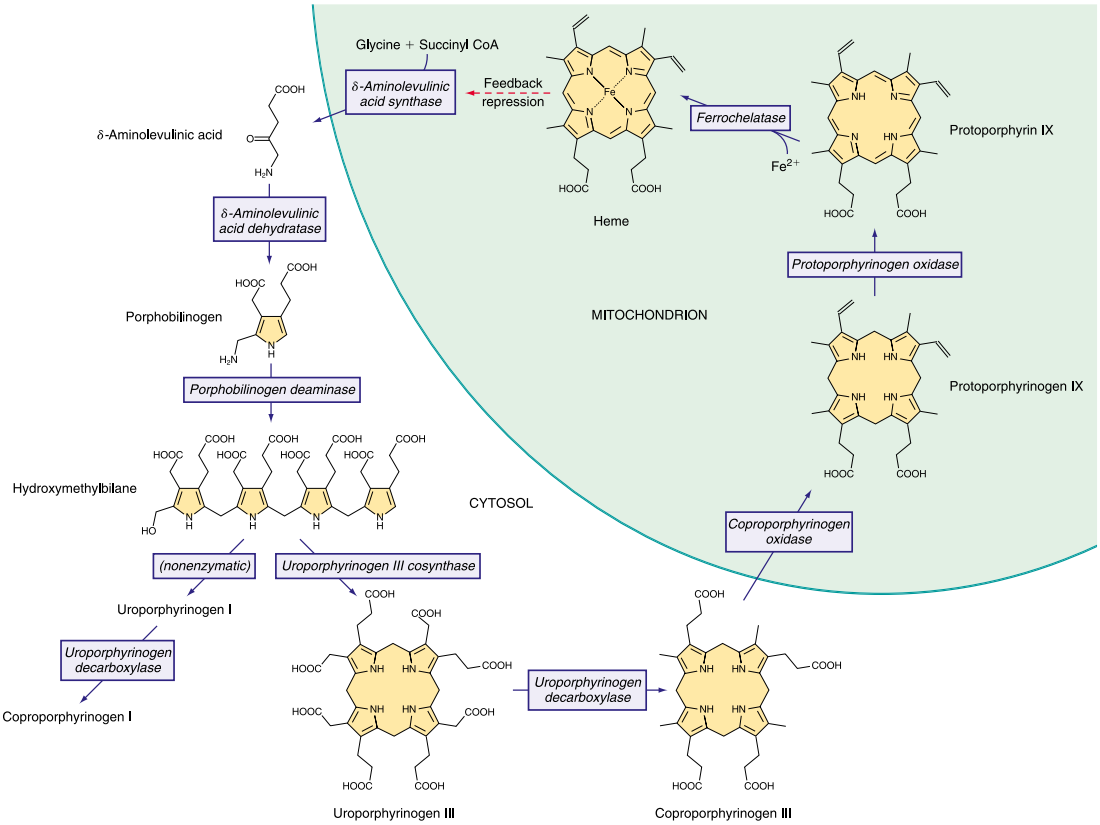

Fig. 112.1 Enzymes and intermediates of the heme biosynthetic pathway. The pathway is regulated in the liver by the end product, heme, mainly by feedback repression *(dashed red arrow)*.

Table 112.1 The Human Porphyrias: Pathogenic Variants, Time of Presentation, and Tissue- and Symptom-Based Classifications

				CLASSIFICATION*			
DISEASE	**ENZYME**	**INHERITANCE**	**PRESENTATION**	**H**	**E**	**A/N**	**C**
X-linked protoporphyria (XLP)	δ-Aminolevulinate synthase 2 (ALAS2)	X-linked	Childhood		X		X
δ-Aminolevulinic acid dehydratase porphyria (ADP)	δ-Aminolevulinic acid dehydratase (ALAD)	Autosomal recessive	Mostly postpuberty	X	X‡	X	
Acute intermittent porphyria (AIP)	Hydroxymethylbilane synthase (HMBS)	Autosomal dominant	Postpuberty	X		X	
Homozygous AIP		Homozygous dominant	Childhood	X	X	X	
Congenital erythropoietic porphyria (CEP)	Uroporphyrinogen III synthase (UROS)	Autosomal recessive	In utero or infancy		X		X
Porphyria cutanea tarda (PCT) type 1	Uroporphyrinogen decarboxylase (UROD)	Sporadic	Adults	X			X
PCT type 2†		Autosomal dominant	Adults	X			X
PCT type 3		Unknown	Adults	X			X
Hepatoerythropoietic porphyria (HEP)		Homozygous dominant	Childhood	X	X‡		X
Hereditary coproporphyria (HCP)	Coproporphyrinogen oxidase (CPOX)	Autosomal dominant	Postpuberty	X		X	X
Homozygous HCP		Homozygous dominant	Childhood	X	X	X	X
Variegate porphyria (VP)	Protoporphyrinogen oxidase (PPOX)	Autosomal dominant	Postpuberty	X		X	X
Homozygous VP		Homozygous dominant	Childhood	X	X	X	X
Erythropoietic protoporphyria (EPP)	Ferrochelatase (FECH)	Autosomal recessive (most commonly heteroallelic with hypomorphic allele)	Childhood		X		X

*Classification abbreviations: H, Hepatic; E, Erythropoietic; A/N, Acute/Neurologic; C, Cutaneous.
†PCT is a result of inhibition of hepatic UROD. Autosomal dominant inheritance of a partial deficiency of UROD is a predisposing factor in cases defined as familial (type 2) PCT. Other genetic factors, such as HFE pathogenic variants, are sometimes found in all types of PCT.
‡ADP and HEP are considered primarily hepatic porphyrias, but substantial increases in erythrocyte zinc protoporphyrin suggest an erythropoietic component.

erythroid-specific and nonerythroid, or "housekeeping," transcripts are known for the first four enzymes in the pathway. The separate forms of ALAS are encoded by genes on different chromosomes, but for each of the other three, erythroid and nonerythroid transcripts are transcribed by alternative promoters in the same gene. Heme also regulates the rate of its synthesis in erythroid cells by controlling the transport of iron into reticulocytes.

Intermediates of the heme biosynthetic pathway are efficiently converted to heme and, normally, only small amounts of the intermediates are excreted. Some may undergo chemical modifications before excretion. Whereas the porphyrin precursors ALA and PBG are colorless, nonfluorescent, and largely excreted unchanged in urine, PBG may degrade to colored products such as the brownish pigment called *porphobilin* or spontaneously polymerize to uroporphyrins. Porphyrins are red in color and display bright-red fluorescence when exposed to long-wavelength ultraviolet (UV) light. Porphyrinogens are the reduced form of porphyrins and are colorless and nonfluorescent, but are readily autoxidized to the corresponding porphyrins when they accumulate or are outside the cell. Only the type III isomers of uroporphyrinogen and coproporphyrinogen are converted to heme (see Fig. 112.1).

ALA and PBG are excreted in urine. Excretion of porphyrins and porphyrinogens in urine or bile is determined by the number of carboxyl groups. Those with many carboxyl groups, such as *uroporphyrin* (octacarboxyl porphyrin) and *heptacarboxyl porphyrin,* are water soluble and readily excreted in urine. Those with fewer carboxyl groups, such as *protoporphyrin* (dicarboxyl porphyrin), are not water soluble and are excreted in bile and feces. *Coproporphyrin* (tetracarboxyl porphyrin) is excreted partly in urine and partly in bile. Because coproporphyrin I is more readily excreted in bile than coproporphyrin III, impaired hepatobiliary function may increase total urinary coproporphyrin excretion and the ratio of these isomers.

CLASSIFICATION AND DIAGNOSIS OF PORPHYRIAS

Two useful classification schemes reflect either the underlying pathophysiology or the clinical features of porphyrias (see Table 112.1). In **hepatic porphyrias** and **erythropoietic porphyrias** the source of excess production of porphyrin precursors and porphyrins is the liver and bone marrow, respectively. **Acute porphyrias** cause neurologic symptoms that are associated with increases of one or both of the porphyrin precursors, ALA and PBG. In the **cutaneous porphyrias,** photosensitivity results from transport of porphyrins in blood from the liver or bone marrow to the skin. **Dual porphyria** refers to the very rare cases of porphyria with deficiencies of two different heme pathway enzymes.

Porphyria cutanea tarda (PCT), acute intermittent porphyria (AIP), and erythropoietic protoporphyria (EPP) are the three most common porphyrias, in that order, considering all age-groups, and are very different in clinical presentation, precipitating factors, methods of diagnosis, and effective therapy (Table 112.2). Two less common acute porphyrias, **hereditary coproporphyria (HCP) and variegate porphyria (VP)**, can also cause blistering photosensitivity (see Table 112.1). **Congenital erythropoietic porphyria (CEP)** causes more severe blistering lesions, often with secondary infection and mutilation. EPP and **X-linked protoporphyria (XLP)** have the same phenotype and are distinct from the other cutaneous porphyrias in causing

Table 112.2 The Three Most Common Human Porphyrias and Major Features

	PRESENTING SYMPTOMS	EXACERBATING FACTORS	MOST IMPORTANT SCREENING TESTS	TREATMENT
Acute intermittent porphyria	Neurologic, adult onset	Drugs (mostly P450 inducers), progesterone, dietary restriction	Urinary porphobilinogen	Hemin, glucose, givosiran
Porphyria cutanea tarda	Skin blistering and fragility (chronic), adult onset	Iron, alcohol, smoking, estrogens, hepatitis C, HIV, halogenated hydrocarbons	Plasma or urine porphyrins	Phlebotomy, low-dose hydroxychloroquine, direct acting antivirals (if hepatitis C is present)
Erythropoietic protoporphyria	Phototoxic pain and swelling (mostly acute), childhood onset	Sunlight exposure	Total erythrocyte protoporphyrin with metal-free and zinc protoporphyrin	Sun protection

nonblistering photosensitivity that occurs acutely after sun exposure. EPP is also the most common porphyria to become manifest before puberty.

First-Line Laboratory Diagnostic Testing

A few sensitive and specific first-line laboratory tests should be obtained whenever symptoms or signs suggest the diagnosis of porphyria. If a first-line or screening test is significantly abnormal, more comprehensive testing should follow to establish the type of porphyria. Overuse of laboratory tests for screening can lead to unnecessary expense and even delay in diagnosis. In patients who present with a past diagnosis of porphyria, laboratory reports that were the basis for the original diagnosis must be reviewed, and if these were inadequate, further testing considered.

Acute porphyria should be suspected in patients with neurovisceral symptoms such as abdominal pain after puberty, when initial clinical evaluation does not suggest another cause. *Urinary PBG* should be measured. Urinary PBG is virtually always increased during acute attacks of AIP, HCP, and VP and is not substantially increased in any other medical conditions. Therefore this measurement is both sensitive and specific. Results from spot (single-void) urine specimens are highly informative because very substantial increases are expected during acute attacks of porphyria. A 24-hour collection can unnecessarily delay diagnosis. The same spot urine specimen should be saved for quantitative determination of PBG (expressed relative to creatinine) to confirm the qualitative PBG result. ALA is often measured as well, but is usually less elevated than PBG in AIP, HCP, and VP. In **ALA dehydratase porphyria (ADP)**, urinary ALA and porphyrins, but not PBG, are greatly elevated. Measurement of urinary porphyrins in addition to PBG is recommended to screen for acute porphyrias because PBG is often less elevated and returns to normal more rapidly in HCP and VP than in AIP. Porphyrin measurement *alone* should be avoided for screening, however, because it is often increased in many disorders other than porphyrias, such as liver diseases, and misdiagnoses of porphyria can result from increases in urinary porphyrins that have no diagnostic significance.

Blistering Cutaneous Porphyrias

Blistering skin lesions caused by porphyria are virtually always accompanied by increases in *total plasma* and *urinary porphyrins.* Porphyrins in plasma in VP are mostly covalently linked to plasma proteins and readily detected by a diagnostic peak in a fluorescence scanning method. The normal range for plasma porphyrins is somewhat increased in patients with end-stage renal disease.

Nonblistering Cutaneous Porphyria

Measurement of total erythrocyte protoporphyrin and, if the total amount is elevated, fractionation of protoporphyrin into its metal-free and zinc-chelated forms, is essential for diagnosis of EPP and XLP. Unfortunately, this is not offered by some major commercial laboratories. Results of zinc protoporphyrin measurements are often recorded (even in the same report) as both *protoporphyrin* and *free erythrocyte protoporphyrin,* with each calculated differently, based on past practices for screening for lead poisoning (which only increases zinc protoporphyrin). Thus the obsolete term *free protoporphyrin* does not mean metal-free protoporphyrin, because it was defined as iron-free protoporphyrin and dates from before it was known that (except in protoporphyrias) protoporphyrin in erythrocytes is mostly zinc chelated. This unnecessary confusion makes diagnosis and reliable exclusion of protoporphyrias difficult. Total plasma porphyrins are elevated in most, but not all, cases of protoporphyria, so a normal level should not be relied on to exclude protoporphyria when total erythrocyte protoporphyrin is elevated.

Increases in erythrocyte total and zinc-chelated protoporphyrin occur in many other conditions, including iron deficiency, lead poisoning, hemolysis, anemia of chronic disease, and other erythrocyte disorders. Therefore the diagnosis of EPP must be confirmed by showing a predominant increase in free and metal-free protoporphyrin. In XLP, both free and zinc protoporphyrin are elevated.

Second-Line Testing

More extensive testing is well justified when a first-line test is positive. A substantial increase in PBG may be caused by AIP, HCP, or VP, and these can be distinguished by measuring urinary porphyrins (using the same spot urine sample), fecal porphyrins, and plasma porphyrins. The various porphyrias that cause blistering skin lesions are differentiated by measuring porphyrins in urine, feces, erythrocytes, and plasma. *Confirmation by genetic testing is important once the diagnosis is established by biochemical testing.*

Testing for Subclinical Porphyria

It is often difficult to diagnose or rule out porphyria in patients who had suggestive symptoms months or years in the past and in asymptomatic relatives of patients with acute porphyrias because porphyrin precursors and porphyrins may be normal. More extensive testing and consultation with a specialist laboratory and physician may be needed. Before evaluating relatives, the diagnosis of porphyria should be firmly established in an index case and the laboratory results reviewed to guide the choice of tests for the family members. Identification of a disease-causing pathogenic variant in an index case greatly facilitates detection of additional gene carriers because biochemical tests in latent carriers may be normal.

δ-AMINOLEVULINIC ACID DEHYDRATASE–DEFICIENT PORPHYRIA

ALA dehydratase–deficient porphyria (ADP) is sometimes termed *Doss porphyria* after the investigator who described the first cases. The term *plumboporphyria* emphasizes the similarity of this condition to lead poisoning, but incorrectly implies that it is caused by lead exposure.

Etiology

This porphyria results from a deficiency of ALA dehydratase (ALAD), which is inherited as an autosomal recessive trait. Only eight cases have been confirmed by pathogenic variant analysis. The prevalence of heterozygous ALAD deficiency was estimated to be <1% in Germany and approximately 2% in Sweden.

Pathology and Pathogenesis

ALAD catalyzes the condensation of two molecules of ALA to form the pyrrole PBG (see Fig. 112.1). The enzyme is subject to inhibition by a number of exogenous and endogenous chemicals. ALAD is the principal lead-binding protein in erythrocytes, and lead can displace the zinc atoms of the enzyme. Inhibition of erythrocyte ALAD activity is a sensitive index of lead exposure.

Eleven abnormal ALAD alleles, most with point pathogenic variants, have been identified, some expressing partial activity, such that heme synthesis is partially preserved. The amount of residual enzyme activity may predict the phenotypic severity of this disease.

ADP is often classified as a hepatic porphyria, although the site of overproduction of ALA is not established. A patient with severe, early-onset disease underwent liver transplantation without significant clinical or biochemical improvement, which might suggest that the excess intermediates did not originate in the liver. Evidence suggests this disease may have an erythropoietic component. Excess urinary coproporphyrin III in ADP might originate from metabolism of ALA to porphyrinogens in a tissue other than the site of ALA overproduction. Administration of large doses of ALA to normal individuals also leads to substantial coproporphyrinuria. Increased erythrocyte zinc protoporphyrin, as in all other homozygous porphyrias, may be explained by accumulation of earlier pathway intermediates in bone marrow erythroid cells during hemoglobin synthesis, followed by their transformation to protoporphyrin after hemoglobin synthesis is complete. Neurologic symptoms are attributed to neurotoxic effects of ALA, but this is unproven.

Clinical Manifestations

In most cases, symptoms resemble other acute porphyrias, including acute attacks of abdominal pain and peripheral neuropathy. Precipitating factors, such as exposure to harmful drugs, have not been evident in most cases. Six of the reported cases were adolescent males. A Swedish infant had more severe disease, with neurologic impairment and failure to thrive. A 63-year-old man in Belgium developed an acute motor polyneuropathy concurrently with a myeloproliferative disorder. A Dutch patient with symptom onset in infancy presented in adulthood with acute symptoms and progressive asymmetric weakness of both extremities.

Laboratory Findings

Urinary ALA, coproporphyrin III, and erythrocyte zinc protoporphyrin are substantially increased. Urinary PBG is normal or slightly increased. Erythrocyte ALAD activity is markedly reduced, and both parents have approximately half-normal activity of this enzyme and normal urinary ALA.

Diagnosis and Differential Diagnosis

The other three acute porphyrias are characterized by substantial increases in both ALA and PBG. In contrast, ALA, but not PBG, is substantially increased in ADP. A marked deficiency of erythrocyte ALAD and half-normal activity in the parents support the diagnosis. Other causes of ALAD deficiency, such as **lead poisoning**, must be excluded. Succinylacetone accumulates in hereditary tyrosinemia type 1 and is structurally similar to ALA, inhibits ALAD, and can cause increased urinary excretion of ALA and clinical manifestations that resemble acute porphyria. Idiopathic acquired ALAD deficiency has been reported. Unlike lead poisoning, the deficient ALAD activity in ADP is not restored by the in vitro addition of sulfhydryl reagents such as dithiothreitol. Even if no other cause of ALAD deficiency is found, it is essential to confirm the diagnosis of ADP by molecular studies.

Treatment

Treatment experience with ADP is limited but is similar to other acute porphyrias. Glucose seems to have minimal effectiveness but may be tried for mild symptoms. **Hemin therapy** was apparently effective for acute attacks in male adolescents, and weekly infusions prevented attacks in two of these patients. Hemin was not effective either biochemically or clinically in the Swedish child with severe disease, and it produced a biochemical response but no clinical improvement in the Belgian man with a late-onset form, who had a peripheral neuropathy but no acute attacks. Hemin is also effective in treating porphyria-like symptoms associated with hereditary tyrosinemia and can significantly reduce urinary ALA and coproporphyrin in lead poisoning. Avoidance of drugs that are harmful in other acute porphyrias is advisable. Liver transplantation was not effective in the child with severe disease. In a recent report, weekly blood transfusions and hydroxycarbamide were used in addition to heme-arginate to suppress erythroid heme synthesis.

Prognosis

Recurrent attacks may occur and require repeated treatment with hemin. The course was unfavorable in the Swedish child with more severe disease and was uncertain in adults with late-onset disease associated with myeloproliferative disorders.

Prevention and Genetic Counseling

Heterozygous parents should be aware that subsequent children are at risk for ADP, as in any autosomal recessive disorder. Prenatal diagnosis is possible but has not been reported.

ACUTE INTERMITTENT PORPHYRIA

AIP is also termed *pyrroloporphyria, Swedish porphyria,* and *intermittent acute porphyria* and is the most common type of acute porphyria in most countries.

Etiology

AIP results from the deficient activity of the housekeeping form of porphobilinogen deaminase (PBGD). This enzyme is also known as **hydroxymethylbilane (HMB) synthase** (the prior term, uroporphyrinogen I synthase, is obsolete). HMB synthase catalyzes the deamination and head-to-tail condensation of four PBG molecules to form the linear tetrapyrrole, HMB (also known as *preuroporphyrinogen;* see Fig. 112.1). A unique dipyrromethane cofactor binds the pyrrole intermediates at the catalytic site until six pyrroles (including the dipyrrole cofactor) are assembled in a linear fashion, after which the tetrapyrrole HMB is released. The apo-deaminase generates the dipyrrole cofactor to form the holodeaminase, and this occurs more readily from HMB than from PBG. Indeed, high concentrations of PBG may inhibit formation of the holodeaminase. The product HMB can cyclize nonenzymatically to form nonphysiologic uroporphyrinogen I, but in the presence of the next enzyme in the pathway is more rapidly cyclized to form uroporphyrinogen III.

Erythroid and housekeeping forms of the enzyme are encoded by a single gene. The two isoenzymes are both monomeric proteins, differ only slightly in molecular weight (approximately 40 and 42 kDa), and result from alternative splicing of two distinct messenger RNA (mRNA) transcripts that arise from two different promoters. The housekeeping promoter functions in all cell types, including erythroid cells.

The pattern of inheritance of AIP is autosomal dominant, with very rare homozygous cases that present in childhood. More than 400 *HMBS* pathogenic variants, including missense, nonsense, and splicing pathogenic variants, and insertions and deletions have been identified in AIP and in many population groups. Most pathogenic variants are found in only one or a few families. Because of founder effects, some are more common in certain geographic areas, such as northern Sweden (W198X), Holland (R116W), Argentina (G116R), Nova Scotia (R173W), and Switzerland (W283X). De novo pathogenic variants may be found in approximately 3% of cases. The nature of the *HMBS* pathogenic variant does not account for the severity of the clinical presentation, which varies greatly within families. **Chester porphyria** was initially described as a variant form of acute porphyria in a large English family but was found to be caused by an *HMBS* pathogenic variant.

Most pathogenic variants lead to approximately half-normal activity of the housekeeping and erythroid isozymes and half-normal amounts of their respective enzyme proteins in all tissues of heterozygotes. In approximately 5% of unrelated AIP patients, the housekeeping isozyme is deficient, but the erythroid-specific isozyme is normal. Pathogenic

variants causing this are usually found within exon 1 or its 5′ splice donor site or initiation of translation codon.

Pathology and Pathogenesis

Induction of the rate-limiting hepatic enzyme ALAS1 is thought to underlie acute exacerbations of this and the other acute porphyrias. AIP remains latent (or asymptomatic) in the great majority of those who are heterozygous carriers of *HMBS* pathogenic variants, and this is almost always the case before puberty. In those with no history of acute symptoms, porphyrin precursor excretion is usually normal, suggesting that half-normal hepatic HMBS activity is sufficient unless hepatic ALAS1 activity is increased. Patients can also be asymptomatic with elevated levels of porphyrin precursors and are classified as *asymptomatic high excretors*. These patients may have a remote history of symptoms. Many factors that lead to clinical expression of AIP, including certain drugs and steroid hormones, have the capacity to induce hepatic ALAS1 and CYPs. When hepatic heme synthesis is increased, half-normal HMBS activity may become limiting, and ALA, PBG, and other heme pathway intermediates may accumulate. In addition, heme synthesis becomes impaired, and heme-mediated repression of hepatic ALAS1 is less effective.

It is not proved, however, that hepatic HMBS remains constant at approximately 50% of normal activity during exacerbations and remission of AIP, as in erythrocytes. An early report suggested that the enzyme activity is considerably less than half-normal in the liver during an acute attack. Hepatic HMBS activity might be reduced further once AIP becomes activated if, as suggested, excess PBG interferes with assembly of the dipyrromethane cofactor for this enzyme. It also seems likely that currently unknown genetic factors play a contributing role in, for example, patients who continue to have attacks even when known precipitants are avoided.

AIP is almost always latent before puberty and becomes active mostly in adult females, which suggests that endocrine factors, and especially adult levels of female steroid hormones, may be important for clinical expression. Premenstrual attacks are probably the result of endogenous progesterone. Acute porphyrias are sometimes exacerbated by exogenous steroids, including oral contraceptive preparations containing progestins. Surprisingly, pregnancy is usually well tolerated, suggesting that beneficial metabolic changes may ameliorate the effects of high levels of progesterone.

Drugs that are unsafe in acute porphyrias (Table 112.3) include those with the capacity to induce hepatic ALAS1, which is closely associated with induction of CYPs. Some chemicals (e.g., griseofulvin) can increase heme turnover by promoting the destruction of specific CYPs to form an inhibitor (e.g., *N*-methyl protoporphyrin) of ferrochelatase (FECH, the final enzyme in the pathway). Sulfonamide antibiotics are harmful but apparently not inducers of hepatic heme synthesis. Ethanol and other alcohols are inducers of ALAS1 and some CYPs.

Nutritional factors, in particular reduced intake of calories and carbohydrates, as may occur with illness or attempts to lose weight, can increase porphyrin precursor excretion and induce attacks of porphyria. Increased carbohydrate intake may ameliorate attacks. Hepatic ALAS1 is modulated by the peroxisome proliferator-activated receptor-γ coactivator-1α, which is an important link between nutritional status and exacerbations of acute porphyria.

Other factors have been implicated. Chemicals in cigarette smoke, such as polycyclic aromatic hydrocarbons, can induce hepatic CYPs and heme synthesis. A survey of AIP patients found an association between smoking and repeated porphyric attacks. Attacks may result from metabolic stress and impaired nutrition associated with major illness, infection, or surgery. Clinical observations suggest an additive effect of multiple predisposing factors, including drugs, endogenous hormones, nutritional factors, and smoking.

Neurologic Mechanisms

The mechanism of neural damage in acute porphyrias is poorly understood. The most favored hypothesis at present is that one or more heme precursors, or perhaps a derivative, are neurotoxic. Increased ALA in AIP, HCP, VP, ADP, plumbism, and hereditary tyrosinemia type 1, which have similar neurologic manifestations, suggests that this substance or a derivative may be neuropathic. Porphyrins derived from ALA after its uptake into cells may have toxic potential. ALA can also interact with γ-aminobutyric acid (GABA) receptors. Severe AIP greatly improves after allogeneic liver transplantation. This experience and the demonstration that recipients of AIP livers develop porphyria support the hypothesis that heme precursors from the liver cause the neurologic manifestations.

Epidemiology

AIP occurs in all ethnic groups and is the most common acute porphyria, with an estimated prevalence in most countries of 5 in 100,000. In Sweden, prevalence was estimated to be 7.7 in 100,000, including latent cases with normal porphyrin precursors. A much higher prevalence of 60-100 in 100,000 in northern Sweden is the result of a founder effect. The combined prevalence of AIP and VP in Finland is approximately 3.4 in 100,000. Population screening by erythrocyte HMBS activity or DNA analysis revealed a prevalence of 200 heterozygotes per 100,000 people in Finland and 1 in approximately 1,675 (60 in 100,000) in France. Studies using exomic/genomic databases show that the estimated frequency of pathogenic variants in the *HMBS* gene is 0.00056 (56 in 100,000), suggesting that the penetrance of this disorder may be as low as 1% and that carriers of *HMBS* pathogenic variants that can cause AIP are much more common than previously believed. Higher penetrance in some families with AIP suggests a strong role of environmental factors and genetic modifiers.

Clinical Manifestations

Neurovisceral manifestations of acute porphyrias may appear any time after puberty, but rarely before it (Table 112.4). Porphyria attacks are exceedingly rare before the onset of puberty. Affected children are more often males as *opposed to affected adolescents and adults*, who are predominantly females. Reported symptomatic childhood cases often lacked adequate biochemical and molecular confirmation. The prepubertal attacks in males may be explained in part by coexisting medical conditions with the potential to upregulate ALAS1. Abdominal pain was the most common presenting symptom in such cases, but seizures, often preceding the diagnosis, were also common. Other manifestations reported in children include tachycardia, peripheral neuropathy, myalgias, hypertension, irritability, lethargy, and behavioral abnormalities. A population-based study in Sweden indicated that symptoms suggestive of porphyria may occur in heterozygotes during childhood, even, in contrast to adults, when urinary porphyria precursors are not elevated. This study did not compare the frequency of such nonspecific symptoms in a control group of children. Very rare cases of homozygous AIP present differently, with severe neurologic manifestations early in childhood.

Acute attacks in adults are characterized by a constellation of nonspecific symptoms, which may become severe and life threatening. **Abdominal pain** occurs in 85–95% of AIP patients and is usually severe, steady, and poorly localized, but is sometimes cramping, and accompanied by signs of ileus, including abdominal distention and decreased bowel sounds. Nausea, vomiting, and constipation are common, but increased bowel sounds and diarrhea may occur. Bladder dysfunction may cause hesitancy and dysuria. **Tachycardia**, the most common physical sign, occurs in up to 80% of attacks. This is often accompanied by **hypertension**, restlessness, coarse or fine tremors, and excess sweating, which are attributed to sympathetic overactivity and increased catecholamines. Other common manifestations include mental symptoms; pain in the extremities, head, neck, or chest; muscle weakness; and sensory loss. Because all these manifestations are neurologic rather than inflammatory, there is little or no abdominal tenderness, fever, or leukocytosis.

Porphyric neuropathy is primarily motor and appears to result from axonal degeneration rather than demyelinization. Sensory involvement is indicated by neuropathic pain in the extremities, which may be described as muscle or bone pain, and by numbness, paresthesias, and dysesthesias. Paresis may occur early in an attack but is more often a late manifestation in an attack that is not recognized

Table 112.3 Drugs Regarded as Unsafe and Safe in Acute Porphyrias

UNSAFE	SAFE
Barbiturates (all)	Narcotic analgesics
Sulfonamide antibiotics*	Aspirin
Meprobamate* (also mebutamate,* tybutamate*)	Acetaminophen (paracetamol)
Carisoprodol*	Phenothiazines
Glutethimide*	Penicillin and derivatives
Methyprylon	Streptomycin
Ethchlorvynol*	Glucocorticoids
Mephenytoin	Bromides
Phenytoin*	Insulin
Succinimides	Atropine
Carbamazepine*	Cimetidine
Clonazepam‡	Ranitidine†
Primidone*	Acetazolamide
Valproic acid*	Allopurinol
Pyrazolones (aminopyrine, antipyrine)	Amiloride
Griseofulvin*	Bethanidine
Ergots	Bumetanide
Metoclopramide* ‡	Coumarins
Rifampin*	Fluoxetine
Pyrazinamide* ‡	Gabapentin
Diclofenac* ‡	Gentamicin
Fluconazole*	Guanethidine
Oral contraceptives	Ofloxacin
Progesterone and synthetic progestins*	Propranolol
Danazol*	Succinylcholine
Alcohol	Tetracycline
ACEIs (especially enalapril) ‡	
Spironolactone	
CCBs (especially nifedipine) ‡	
Ketoconazole	
Ketamine*	

*Porphyria has been listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs. Estrogens are also listed as harmful in porphyria but have been implicated as harmful in acute porphyrias, mostly based only on experience with estrogen-progestin combinations. Although estrogens can exacerbate porphyria cutanea tarda, there is little evidence they are harmful in the acute porphyrias.
†Porphyria has been listed as a precaution in U.S. labeling for this drug. However, this drug is regarded as safe by other sources.
‡These drugs have been classified as probably safe by some sources, but this is controversial, and they should be avoided.
This partial listing does not include all available information about drug safety in acute porphyrias. Other sources should be consulted for drugs not listed here.
ACEIs, Angiotensin-converting enzyme inhibitors; CCBs, calcium channel blockers.

and adequately treated. Rarely, severe neuropathy develops when there is little or no abdominal pain. Motor weakness most commonly begins in the proximal muscles of the upper extremities and then progresses to the lower extremities and the periphery. It is usually symmetric, but occasionally asymmetric or focal. Initially, tendon reflexes may be little affected or hyperactive and become decreased or absent. Cranial nerves, most often X and VII, may be affected, and blindness from involvement of the optic nerves or occipital lobes has been reported. More common central nervous system (CNS) manifestations include seizures, anxiety, insomnia, depression, disorientation, hallucinations, and paranoia. Seizures may result from hyponatremia, porphyria itself, or an unrelated cause. Chronic depression and other mental symptoms occur in some patients, but attribution to porphyria is often difficult.

Hyponatremia is common during acute attacks. Inappropriate antidiuretic hormone (ADH) secretion is often the most likely mechanism, but salt depletion from excess renal sodium loss, gastrointestinal (GI) loss, and poor intake have been suggested as causes of hyponatremia in some patients. Unexplained reductions in total blood and red blood cell volumes are sometimes found, and increased ADH secretion might then be an appropriate physiologic response. Other electrolyte abnormalities may include hypomagnesemia and hypercalcemia.

The attack usually resolves within several days unless treatment is delayed. Abdominal pain may resolve within a few hours and paresis within a few days. Even severe motor neuropathy can improve over months or several years but may leave some residual weakness. Progression of neuropathy to respiratory paralysis and death seldom occurs with appropriate treatment and removal of harmful drugs. Sudden death may result from cardiac arrhythmia.

Laboratory Findings

Levels of ALA and PBG are substantially increased during acute attacks. These levels may decrease after an attack but usually remain increased unless the disease becomes asymptomatic for a prolonged period.

Porphyrins are also markedly increased, which accounts for reddish urine in AIP. These are predominantly uroporphyrins, which can form nonenzymatically from PBG. The increased urinary porphyrins in AIP are predominantly isomer III; however, their formation is likely to be largely enzymatic, which might occur if excess ALA produced in the liver enters cells in other tissues and is then converted to porphyrins by the heme biosynthetic pathway. Porphobilin, a degradation product of PBG, and dipyrrolomethanes appear to account for brownish urinary discoloration. Total fecal porphyrins and plasma porphyrins are normal or slightly increased in AIP. Erythrocyte protoporphyrin may be somewhat increased in patients with manifest AIP.

Erythrocyte HMBS activity is approximately half-normal in most patients with AIP. The normal range is wide and overlaps with the range for AIP heterozygotes. Some *HMBS* pathogenic variants cause the enzyme to be deficient only in nonerythroid tissues. HMBS activity is also highly dependent on erythrocyte age, and an increase in erythropoiesis from concurrent illness in an AIP patient may raise the activity into the normal range. Thus measurement of erythrocyte HMBS activity alone is insufficient in testing for AIP.

Diagnosis and Differential Diagnosis

An increased urinary PBG level establishes that a patient has one of the three most common acute porphyrias (see Table 112.2). Measuring PBG in serum is preferred when there is coexistent severe renal disease but is less sensitive when renal function is normal. Measurement of urinary ALA is less sensitive than PBG and also less specific, but will detect ADP, the fourth type of acute porphyria. Measurement of urinary porphyrins is also useful, because they may remain elevated after ALA and PBG return to normal and are also elevated in ADP. Decreased erythrocyte PBGD activity helps confirm the diagnosis of AIP, but is not found in all AIP patients.

Knowledge of the *HMBS* pathogenic variant in a family enables reliable identification of other pathogenic variant carriers. Prenatal diagnosis can be performed by amniocentesis or chorionic villus sampling (CVS) in a fetus with a known *HMBS* pathogenic variant in the family. Prenatal diagnosis is typically not performed because of the low penetrance of the disorder and favorable prognosis with treatment.

Complications

AIP and other acute porphyrias are typically associated with mild abnormalities in liver function tests; some patients develop chronic liver disease. The risk of hepatocellular carcinoma is also increased, perhaps 60- to 70-fold after age 50, even in asymptomatic individuals. Few patients who developed this neoplasm had increases in serum α-fetoprotein. Patients with acute porphyrias, especially >50 years old, should be screened by ultrasound or an alternative imaging method at 6-month intervals.

Table 112.4 Common Presenting Symptoms and Signs of Acute Porphyria

SYMPTOMS AND SIGNS	FREQUENCY (%)	COMMENT
GASTROINTESTINAL		
Abdominal pain	85–95	Usually unremitting (for hours or longer) and poorly localized but can be cramping.
Vomiting	43–88	Neurologic in origin and rarely accompanied by peritoneal signs, fever, or leukocytosis.
Constipation	48–84	Nausea and vomiting often accompany abdominal pain. May be accompanied by bladder paresis.
Diarrhea	5–12	
NEUROLOGIC		
Pain in extremities, back	50–70	Pain may begin in the chest or back and move to the abdomen. Extremity pain from the chest, neck, or head indicates involvement of sensory nerves; objective sensory loss reported in 10–40% of cases.
Paresis	42–68	May occur early or late during a severe attack. Muscle weakness usually begins proximally rather than distally and more often in the upper than lower extremities.
Respiratory paralysis	9–20	Preceded by progressive peripheral motor neuropathy and paresis.
Mental symptoms	40–58	May range from minor behavioral changes to agitation, confusion, hallucinations, and depression.
Convulsions	10–20	A central neurologic manifestation of porphyria or caused by hyponatremia, which often results from syndrome of inappropriate antidiuretic hormone secretion or sodium depletion.
CARDIOVASCULAR		
Tachycardia	64–85	May warrant treatment to control rate, if symptomatic.
Systemic arterial hypertension	36–55	May require treatment during acute attacks, and sometimes becomes chronic.

From Anderson KE, Bloomer JR, Bonkovsky HL, et al. Desnick recommendations for the diagnosis and treatment of the acute porphyrias, *Ann Intern Med.* 2005;142(6):439–450.

The risk of chronic hypertension and impaired renal function is increased in these patients, most often with evidence of interstitial nephritis. A nephrotoxic effect of ALA may contribute. This may progress to severe renal failure and require renal transplantation.

Patients with recurrent attacks may develop **chronic neuropathic pain**, although this has not been well characterized. Referral to a neurologist is recommended for any patient with ongoing or residual neurologic symptoms. In addition, depression and anxiety are common in these patients.

Treatment

Hemin

Intravenous (IV) hemin is the treatment of choice for most acute attacks of porphyria. There is a favorable biochemical and clinical response to early treatment with hemin, but less rapid clinical improvement if treatment is delayed. It is no longer recommended that therapy with hemin for a severe attack be started only after an unsuccessful trial of IV glucose for several days. Mild attacks without severe manifestations, such as paresis, seizures, hyponatremia, or pain requiring opioids, may be treated with IV glucose. After IV administration, hemin binds to hemopexin and albumin in plasma and is taken up primarily in hepatocytes, where it augments the regulatory heme pool in hepatocytes, represses the synthesis of hepatic ALAS1, and dramatically reduces porphyrin precursor overproduction.

Hemin* is available for IV administration in the United States as *lyophilized hematin* (Panhematin, Recordati). Degradation products begin to form as soon as the lyophilized product is reconstituted with sterile water, and these can cause infusion site phlebitis and a transient anticoagulant effect. Repeated treatment can lead to loss of venous access and iron overload. Reconstitution with 30% human albumin can enhance stability and prevent these adverse effects and is recommended especially if a peripheral vein is used for the infusion. Uncommon side effects of hemin include fever, aching, malaise, hemolysis, anaphylaxis, and circulatory collapse. Heme arginate, a more stable hemin preparation, is available in Europe and South Africa.

Hemin treatment should be instituted only after a diagnosis of acute porphyria has been initially confirmed by a marked increase in urinary PBG. When prior documentation of the diagnosis is available for review, it is not essential to confirm an increase in PBG with every recurrent attack if other causes of the symptoms are excluded clinically. The standard regimen of hemin for treatment of acute porphyric attacks is 3-4 mg/kg/day for 4 days. Lower doses have less effect on porphyrin precursor excretion and probably less clinical benefit.

Givosiran, an ALAS1-directed interfering RNA therapeutic, is effective for preventing frequent attacks in adults with acute hepatic porphyrias. Clinical trials have demonstrated rapid lowering of ALA and PBG, resulting in a reduction in attacks, chronic symptoms, and hemin utilization.

General and Supportive Measures

Drugs that may exacerbate porphyrias (see Table 112.3) should be discontinued whenever possible, and other precipitating factors identified. Hospitalization is warranted, except for mild attacks; for treatment of severe pain, nausea, and vomiting; for administration of hemin and fluids; and for monitoring vital capacity, nutritional status, neurologic function, and electrolytes. Pain usually requires an opioid; there is low risk for addiction after recovery from the acute attack. Ondansetron or promethazine is needed for nausea and vomiting and short-acting benzodiazepines for anxiety and restlessness. β-Adrenergic blocking agents may be useful to control tachycardia and hypertension but may be hazardous in patients with hypovolemia and incipient cardiac failure.

Carbohydrate Loading

The effects of carbohydrates on repressing hepatic ALAS1 and reducing porphyrin precursor excretion are weak compared with those of hemin. Therefore carbohydrate loading is recommended only for

* Hemin is the generic name for all heme preparations used for IV administration. Hemin is also a chemical term that refers to the oxidized (ferric) form of heme (iron protoporphyrin IX) and is usually isolated as hemin chloride. In alkaline solution, the chloride is replaced by the hydroxyl ion, forming hydroxyheme, or hematin.

mild attacks (e.g., without severe nausea or vomiting, hyponatremia, seizures, paresis, or pain requiring opioids). Glucose polymer solutions by mouth are sometimes tolerated. At least 300 g of IV glucose, usually given as a 10% solution, has been recommended for adults hospitalized with attacks of porphyria. Amounts up to 500 g daily may be more effective, but large volumes may favor the development of hyponatremia.

Other Therapies

Liver transplantation is effective in patients with severe AIP who are refractory to pharmacologic therapy. Patients can generally expect a complete biochemical and symptomatic resolution after transplantation. However, liver transplantation is a high-risk procedure and should be considered only as a last resort.

Seizures and Other Complications

Patients who experience seizures during an acute attack, especially if caused by hyponatremia or other electrolyte imbalances, may not require prolonged treatment with anticonvulsant drugs, most of which have at least some potential for exacerbating acute porphyrias. Gabapentin, pregabalin, levetiracetam, and vigabatrin are considered safe or probably safe, and clonazepam is probably less harmful than phenytoin, barbiturates, or valproic acid.

Control of hypertension is important and may help prevent chronic renal impairment, which can progress and require renal transplantation.

Safe and Unsafe Drugs

Patients often do well with avoidance of harmful drugs. Listings are available from the **European Porphyria Network** (www.porphyria-europe.com) and **American Porphyria Foundation** (https://porphyriafoundation.org/drugdatabase/), but some listings are controversial. Information regarding safety is lacking for many drugs, especially for those recently introduced.

Exogenous progestins can induce attacks of porphyria. Estrogens are seldom reported to be harmful when given alone. Synthetic steroids with an ethynyl substituent can cause a mechanism-based destruction of hepatic CYPs and should probably be avoided in patients with acute porphyria. Danazol is especially contraindicated.

Other Situations

Major surgery can be carried out safely in patients with acute porphyria, especially if barbiturates are avoided. Halothane has been recommended as an inhalation agent and propofol and midazolam as IV induction agents.

Pregnancy is usually well tolerated, which is surprising, because levels of progesterone, a potent inducer of hepatic ALAS1, are considerably increased during pregnancy. Some females do experience continuing attacks during pregnancy. This has sometimes been attributed to reduced caloric intake or metoclopramide, a drug sometimes used to treat hyperemesis gravidarum and considered by some to be harmful in acute porphyrias.

Diabetes mellitus and other endocrine conditions are not known to precipitate attacks of porphyria. In fact, the onset of diabetes mellitus and resulting high circulating glucose levels may decrease the frequency of attacks and lower porphyrin precursor levels in AIP.

Prognosis

In Finland, 74% of patients with AIP or VP reported that they led normal lives, and <30% had recurrent attacks during several years of follow-up. In those presenting with acute symptoms, recurrent attacks were most likely within the next 1-3 years. Moreover, only 6% of gene carriers who had never had attacks developed symptoms. The positive outlook may result from earlier detection, better treatment of acute attacks, and replacement of harmful drugs such as barbiturates and sulfonamides with safer drugs. However, some patients continue to have recurrent attacks, chronic pain, and other symptoms, even after avoiding known exacerbating factors.

Prevention

For prevention of attacks, it is important to identify multiple inciting factors and remove as many as possible. Drugs for concurrent medical conditions should be reviewed. Because dietary factors are often unapparent, consultation with a dietitian may be useful. A well-balanced diet that is somewhat high in carbohydrate (60–70% of total calories) and sufficient to maintain weight is recommended. There is little evidence that additional dietary carbohydrate helps further in preventing attacks, and it may lead to weight gain. Patients who wish to lose excess weight should do so gradually and when they are clinically stable. Rapid weight loss after bariatric surgery may exacerbate acute porphyrias. Iron deficiency, which can be detected by a low serum ferritin level, should be corrected.

Gonadotropin-releasing hormone (GnRH) analogs, which reversibly suppress ovulation, can be dramatically effective for preventing frequently recurring luteal-phase attacks, but baseline and continuing gynecologic evaluation and bone mineral density measurements are important; transdermal estrogen or a bisphosphonate may be added to prevent bone loss. Hemin administered once or twice weekly can prevent frequent attacks of porphyria in some patients. Alternatively, single-dose hemin can be administered "on demand" at an outpatient infusion center to abort an attack and prevent hospitalization, if a patient can recognize early "prodromal" symptoms.

Givosiran (Givlaari, Alnylam) an interfering RNA therapeutic that is administered subcutaneously every month, has been approved by the Food and Drug Administration (FDA) and European Medicines Agency (EMA) for prevention of acute attacks of an AHP.

Genetic Counseling

A pathogenic variant identified in the index case can be sought in offspring at any age. Counseling should emphasize that the great majority of those who inherit an *HMBS* pathogenic variant never develop symptoms, and the prognosis of those who do is favorable. Therefore a normal, healthy life is expected, especially with avoidance of harmful drugs and other factors and prompt recognition and treatment of symptoms should they occur. Given this favorable outlook, even during pregnancy, having children is not precluded for those who have inherited a pathogenic variant, and prenatal diagnosis of acute porphyrias is less important than it is for many other inherited diseases.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

Also termed *Günther disease,* this rare disease usually presents with photosensitivity shortly after birth or in utero as nonimmune hydrops.

Etiology

CEP is an autosomal recessive disease caused by a marked deficiency of uroporphyrinogen III synthase (UROS). Many *UROS* pathogenic variants have been identified among CEP families. Later-onset disease in adults is often less severe and likely to be associated with myeloproliferative disorders and expansion of a clone of erythroblasts that carry a *UROS* pathogenic variant.

Pathology and Pathogenesis

UROS, which is extremely deficient in CEP, catalyzes inversion of pyrrole ring D of HMB and rapid cyclization of the linear tetrapyrrole to form uroporphyrinogen III. This enzyme is also termed *uroporphyrinogen III cosynthase.* The human enzyme is a monomer. The gene for the enzyme is found on chromosome 10q25.3→q26.3 and contains 10 exons. Erythroid and housekeeping transcripts are generated by alternative promoters but encode the same enzyme.

In CEP, HMB accumulates in erythroid cells during hemoglobin synthesis and cyclizes nonenzymatically to form uroporphyrinogen I, which is auto-oxidized to uroporphyrin I. Some of the uroporphyrinogen I that accumulates is metabolized to coproporphyrinogen I, which accumulates because it is not a substrate for coproporphyrinogen oxidase. Thus both uroporphyrin I and coproporphyrin I accumulate in the bone marrow and are then found in circulating erythrocytes, plasma, urine, and feces.

A variety of *UROS* pathogenic variants have been identified in CEP, including missense and nonsense pathogenic variants, large and small deletions and insertions, splicing defects, and intronic branch-point pathogenic variants. At least four pathogenic variants have been identified in the erythroid-specific promoter. Many patients inherited a different pathogenic variant from each parent, and most pathogenic variants have been detected in only one or a few families. An exception is a common pathogenic variant, C73R, which is at a pathogenic variant hot spot and was found in approximately 33% of alleles. One child with CEP had a *GATA1* pathogenic variant, with no *UROS* pathogenic variant. The CEP phenotype may be modulated by gain-of-function *ALAS2* pathogenic variants, which were first identified as causing XLP.

Genotype-phenotype correlations have been based on the in vitro expression of various CEP pathogenic variants and the severity of associated phenotypic manifestations. The C73R allele, which is associated with a severe phenotype in homozygotes or in patients heteroallelic for C73R and another pathogenic variant expressing little residual activity, resulted in <1% of normal enzyme activity. Patients with the C73R allele and heteroallelic for other pathogenic variants expressing more residual activity have milder disease.

Hemolysis is a common feature of CEP. Excess porphyrins in circulating erythrocytes cause cell damage, perhaps by a phototoxic mechanism, leading to both intravascular hemolysis and increased splenic clearance of erythrocytes. Also important is ineffective erythropoiesis, with intramedullary destruction of porphyrin-laden erythroid cells and breakdown of heme. Expansion of the bone marrow as a result of erythroid hyperplasia may contribute, along with vitamin D deficiency, to bone loss. Nutrient deficiencies sometimes cause erythroid hypoplasia. Despite the marked deficiency of UROS, heme production in the bone marrow is increased because of hemolysis and a compensatory increase in hemoglobin production. This occurs, however, at the expense of marked accumulation of HMB, which is converted to porphyrinogens and porphyrins.

Clinical Manifestations

In severe cases, CEP can cause fetal loss or may be recognized in utero as causing intrauterine hemolytic anemia and nonimmune hydrops fetalis. CEP may be associated with neonatal hyperbilirubinemia, and *phototherapy may unintentionally induce severe cutaneous photosensitivity and scarring.*

The most characteristic presentation is reddish urine or pink staining of diapers by urine or meconium shortly after birth (Fig. 112.2). With sun exposure, severe blistering lesions appear on exposed areas of skin on the face and hands and have been termed *hydroa estivale* because they are more severe with greater sunlight exposure during summer (Fig. 112.3). Vesicles and bullae, as well as friability, hypertrichosis, scarring, thickening, and areas of hypopigmentation and hyperpigmentation, are very similar to those seen in PCT but usually much more severe. Infection and scarring sometimes cause loss of facial features and fingers and damage to the cornea, ears, and nails. Porphyrins are deposited in dentin and bone in utero. Reddish-brown teeth in normal light, an appearance termed **erythrodontia**, display reddish fluorescence under long-wave UV light (Fig. 112.4). Unaffected children born to a mother with CEP may have erythrodontia. Hemolysis and splenomegaly are common in CEP. Bone marrow compensation may be adequate, especially in milder cases. Patients with severe phenotypes, however, are often transfusion dependent. Splenomegaly may contribute to the anemia and cause leukopenia and thrombocytopenia, which may be complicated by significant bleeding. Neuropathic symptoms are absent, and there is no sensitivity to drugs, hormones, or carbohydrate restriction. The liver may be damaged by iron overload, viral hepatitis, or other causes.

Milder cases of CEP with onset of symptoms in adult life and without erythrodontia may be misdiagnosed initially as PCT. Late-onset cases are likely to be associated with myeloproliferative disorders and expansion of a clone of erythroid cells carrying a *UROS* pathogenic variant.

Fig. 112.2 Congenital erythropoietic porphyria (CEP). The diaper of a baby with CEP demonstrates the red color of urine. (*From Paller AS, Macini AJ. Hurwitz Clinical Pediatric Dermatology, 3rd ed. Philadelphia: Saunders; 2006: p. 517.*)

Fig. 112.4 Congenital erythropoietic porphyria. Brownish teeth that fluoresce under Wood's lamp examination. (*From Paller AS, Macini AJ. Hurwitz Clinical Pediatric Dermatology, 3rd ed. Philadelphia: Saunders; 2006: p. 517.*)

Laboratory Findings

Urinary porphyrin excretion and circulating porphyrin levels in CEP are much higher than in almost all other porphyrias. Urinary porphyrin excretion can be as high as 50-100 mg daily and consists mostly of uroporphyrin I and coproporphyrin I. ALA and PBG are normal. Fecal porphyrins are greatly increased, with a predominance of coproporphyrin I.

Marked increases in erythrocyte porphyrins in CEP also consist mostly of uroporphyrin I and coproporphyrin I. These porphyrins are also increased in bone marrow, spleen, plasma, and to a lesser extent, liver. The porphyrin pattern in erythrocytes is influenced by rates of erythropoiesis and erythroid maturation. A predominance of protoporphyrin has been noted in some CEP patients, and in one such patient, uroporphyrin and coproporphyrin increased when erythropoiesis was stimulated by blood removal.

Diagnosis and Differential Diagnosis

The diagnosis of CEP should be documented by full characterization of porphyrin patterns and identification of the underlying pathogenic variants. In later-onset cases, an underlying myeloproliferative disorder and a *UROS* somatic pathogenic variant should be suspected and studied in detail.

The clinical picture in hepatoerythropoietic porphyria (HEP) may be similar, but the porphyrin patterns in urine and feces in HEP resemble PCT. A predominant increase in erythrocyte protoporphyrin is not expected in CEP, except in mild cases, but is characteristic of HEP and rare homozygous cases of AIP, HCP, and VP. EPP and XLP are also distinguished by normal urinary porphyrins and by increases in erythrocyte metal-free protoporphyrin, whereas the increased protoporphyrin in other conditions is mostly complexed with zinc.

CEP should be suspected as a cause of nonimmune hydrops or hemolytic anemia in utero. With recognition of the disease at this stage, intrauterine transfusion can be considered, and phototherapy for hyperbilirubinemia after birth, which can cause severe blistering and scarring, can be avoided. Prenatal diagnosis is feasible by finding red-brown discoloration and increased porphyrins in amniotic fluid and measuring porphyrins in fetal erythrocytes and plasma. *UROS* pathogenic variants can be identified in chorionic villi or cultured amniotic cells.

Treatment

Advising patients to avoid sunlight exposure is essential, because sunlight exposure does not cause immediate severe pain in CEP, in contrast to the protoporphyrias. Minimizing skin trauma and prompt treatment of any cutaneous infections are also essential. Sunscreen lotions and beta-carotene are of little benefit. Transfusions to achieve a level of hemoglobin sufficient to significantly suppress erythropoiesis can be quite effective in reducing porphyrin levels and photosensitivity. Concurrent deferoxamine to reduce iron overload and hydroxyurea to suppress erythropoiesis further may provide additional benefit. Splenectomy reduces hemolysis and transfusion requirements in some patients. Iron restriction by phlebotomy or iron chelators may improve photosensitivity in CEP patients by decreasing ALAS2 activity and porphyrin production.

The most effective treatment is marrow stem cell transplantation in early childhood, which has greatly reduced porphyrin levels and photosensitivity and increased long-term survival.

Prognosis

The outlook is favorable in milder cases and in patients with more severe disease, especially after successful bone marrow or stem cell transplantation. Otherwise, prognosis relates to adherence to sunlight avoidance.

Prevention and Genetic Counseling

Genetic counseling is important for affected families because CEP can be recognized before birth, and a severe phenotype can often be predicted by identifying the nature of the *UROS* pathogenic variants.

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda is the most common and readily treated human porphyria (see Table 112.2). It occurs in mid or late adult life and is rare in children. Previous terms include *symptomatic porphyria, PCT symptomatica,* and *idiosyncratic porphyria.* The underlying cause is a liver-specific acquired deficiency of uroporphyrinogen decarboxylase (UROD) with contributions by genetic and acquired susceptibility factors, including heterozygous *UROD* pathogenic variants in familial PCT. HEP, the homozygous form of familial PCT, usually has a more severe presentation in childhood, resembling CEP clinically.

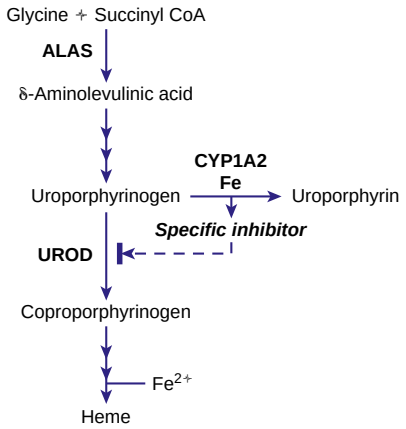

Fig. 112.5 Formation of a specific inhibitor of uroporphyrinogen decarboxylase in the liver in porphyria cutanea tarda. ALAS, δ-Aminolevulinic acid synthase; CYP1A2, cytochrome P450 1A2; UROD, uroporphyrinogen decarboxylase.

Etiology

PCT is caused by a reduction of hepatic UROD activity to ≤20% of normal activity. An inhibitor of hepatic UROD has been characterized as a *uroporphomethene,* which is derived from partial oxidation of the enzyme substrate uroporphyrinogen. CYPs, such as CYP1A2, as well as iron, are involved in its formation (Fig. 112.5). Although enzyme activity is inhibited, the amount of hepatic enzyme protein measured immunochemically remains at its genetically determined level.

UROD catalyzes the decarboxylation of the four acetic acid side chains of uroporphyrinogen (an octacarboxyl porphyrinogen) to form coproporphyrinogen (a tetracarboxyl porphyrinogen). The enzyme reaction occurs in a sequential, clockwise fashion, with the intermediate formation of hepta-, hexa-, and pentacarboxyl porphyrinogens. Uroporphyrinogen III, as compared with other uroporphyrinogen isomers, is the preferred substrate. Human UROD is a dimer with the two active site clefts juxtaposed. The *UROD* gene contains 10 exons, with only one promoter. Therefore the gene is transcribed as a single mRNA in all tissues.

The majority of PCT patients (80%) have no *UROD* pathogenic variants and have sporadic **(type 1)** disease. Some are heterozygous for *UROD* pathogenic variants and have familial **(type 2)** PCT. Described pathogenic variants include missense, nonsense, and splice-site pathogenic variants; several small and large deletions; and small insertions, with only a few identified in more than one family. A few of these pathogenic variants may be located near the active site cleft, but most appear to involve regions with important structural roles. Being heterozygous for a *UROD* pathogenic variant is insufficient to cause PCT. Individuals with type 2 PCT are born with 50% of normal UROD activity, and later in life other susceptibility factors (as in type 1) lead to production of the uroporphomethene inhibitor and further reduction on hepatic UROD activity to <20% of normal. Because penetrance of the genetic trait is low, many patients with familial PCT have no family history of the disease.

Induction of hepatic ALAS1 is not a prominent feature in PCT, although alcohol may increase this enzyme slightly. Iron and estrogens are not potent inducers of ALAS1, and drugs that are potent inducers of ALAS1 and CYPs are much less frequently implicated in PCT than in acute porphyrias.

Blistering skin lesions result from porphyrins that circulate from the liver. Sunlight exposure leads to generation of reactive oxygen species (ROS) in the skin, complement activation, and lysosomal damage.

Epidemiology

Differences in prevalence probably relate to geographic variations in susceptibility factors such as hepatitis C and ethanol use. The yearly incidence in the United Kingdom was estimated at 2-5 in 1 million in the general population, and the prevalence in the United States and Czechoslovakia was estimated at 1 in 25,000 and 1 in 5,000 in the general population, respectively. The disease was reported to be prevalent in the Bantus of South Africa in association with iron overload. PCT is more common in males, possibly because of greater alcohol intake, and in women it is usually associated with estrogen use.

A massive outbreak of PCT occurred in eastern Turkey in the 1950s. Wheat intended for planting and treated with hexachlorobenzene as a fungicide was consumed by many during a food shortage. Cases and small outbreaks of PCT after exposure to other chemicals, including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, dioxin), have been reported. The manifestations improved in most cases when the exposure was stopped. There are reported cases of delayed onset many years after chemical exposure.

Pathology and Pathogenesis

Generation of a UROD inhibitor in the liver plays an important role in all three types of PCT. Eighty percent of patients with type 1 **(sporadic)** PCT have no *UROD* pathogenic variants, and UROD activity is normal in nonhepatic tissues such as erythrocytes. In type 2 **(familial)** PCT, a heterozygous *UROD* pathogenic variant results in a partial (approximately 50%) deficiency of UROD in all tissues from birth, and the disease becomes active in some heterozygotes after further reduction of hepatic UROD activity to ≤20% of normal. **Type 3** is rare and describes PCT without a *UROD* pathogenic variant occurring in more than one family member. Another genetic basis, such as *HFE* pathogenic variants, may be identified. HEP results from inheritance of a *UROD* pathogenic variant from each parent and typically causes severe photosensitivity resembling CEP starting in early childhood. Some developed symptoms in childhood more typical of PCT.

CYPs, especially CYP1A2, can catalyze the oxidation of uroporphyrinogen to uroporphyrin. This uroporphyrinogen oxidase activity is enhanced by iron and leads to formation of a UROD inhibitor (see Fig. 112.5). CYP1a2 seems essential for development of uroporphyria in rodents, because experimental uroporphyria does not develop in *CYP1a2* knockout mice.

Susceptibility Factors

The following factors are implicated in the development of PCT, and these occur in various combinations in individual patients.

Iron

PCT is an iron-related disorder, and a normal or increased amount of iron in the liver is essential for its development. Moreover, treatment by phlebotomy to reduce hepatic iron leads to remission. Serum ferritin levels are usually in the upper part of the normal range or moderately increased, and liver histology commonly shows increased iron staining. Prevalence of the C282Y pathogenic variant of the *HFE* gene, which is the major cause of hemochromatosis in people of Northern European ancestry, is increased in both type 1 and type 2 PCT, and approximately 10% of patients are C282Y homozygotes. In Southern Europe the H63D pathogenic variant is more prevalent. PCT may develop in patients with secondary iron overload. Reduced hepatic expression of the hormone hepcidin occurs in hemochromatosis and also in PCT, regardless of *HFE* genotype, which may explain hepatic siderosis in this condition.

Hepatitis C

Hepatitis C virus (HCV) infection is highly prevalent in PCT in most geographic locations; in the United States, for example, HCV is present in 56–74% of cases, which is similar to rates in Southern Europe. Prevalence of hepatitis C in PCT is lower in Northern Europe (<20%). Steatosis and oxidative stress in HCV infection may favor iron-mediated generation of ROS and a UROD inhibitor. Dysregulation of hepcidin occurs in hepatitis C and may lead to increased iron absorption.

Human Immunodeficiency Virus

Many reports suggest that HIV infection can contribute to the development of PCT, although less frequently than HCV.

Ethanol

The long-recognized association between alcohol and PCT may be explained by the generation of ROS, which may cause oxidative damage, mitochondrial injury, depletion of reduced glutathione and other antioxidant defenses, increased production of endotoxin, and activation of Kupffer cells. Also, alcohol may contribute to iron overload by impairing hepcidin production.

Smoking and Cytochrome P450 Enzymes

Although not extensively studied as a susceptibility factor, smoking is often associated with alcohol use in PCT. It may act to induce hepatic CYPs and oxidative stress. Hepatic CYPs are thought to be important in oxidizing uroporphyrinogen and generating a UROD inhibitor (see Fig. 112.5). Genetic polymorphisms of *CYP1A2* and *CYP1A1* have been implicated in human PCT. The frequency of an inducible *CYP1A2* genotype was more common in PCT patients than in controls in several studies.

Antioxidant Status

Ascorbic acid deficiency contributes to uroporphyria in laboratory models and perhaps in human PCT. In one series, plasma ascorbate levels were substantially reduced in 84% of patients with PCT. Low levels of serum carotenoids were also described, further suggesting that oxidant stress in hepatocytes is important in PCT.

Estrogens

Use of estrogen-containing oral contraceptives (OCs) or postmenopausal estrogen replacement therapy is frequently associated with PCT (type 1 or 2) in women. PCT sometimes occurs during pregnancy, although it is not clear whether the risk is increased.

Cancer Chemotherapy

Cancer chemotherapeutic agents are commonly associated with rare childhood cases of PCT, although specific agents have not been implicated. Susceptibility factors found in adults are rare in children with PCT.

Clinical Manifestations

Cutaneous Manifestations

PCT is readily recognized by blistering and crusted skin lesions on the backs of the hands, which are the most sun-exposed areas of the body, and less often on the forearms, face, ears, neck, legs, and feet (Fig. 112.6). The fluid-filled vesicles usually rupture and become crusted or denuded areas, heal slowly, and are subject to infection. The skin is friable, and minor trauma may cause blisters or denudation of skin. Small white plaques, termed *milia,* may precede or follow vesicle formation. Facial hypertrichosis and hyperpigmentation are also common. Severe scarring and thickening of sun-exposed skin may resemble scleroderma. Skin biopsy findings include subepidermal blistering and deposition of periodic acid–Schiff-(PAS)–positive material around blood vessels and fine fibrillar material at the dermoepithelial junction, which may be related to excessive skin fragility. IgG, other immunoglobulins, and complement are also deposited at the dermoepithelial junction and around dermal blood vessels. The skin lesions and histologic changes are not specific for PCT. The same findings occur in VP and HCP and resemble those of CEP and HEP but are usually less severe. PCT usually develops in mid or late adult life. Earlier onset may be seen in those with *UROD* or *HFE* pathogenic variants and childhood onset with cancer chemotherapy and *UROD* pathogenic variants.

Liver Abnormalities

PCT is almost always associated with nonspecific liver abnormalities, especially increased serum transaminases and γ-glutamyltranspeptidase, even in the absence of heavy alcohol intake or hepatitis C. Most histologic findings, such as necrosis, inflammation,

Fig. 112.6 Porphyria cutanea tarda (PCT). A, Right hand of a patient with PCT, revealing numerous erosions and erythematous patches. B, Close-up of right hand. (*From Horner ME, Alikhan A, Tintle S, et al. Cutaneous porphyrias. Part 1. Epidemiology, pathogenesis, presentation, diagnosis, and histopathology. Int J Dermatol. 2013;52:1464–1480, Fig. 2.*)

increased iron, and increased fat, are nonspecific. Specific findings include red fluorescence of liver tissue and fluorescent, birefringent, needle-like inclusions presumably consisting of porphyrins. Electron microscopy shows these inclusions are in lysosomes, and paracrystalline inclusions are found in mitochondria. Distorted lobular architecture and cirrhosis are more common with long-standing disease.

The risk of developing hepatocellular carcinoma is increased, with reported incidences ranging from 4% to 47% in PCT. These tumors seldom contain large amounts of porphyrins.

Other Features and Associations

Mild or moderate erythrocytosis in some adult patients is not well understood, but chronic lung disease from smoking may contribute. An earlier onset of symptoms may be noted in patients with genetic predisposing factors, such as an inherited partial deficiency of UROD or the C282Y/C282Y *HFE* genotype. Iron overload secondary to conditions such as myelofibrosis and end-stage renal disease (ESRD) may be associated with PCT. The disease can be especially severe in patients with ESRD because the lack of urinary excretion leads to much higher concentrations of porphyrins in plasma, and the excess porphyrins are poorly dialyzable. PCT occurs more frequently in patients with systemic lupus erythematosus and other immunologic disorders than would be expected by chance.

Laboratory Findings

Porphyrins accumulate in the liver mostly as the oxidized porphyrins rather than porphyrinogens in PCT, as indicated by the immediate *red fluorescence* observed in liver tissue. This develops over weeks or months before porphyrins appear in plasma and are transported to the skin, causing photosensitivity. In contrast to the acute hepatic porphyrias, only a very small increase in synthesis of heme pathway intermediates and little or no increase in hepatic ALAS1 are required to account for the excess porphyrins excreted in PCT.

Hepatic UROD deficiency leads to a complex pattern of excess porphyrins, which initially accumulate as porphyrinogens and then undergo nonenzymatic oxidation to the corresponding porphyrins (uro-, hepta-, hexa-, and pentacarboxyl porphyrins, and isocoproporphyrins). Uroporphyrin and heptacarboxyl porphyrin predominate in urine, with lesser amounts of coproporphyrin and penta- and hexacarboxyl porphyrin. A normally minor pathway is accentuated by UROD deficiency, whereby pentacarboxyl porphyrinogen is oxidized by coproporphyrinogen oxidase (CPOX; the next enzyme in the pathway), forming isocoproporphyrinogen, an atypical tetracarboxyl porphyrinogen. Relative to normal values, urinary porphyrins are increased to a greater extent than fecal porphyrins. However, the total amount of porphyrins excreted in feces in PCT exceeds that in urine, and total excretion of type III isomers (including isocoproporphyrins, which are mostly derived from the type III series) exceeds that of type I isomers. Perhaps because uroporphyrinogen III is the preferred substrate for UROD, more uroporphyrinogen I than III accumulates and is excreted as uroporphyrin I in PCT. Hepta- and hexacarboxyl porphyrin are mostly isomer III, and pentacarboxyl porphyrin and coproporphyrin are approximately equal mixtures of isomers I and III.

Diagnosis and Differential Diagnosis

Plasma and urine porphyrins are always increased in clinically manifest PCT, and their measurement is useful for screening. A normal value rules out PCT and other porphyrias that produce blistering skin lesions. It is useful to determine the plasma fluorescence emission maximum at neutral pH, because a maximum near 619 nm is characteristic of PCT (as with CEP and HCP) and, importantly, excludes VP, which has a distinctly different fluorescence maximum. Increased urinary or plasma porphyrins, with a predominance of uroporphyrin and heptacarboxyl porphyrin, is characteristic, although not absolutely specific, for PCT and may occasionally be seen in other porphyrias. Nonspecific increases in urine porphyrins, especially of coproporphyrin, occur in liver disease and other medical conditions. Urinary ALA may be increased slightly in PCT, and PBG is normal. Mild cases of CEP can mimic PCT clinically, and this possibility is ruled out by finding normal or only mildly increased levels of erythrocyte porphyrins.

Familial (type 2) can be distinguished from sporadic (type 1) PCT by finding decreased erythrocyte UROD activity (in type 2) or, more reliably, by finding a disease-related *UROD* pathogenic variant. Type 3 is distinguished from type 1 only by occurrence of PCT in a relative. Biochemical findings in HEP are similar to those in PCT, but with an additional marked increase in erythrocyte zinc protoporphyrin.

Pseudoporphyria (also known as *pseudo-PCT*) presents with skin lesions that closely resemble PCT, but without significant increases in plasma or urine porphyrins. A photosensitizing agent such as a nonsteroidal antiinflammatory drug (NSAID) is sometimes implicated. Both PCT and pseudoporphyria may occur in patients with ESRD.

Complications

Cutaneous blisters may rupture and become infected, sometimes leading to cellulitis. In more severe disease in patients with ESRD, repeated infections can be mutilating, as in CEP. **Pseudoscleroderma**, with scarring, contraction, and calcification of skin and subcutaneous tissue, is a rare complication. Other complications include advanced liver disease and hepatocellular carcinoma.

Treatment

Two specific and effective forms of treatment, phlebotomy and low-dose hydroxychloroquine, are available. Susceptibility factors should be removed when possible. The diagnosis of PCT must be firmly established because conditions, including other porphyrias, that produce identical cutaneous lesions do not respond to these treatments. Treatment can usually be started after demonstrating an increase in plasma total porphyrins and excluding VP by analysis of the fluorescence spectrum at neutral pH, while urine and fecal studies are still pending. Use of alcohol, estrogens (in women), and smoking should be stopped, and patients tested for HCV, HIV, and *HFE* pathogenic variants. Susceptibility factors and degree of iron overload, as assessed by the serum ferritin concentration, can influence the choice of treatment.

Phlebotomy is considered standard therapy and is effective in both children and adults with PCT because it reduces hepatic iron content. Treatment is guided by plasma (or serum) ferritin and porphyrin levels. Hemoglobin or hematocrit levels should be followed to prevent symptomatic anemia. For adults, a unit of blood (450 mL) is removed at about 2-week intervals until a target serum ferritin near the lower limit of normal (15 ng/mL) is achieved. A total of six to eight phlebotomies is often sufficient in adults. After this, plasma porphyrin

concentrations continue to fall from pretreatment levels (generally 10-25 μg/dL) to below the upper limit of normal (1 μg/dL), usually after several more weeks. This is followed by gradual clearing of skin lesions, sometimes including pseudoscleroderma. Liver function abnormalities may improve, and hepatic siderosis, needle-like inclusions, and red fluorescence of liver tissue will disappear. Although remission usually persists even if ferritin levels later return to normal, it is advisable to follow porphyrin levels and reinstitute phlebotomies if porphyrins begin to increase. Infusions of deferoxamine, an iron chelator, may be used when phlebotomy is contraindicated.

An alternative when phlebotomy is contraindicated or poorly tolerated is a low-dose regimen of hydroxychloroquine (or chloroquine). Normal doses of these 4-aminoquinoline antimalarials in PCT increase plasma and urinary porphyrin levels and increase photosensitivity, reflecting an outpouring of porphyrins from the liver. This is accompanied by acute hepatocellular damage, with fever, malaise, nausea, and increased serum transaminases, but is followed by complete remission of the porphyria. These adverse consequences of normal doses are largely avoided by a low-dose regimen (for adults, hydroxychloroquine 100 mg or chloroquine 125 mg, i.e., half a normal tablet, twice weekly), which can be continued until plasma or urine porphyrins are normalized. In young children, half the adult dose is recommended. There is at least some risk of retinopathy, which may be lower with hydroxychloroquine. The mechanism of action of 4-aminoquinolines in PCT is not known but is quite specific, because these drugs are not useful in other porphyrias. Recent studies indicate that low-dose hydroxychloroquine is as safe and effective as phlebotomy in adults with PCT.

Experience to date supports treatment of patients with PCT and hepatitis C with direct-acting antiviral agents to achieve cure of this viral infection within a few months as well as remission of PCT and avoiding treatment by phlebotomy or low-dose hydroxychloroquine.

PCT in patients with ESRD is often more severe and difficult to treat. However, erythropoietin administration can correct anemia, mobilize iron, and support phlebotomy in many cases. Improvement is expected after renal transplantation, related in part to resumption of endogenous erythropoietic production.

Liver imaging and a serum α-fetoprotein determination may be advisable in all PCT patients with cirrhosis or advanced fibrosis at 6-month intervals for early detection of hepatocellular carcinoma. Finding low-erythrocyte UROD activity or a *UROD* pathogenic variant identifies those with an underlying genetic predisposition, which does not alter treatment but is useful for genetic counseling.

Prognosis

Porphyria cutanea tarda is the most readily treated form of porphyria, and complete remission is expected with treatment by phlebotomy or low-dose hydroxychloroquine or by treatment of hepatitis C. There is little information on rates of recurrence and long-term outlook. Risk for cirrhosis and hepatocellular carcinoma is increased, and some susceptibility factors such as alcohol, hepatitis C, and iron overload can contribute to such risks.

Prevention and Genetic Counseling

A heritable *UROD* pathogenic variant can usually be detected or excluded by measuring erythrocyte UROD activity, although DNA studies are more sensitive. Relatives of patients with *UROD* pathogenic variants have an increased risk for developing PCT and may have increased motivation to avoid adverse behaviors such as ethanol and tobacco use and exposures to HCV and HIV (although such counseling would be given to anyone). The finding of *HFE* pathogenic variants, and especially C282Y, should prompt screening of relatives, some of whom may be C282Y homozygotes and warrant lifelong monitoring of serum ferritin.

HEPATOERYTHROPOIETIC PORPHYRIA

HEP is the homozygous form of familial (type 2) PCT; it resembles CEP clinically. Excess porphyrins originate mostly from liver, with a pattern consistent with severe UROD deficiency.

Etiology

HEP is an autosomal recessive disorder, and most patients have inherited different pathogenic variants from unrelated parents. In contrast to most pathogenic variants in familial PCT, most causing HEP are associated with expression of some residual enzyme activity. At least one genotype is associated with the predominant excretion of pentacarboxyl porphyrin.

Pathology and Pathogenesis

Excess porphyrins originate primarily from the liver in HEP, although the substantial increase in erythrocyte zinc protoporphyrin indicates that the heme biosynthetic pathway is also impaired in bone marrow erythroid cells. Apparently, porphyrinogens accumulate in the marrow while hemoglobin synthesis is most active and are metabolized to protoporphyrin after hemoglobin synthesis is complete. The cutaneous lesions are a result of photoactivation of porphyrins in skin, as in other cutaneous porphyrias.

Clinical Manifestations

This disease usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood. *Sclerodermoid* skin changes are sometimes prominent. Unusually mild cases have been described. Concurrent conditions that affect liver function can alter disease severity; the disease manifested because of hepatitis A in a 2-year-old child and then improved with recovery of liver function.

Laboratory Findings

Biochemical findings resemble those in PCT, with accumulation and excretion of uroporphyrin, heptacarboxyl porphyrin, and isocoproporphyrin. In addition, erythrocyte zinc protoporphyrin is substantially increased.

Diagnosis and Differential Diagnosis

HEP is distinguished from CEP by increases in both uroporphyrin and heptacarboxyl porphyrin and isocoproporphyrins. In CEP, the excess erythrocyte porphyrins are predominantly uroporphyrin I and coproporphyrin I rather than protoporphyrin. Blistering skin lesions are unusual in EPP, the excess erythrocyte protoporphyrin in that disease is metal-free and not complexed with zinc, and urinary porphyrins are normal.

Treatment and Prognosis

Avoiding sunlight exposure is most important in managing HEP, as in CEP. Oral charcoal was helpful in a severe case associated with dyserythropoiesis. Phlebotomy has shown little or no benefit. The outlook depends on the severity of the enzyme deficiency and may be favorable if sunlight can be avoided.

Prevention and Genetic Counseling

As part of genetic counseling in affected families, it is feasible to diagnose HEP in utero, either by analysis of porphyrins in amniotic fluid or DNA studies.

HEREDITARY COPROPORPHYRIA

This autosomal dominant hepatic porphyria is caused by a deficiency of CPOX. The disease presents with acute attacks, as in AIP. Cutaneous photosensitivity may occur, but much less often than in VP. Rare homozygous cases present in childhood, including a variant form known as *harderoporphyria*.

Etiology

A partial (50%) deficiency in CPOX activity has been found in all cells studied from patients with HCP. A much more profound deficiency is found in homozygous cases. Human CPOX is a homodimer composed of 39-kDa subunits and contains no metals or prosthetic groups. The enzyme requires molecular oxygen and is localized in the mitochondrial intermembrane space. A single active site on the enzyme catalyzes the oxidative decarboxylation of two of the four propionic acid groups of coproporphyrinogen III to form the two vinyl groups at positions

two and four, on rings A and B, respectively, of protoporphyrinogen IX. Most of the intermediate tricarboxyl porphyrinogen, termed *harderoporphyrinogen,* is not released before undergoing the second decarboxylation to protoporphyrinogen IX. Coproporphyrinogen I is not a substrate for this enzyme.

The human *CPOX* gene contains a single promoter with elements for both housekeeping and erythroid-specific expression. A variety of *CPOX* pathogenic variants have been described in HCP, with a predominance of missense pathogenic variants and no genotype-phenotype correlations. **Harderoporphyria**, an autosomal recessive biochemical variant form of HCP, is caused by *CPOX* pathogenic variants that impair substrate binding, leading to premature release of harderoporphyrinogen.

Epidemiology

HCP is less common than AIP and VP, but its prevalence has not been carefully estimated. Homozygous HCP is rare and presents during childhood. Harderoporphyria, a biochemically distinguishable variant of HCP, has been recognized in heteroallelic and homoallelic forms.

Pathology and Pathogenesis

Increased ALA and PBG during acute attacks of HCP may be explained by induction of ALAS1 and by the normally relatively low activity of PBGD in the liver. Hepatic ALAS1 is increased during acute attacks but is normal when the disease is latent and porphyrin precursor excretion is normal. Because coproporphyrinogen III concentration in the liver is probably less than the K_m for CPOX, the reaction rate is likely to be determined in part by substrate concentration. The substrate coproporphyrinogen appears to be lost more readily from the liver cell than, for example, uroporphyrinogen, especially when heme synthesis is stimulated. Coproporphyrin and coproporphyrinogen are both transported into bile and excreted in urine and do not appear to accumulate in the liver in HCP.

Clinical Manifestations

Symptoms are identical to those of AIP except that attacks are generally milder, and cutaneous lesions that resemble those in PCT develop occasionally. *Severe motor neuropathy and respiratory paralysis can occur*. HCP is almost always latent before puberty, and symptoms are most common in adult women. Attacks are precipitated by the same factors that cause attacks in AIP, including fasting, OCs, and hormone increases during the luteal phase of the menstrual cycle. Concomitant liver diseases may increase porphyrin retention and photosensitivity. The risk of hepatocellular carcinoma is increased.

The clinical features of homozygous HCP or harderoporphyria begin in early childhood and include jaundice, hemolytic anemia, hepatosplenomegaly, and skin photosensitivity. These symptoms are generally quite distinct from those seen in heterozygotes. Hematologic features are particularly characteristic in harderoporphyria.

Laboratory Findings

The porphyrin precursors ALA and PBG are increased during acute attacks in HCP but may decrease more rapidly than in AIP. Marked increases in coproporphyrin III in urine and feces are more persistent in HCP. Plasma porphyrins are usually normal or only slightly increased.

In homozygous cases, porphyrin excretion may be more increased and is accompanied by substantial increases in erythrocyte zinc protoporphyrin. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin (tricarboxyl porphyrin) and in coproporphyrin.

Diagnosis and Differential Diagnosis

The diagnosis of HCP is readily established in patients with clinically manifest disease, although urinary ALA, PBG, and uroporphyrin may revert to normal more quickly than in AIP. Urinary coproporphyrin III is increased. Urinary porphyrins, especially coproporphyrin, can be increased in many medical conditions (e.g., liver disease), and small increases that are not diagnostically significant may lead to an incorrect diagnosis of HCP. Fecal porphyrins are mostly coproporphyrin (isomer III) in HCP, whereas in VP, coproporphyrin III and protoporphyrin are often increased approximately equally. Plasma porphyrins are usually normal in HCP and increased in VP.

The ratio of fecal coproporphyrin III to coproporphyrin I is especially sensitive for detecting latent heterozygotes (especially in adults). Assays for CPOX, a mitochondrial enzyme, require cells such as lymphocytes and are not widely available. Identification of a *CPOX* pathogenic variant in an index case greatly facilitates screening family members.

Treatment and Prognosis

Acute attacks of HCP are treated as in AIP, which includes IV hemin and identifying and avoiding precipitating factors. Phlebotomy and chloroquine are not effective. GnRH analogs can be effective for prevention of cyclic attacks. The prognosis is generally better than in AIP. Givosiran, an siRNA therapeutic agent, has been approved for the prevention of acute attacks in all acute hepatic porphyrias, although experience in HCP is limited.

Prevention and genetic counseling are the same as in other acute porphyrias.

VARIEGATE PORPHYRIA

This hepatic porphyria is caused by a deficiency of protoporphyrinogen oxidase (PPOX), which is inherited as an autosomal dominant trait. The disorder is termed *variegate* because it can present with neurologic or cutaneous manifestations or both. Other terms have included *porphyria variegata, protocoproporphyria,* and *South African genetic porphyria.* Rare cases of homozygous VP are symptomatic in childhood.

Etiology

PPOX is approximately half-normal in all cells studied in patients with VP. The enzyme is more markedly deficient in rare cases of homozygous VP, with approximately half-normal enzyme activity in parents.

Human PPOX is a homodimer that contains flavin adenine dinucleotide and is localized to the cytosolic side of the inner mitochondrial membrane. Membrane-binding domains may be docked onto human FECH, the next enzyme in the pathway, which is embedded in the opposite side of the membrane. PPOX catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX by the removal of six hydrogen atoms. The enzyme requires molecular oxygen. The substrate is readily oxidized nonenzymatically to protoporphyrin under aerobic conditions or if exported into the cytosol. PPOX is highly specific for protoporphyrinogen IX and is inhibited by tetrapyrroles such as heme, biliverdin, and bilirubin and by certain herbicides that cause protoporphyrin to accumulate and induce phototoxicity in plants. Inhibition by bilirubin may account for decreased PPOX activity in Gilbert disease.

The human *PPOX* gene consists of one noncoding and 12 coding exons. Many *PPOX* pathogenic variants have been reported in VP families. A missense pathogenic variant, R59W, is prevalent in South Africa. No convincing genotype-phenotype correlations have been identified. Pathogenic variants in homozygous cases of VP are more likely to encode enzyme proteins with residual activity.

Epidemiology

VP is less common than AIP in most countries. The R59W pathogenic variant is highly prevalent in South African Whites (3 in 1,000 in this population). This example of "genetic drift" or founder effect has been traced to a man or his wife who emigrated from Holland to South Africa in 1688. In Finland, prevalence is 1.3 in 100,000 people and is about as common as AIP.

Pathology and Pathogenesis

Acute attacks develop in a minority of heterozygotes for PPOX deficiency and are often attributable to drugs, steroids, and nutritional factors that play a role in other acute porphyrias. Protoporphyrinogen IX accumulates and undergoes autoxidation to protoporphyrin IX. Coproporphyrinogen III accumulates, perhaps as the result of a close functional association between PPOX in the inner mitochondrial

membrane and CPOX in the intermembrane space. Liver porphyrin content is not increased. The increased porphyrin content in plasma consists of porphyrin-peptide conjugates, which may be formed from protoporphyrinogen. Increased ALA and PBG during acute attacks may be explained, as in HCP, by induction of ALAS1 by exacerbating factors and by the normally relatively low activity of PBGD in liver. Furthermore, PBGD is inhibited by protoporphyrinogen, the substrate for PPOX.

Clinical Manifestations

Symptoms develop in some heterozygotes after puberty. Neurovisceral symptoms occurring as acute attacks are identical to AIP but are generally milder and less often fatal. Drugs, steroids, and nutritional alterations such as fasting, which are harmful in AIP, can also induce attacks of VP. Attacks occur equally in males and females, at least in South Africa. Cutaneous fragility, vesicles, bullae, hyperpigmentation, and hypertrichosis of sun-exposed areas are much more common than in HCP. They are likely to occur apart from and to be longer lasting than the neurovisceral symptoms. OCs can precipitate cutaneous manifestations. Acute attacks have become less common, and skin manifestations are more frequently the initial presentation; this may result from earlier diagnosis and counseling. The risk of hepatocellular carcinoma is increased.

Symptoms of homozygous VP begin in infancy or childhood. These children generally have severe photosensitivity, neurologic symptoms, seizures, developmental disturbances, and sometimes growth retardation, but they do not have acute attacks.

Laboratory Findings

Urinary ALA, PBG, and uroporphyrin are increased during acute attacks, but often less so than in AIP, and may be normal or only slightly increased during remission. Plasma porphyrins, urinary coproporphyrin III, and fecal coproporphyrin III and protoporphyrin are more persistently increased between attacks. The pattern of urinary porphyrins can sometime resemble that seen in PCT. Erythrocyte zinc protoporphyrin levels are greatly increased in homozygous VP and may be modestly increased in heterozygous cases.

Diagnosis and Differential Diagnosis

VP is readily distinguished biochemically from AIP and HCP, which also present with acute attacks and increases in PBG. Plasma porphyrin analysis is especially useful because the plasma porphyrins in VP are tightly protein bound, resulting in a characteristic fluorescence emission spectrum at neutral pH. Fecal porphyrins are increased, with approximately equal amounts of coproporphyrin III and protoporphyrin. Fluorometric detection of plasma porphyrins is more sensitive than stool porphyrin analysis in asymptomatic VP. PPOX assays using cells that contain mitochondria, such as lymphocytes, are sensitive for identifying asymptomatic carriers but are not widely available. Knowing the *PPOX* pathogenic variant in an index case enables the identification of relatives who carry the same pathogenic variant.

Treatment

Acute attacks are treated as in AIP. Hemin is beneficial for acute attacks but not for cutaneous symptoms. Light protection is important in patients with skin manifestations, using long-sleeved clothing, gloves, a broad-brimmed hat, and opaque sunscreen preparations. Exposure to short-wavelength UV light, which does not excite porphyrins, may increase skin pigmentation and provide some protection. Phlebotomy and chloroquine are not effective. Surprisingly, oral activated charcoal was reported to increase porphyrin levels and worsen skin manifestations.

Prognosis and Prevention

The outlook of patients with VP has improved, which may be attributed to improved treatment, earlier diagnosis, and detection of latent cases. Cyclic acute attacks in women can be prevented with a GnRH analog, as in AIP. Givosiran, an siRNA therapeutic agent, has been approved for the prevention of acute attacks in all acute hepatic porphyrias, although experience in VP is limited. A diagnosis of VP or any other acute porphyria should not lead to difficulty obtaining insurance, because the prognosis is usually good once the diagnosis is established.

Genetic counseling is the same as in other acute porphyrias.

ERYTHROPOIETIC PROTOPORPHYRIA AND X-LINKED PROTOPORPHYRIA

These forms of protoporphyria are genetically distinct but have essentially the same phenotype. In EPP, an autosomal recessive disorder, protoporphyrin accumulates as the result of a marked deficiency of FECH, the last enzyme in the heme biosynthetic pathway, because of *FECH* pathogenic variants. EPP is sometimes termed *erythrohepatic protoporphyria,* although the liver does not contribute substantially to production of excess protoporphyrin. XLP is the most recently described porphyria, in which gain-of-function *ALAS2* pathogenic variants lead to overproduction of ALA in the marrow, where it is metabolized to excess amounts of protoporphyrin.

Etiology

Ferrochelatase (FECH), the enzyme that is deficient in EPP, catalyzes the final step in heme synthesis, which is insertion of ferrous iron (Fe^{2+}) into protoporphyrin IX (see Fig. 112.1). The enzyme is also termed *heme synthetase* or *protoheme ferrolyase.* The human enzyme is a dimer, and each homodimer contains a [2Fe-2S] cluster, which may have a role in bridging homodimers. FECH is found in the mitochondrial inner membrane, where its active site faces the mitochondrial matrix. It may be associated with complex I of the mitochondrial electron transport chain, and the ferrous iron substrate may be produced on nicotinamide adenine dinucleotide oxidation. FECH is specific for the reduced form of iron but can use other metals, such as Zn^{2+} and Co^{2+}, and other dicarboxyl porphyrins. Accumulation of metal-free protoporphyrin rather than zinc protoporphyrin in EPP indicates that formation of the latter is dependent on FECH activity in vivo.

The human *FECH* gene has a single promoter sequence and contains 11 exons. Two mRNAs of 1.6 and 2.5 kb were described, which may be explained by the use of two alternative polyadenylation signals. The larger transcript is more abundant in murine erythroid cells, suggesting erythroid-specific regulation of FECH. A variety of *FECH* pathogenic variants have been reported in EPP, including missense, nonsense, and splicing pathogenic variants; small and large deletions; and an insertion.

The inheritance of two alleles associated with reduced FECH activity is required for disease expression. This is consistent with FECH activities as low as 15–25% of normal in EPP patients. In most patients, a pathogenic variant on one *FECH* allele is combined with a common variant affecting the other allele. This common-variant *FECH* allele (IVS3-48T>C) produces less-than-normal amounts of enzyme because it expresses an aberrantly spliced mRNA that is degraded by a nonsense-mediated RNA decay mechanism. The IVS3-48T>C *FECH* variant by itself does not cause disease, even when homozygous. In a few families, two severe *FECH* pathogenic variants have been found without the IVS3-48T>C allele. EPP with autosomal recessive inheritance occurs naturally in cattle and in mouse models.

XLP is associated with gain-of-function deletions in the last exon of *ALAS2*. These lesions delete the last 10-20 amino acids of the ALAS2 polypeptide and apparently make the enzyme more stable. Metal-free protoporphyrin predominates in erythrocytes in these cases, but because FECH activity is normal, the proportion of zinc protoporphyrin is greater than in EPP. XLP accounts for approximately 2% of cases with the EPP phenotype in Europe and approximately 10% of cases in North America.

EPP is sometimes associated with myelodysplastic or myeloproliferative disorders and expansion of a clone of hematopoietic cells with deletion of one *FECH* allele or with other *FECH* pathogenic variants. In such cases there is late onset of the disease.

Epidemiology

EPP is the most common porphyria to cause symptoms in children but is often not diagnosed until adult life. Overall, it is the third most

common porphyria, although its prevalence is not precisely known (see Table 112.2). An analysis from the UK biobank exome sequencing data suggests that EPP is 1.7-3.0 times more common than previously thought in the UK. It is described mostly in Whites but occurs in other ancestries. The IVS3-48T>C splice variant is common in Whites and Japanese but rare in Africans, which explains lower disease prevalence in populations of African origin.

Pathology and Pathogenesis

FECH is deficient in all tissues in EPP, but bone marrow reticulocytes are thought to be the primary source of the excess protoporphyrin, some of which enters plasma and circulates to the skin. Circulating erythrocytes are no longer synthesizing heme and hemoglobin, but they contain excess free protoporphyrin, which also contributes. In XLP caused by terminal deletions in exon 11 of *ALAS2,* all intermediates of the heme pathway are overproduced and ultimately accumulate in bone marrow erythroblasts as protoporphyrin. FECH is not deficient in XLP, so this enzyme chelates some of the excess protoporphyrin with zinc. An aberrantly spliced mitoferrin transcript, which limits iron transport into mitochondria, has also been described in EPP. The liver functions as an excretory organ rather than a major source for excess protoporphyrin. FECH deficiency in the skin and liver may be important, however, because tissue transplantation studies in mice suggest that skin photosensitivity and liver damage occur only when FECH is deficient in these tissues.

Patients with EPP and XLP are maximally sensitive to light in the 400-nm range, which corresponds to the so-called *Soret band,* the narrow peak absorption maximum that is characteristic for protoporphyrin and other porphyrins. Having absorbed light, porphyrins enter an excited energy state and release energy as fluorescence, singlet oxygen, and other ROS. Resulting tissue damage is accompanied by lipid peroxidation, oxidation of amino acids, cross linking of proteins in cell membranes, and damage to capillary endothelial cells. Such damage may be mediated by photoactivation of the complement system and release of histamine, kinins, and chemotactic factors. Repeated acute damage leads to thickening of the vessel walls and perivascular deposits from accumulation of serum components. Deposition of amorphous material containing immunoglobulin, complement components, glycoproteins, acid glycosaminoglycans, and lipids occurs around blood vessels in the upper dermis.

There is little evidence for impaired erythropoiesis or hemolysis in EPP. However, mild anemia with microcytosis, hypochromia, and reticulocytosis is common. Iron accumulation in erythroblasts and ring sideroblasts has been noted in bone marrow in some patients. Decreased transferrin saturation and low or low-normal serum ferritin suggest iron deficiency. Iron status should be carefully evaluated in EPP patients. Poor response to oral iron supplements is described in EPP and is unexplained, because iron absorption is not impaired. Some patients report increased photosensitivity when given iron supplements, but whether this is from transient increases in porphyrins when iron deficiency is corrected and erythropoiesis increases is not known. Case reports suggest that iron supplementation decreases protoporphyrin and improves anemia, especially in patients with XLP. However, recent evidence suggests that iron deficiency may reduce protoporphyrin levels in some EPP patients.

Liver damage develops in a small proportion of EPP and XLP patients and is attributed to excess protoporphyrin, which is insoluble in water and excreted only by hepatic uptake and biliary excretion. Some may be reabsorbed by the intestine and undergo enterohepatic circulation. At very high levels, protoporphyrin is cholestatic, can damage cholangiocytes, and can accumulate in hepatocytes to form crystalline structures and impair mitochondrial function.

Clinical Manifestations

Symptoms of cutaneous photosensitivity begin in childhood and consist of acute pain and itching, often occurring within minutes of sunlight exposure and followed by redness and swelling with continued exposure (Fig. 112.7). Petechiae and purpuric lesions may be seen, but blisters are rare. Swelling may resemble angioneurotic edema and *solar urticaria.* Symptoms are usually worse in the spring and summer. Chronic changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes, but changes in pigmentation and pronounced scarring are unusual. Although physical findings in EPP and XLP may not be impressive, efforts to avoid sunlight and resulting symptoms significantly impair quality of life. An association between EPP caused by pathogenic variants affecting both FECH alleles and seasonal palmar keratoderma is unexplained. Neuropathy develops only in some patients with severe hepatic decompensation. XLP males have a more severe phenotype with higher protoporphyrin levels than most EPP patients. XLP females have a variable clinical presentation—some with no symptoms or mild symptoms and others with severe symptoms similar to XLP males. This variability in females is likely the result of random X chromosome inactivation.

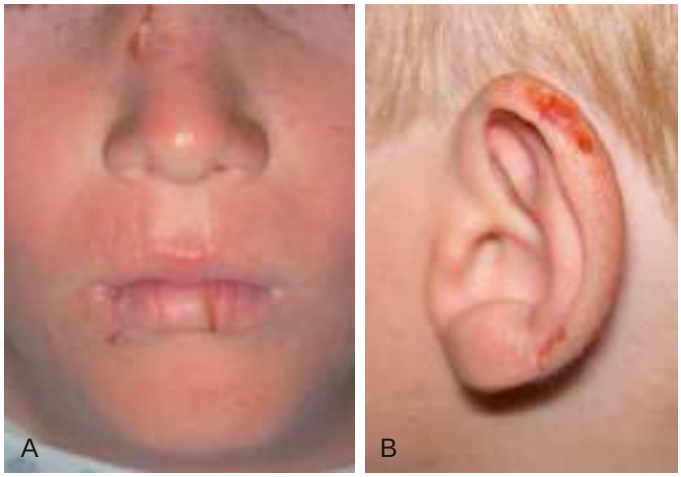

Fig. 112.7 Erythropoietic protoporphyria (EPP). **A,** Linear erosions of the lateral nasal bridge and lower lip in a patient with EPP. **B,** Erosions with crusting on the left helix of a patient with EPP. (*From Horner ME, Alikhan A, Tintle S, et al. Cutaneous porphyrias. Part 1. epidemiology, pathogenesis, presentation, diagnosis, and histopathology. Int J Dermatol. 2013;52:1464–1480, Figs. 7 and 8.*)

Unless hepatic or other complications develop, protoporphyrin levels and symptoms of photosensitivity remain remarkably stable for many years in most patients. Factors that exacerbate hepatic porphyrias play little or no role in EPP or XLP. Erythrocyte protoporphyrin levels may decrease and sunlight tolerance may improve during pregnancy, which is unexplained.

Laboratory Findings

Protoporphyrin is substantially increased in circulating erythrocytes in EPP and consists almost entirely of metal-free protoporphyrin. In XLP, both zinc protoporphyrin and metal-free protoporphyrin are increased, although the latter still predominates. Protoporphyrin is also increased in bone marrow, plasma, bile, and feces. Other porphyrins and porphyrin precursors are normal in uncomplicated EPP and XLP.

Diagnosis and Differential Diagnosis

A diagnosis of EPP is confirmed biochemically by finding a substantially elevated concentration of total erythrocyte protoporphyrin, which is predominantly (at least 85%) metal-free and not complexed with zinc. In XLP, both metal-free and zinc-complexed protoporphyrins are elevated. Erythrocyte total protoporphyrin levels are, on average, higher in XLP and more variable between individuals in EPP, possibly reflecting differences in severity of the many reported *FECH* pathogenic variants. Erythrocyte zinc protoporphyrin concentration is increased with little increase in metal-free protoporphyrin in homozygous porphyrias (except CEP), iron deficiency, lead poisoning, anemia of chronic disease, hemolytic conditions, and many other erythrocytic disorders. Measurement of FECH activity requires cells containing mitochondria and is not widely available.

Plasma total porphyrin concentration is often less increased in EPP than in other cutaneous porphyrias and may be normal. Great care must be taken to avoid light exposure during sample processing, because plasma porphyrins in EPP are particularly subject to photodegradation. Urinary porphyrin precursors and porphyrins are not increased.

DNA studies are strongly recommended for confirming *FECH* or *ALAS2* pathogenic variants and for genetic counseling.

Life-threatening **protoporphyric hepatopathy** is characterized by greater increases in erythrocyte and plasma protoporphyrin levels, increased photosensitivity, and either chronically abnormal liver function tests or rapidly progressive hepatic failure. Presumably this is heralded by increases above the patient's baseline erythrocyte and plasma porphyrin levels, but this has not been documented, because most such patients have not had sufficiently long-term determinations of porphyrin values. Increases in urinary porphyrins, especially coproporphyrin, in this setting are attributable to liver dysfunction.

Complications

There is an increased risk of biliary stones, which contain protoporphyrin and are sometimes symptomatic, requiring cholecystectomy. Protoporphyric hepatopathy occurs in <5% of protoporphyria patients, including children, and may be chronic or progress rapidly to death from liver failure. Rarely, hepatopathy is the major presenting feature of EPP or XLP. Protoporphyric hepatopathy can cause acute upper abdominal pain suggesting biliary obstruction, and unnecessary laparotomy to exclude this possibility can be detrimental. Other types of liver disease, such as viral hepatitis or alcohol- or drug-induced liver disease, must be excluded, or may contribute to the development of protoporphyric hepatopathy. Whether iron deficiency may contribute is unclear. Liver histology shows marked deposition of protoporphyrin as inclusions in liver cells and bile canaliculi. The bone marrow is probably the major source of protoporphyrin, even in EPP patients with hepatic failure.

Treatment

Exposure to sunlight should be avoided, which is aided by wearing closely woven clothing. Beta-carotene, oral cysteine, and vitamin C have no proven efficacy. One report suggested that high doses of cimetidine were effective in reducing symptoms in three children with EPP, but no objective clinical evidence of efficacy was presented.

Increasing skin melanin by narrow-band UV-B phototherapy may improve sunlight tolerance. Studies in the United States and Europe of afamelanotide, a synthetic analog of melanocyte-stimulating hormone, darkened the skin, increased pain-free sun exposure, and improved quality of life in patients with protoporphyria. This drug is approved for use in adults in Europe and the United States. Dersimelagon, an orally administered small molecule and a selective melanocortin-1 receptor (MC1R) agonist that increases skin melanin, is currently in phase 3 trials in EPP and XLP in the United States and other countries.

Drugs or hormone preparations that impair hepatic excretory function should be avoided. Iron deficiency should be corrected, particularly in XLP. Vitamin D supplementation and hepatitis A and B vaccination are recommended.

Treatment of protoporphyric hepatopathy must be individualized and exclude other causes of liver disease. Spontaneous resolution may occur, especially if another reversible cause of liver dysfunction, such as viral hepatitis or alcohol abuse, is contributing. In patients with severe hepatic decompensation, combined treatment with plasmapheresis, transfusion to correct anemia and suppress erythropoiesis, IV hemin to suppress erythroid and possibly hepatic protoporphyrin production, ursodeoxycholic acid, vitamin E, and cholestyramine may be beneficial and bridge patients to liver transplantation.

Motor neuropathy resembling that seen in acute porphyrias sometimes develops in protoporphyria patients with liver disease before or after transfusion or liver transplantation and is sometimes reversible. Artificial lights, such as operating room lights during liver transplantation or other surgery, may cause severe photosensitivity, with extensive burns of the skin and peritoneum and damage to circulating erythrocytes.

Although liver disease may recur in the transplanted liver as a result of continued bone marrow production of excess protoporphyrin, outcomes are comparable to transplantation for other types of liver disease. Bone marrow transplantation can be considered after liver transplantation if a suitable donor is available.

Prognosis

Typical EPP patients have lifelong photosensitivity but can otherwise expect normal longevity. Protoporphyric liver disease is often life-threatening; however, the incidence is low.

Prevention and Genetic Counseling

Symptoms can be prevented by avoiding sunlight. Avoiding agents that may cause liver damage may help prevent liver complications. Opinions vary on the value of iron replacement, and this is currently under study.

DNA studies to identify *FECH* pathogenic variants, the common IVS3–48T>C *FECH* hypoexpression allele, or *ALAS2* exon 11 deletions are important for genetic counseling. When EPP is caused by a severe *FECH* pathogenic variant and the common IVS3–48T>C *FECH* allele, DNA studies in the spouse to determine the presence, or more likely the absence, of the hypoexpression allele can predict whether offspring are at risk for EPP. EPP may improve during pregnancy.

DUAL PORPHYRIA

An unusual pattern of porphyrin precursors and porphyrins has led to documentation of pathogenic variants of two heme pathway enzymes. One such patient presented with acute porphyria and had heterozygous pathogenic variants of both *CPOX* and *ALAD*. Another had symptoms of AIP and PCT and was reported to have both *HMBS* and *UROD* pathogenic variants. In other reported cases, one or both enzyme deficiencies were based on enzyme measurements.

PORPHYRIA RESULTING FROM TUMORS

Erythropoietic porphyrias can develop late in life in patients with myelodysplastic or myeloproliferative diseases and clonal expansion of erythroid cells with an inherited or somatic pathogenic variant of an enzyme in the heme biosynthetic pathway.

Chapter 113

Hypoglycemia

Katherine Lord and Diva D. De León-Crutchlow

Glucose plays a central role in fuel metabolism and energy storage in the body. It provides 38 mol of adenosine triphosphate (ATP) per mole of glucose oxidized. Glucose is also essential for energy metabolism in the brain, where it is the preferred substrate. Its use accounts for nearly all the brain's oxygen consumption. Cerebral transport of glucose is a glucose transporter-1 (GLUT-1)–facilitated diffusion process that is dependent on blood glucose concentration and not regulated by insulin. *Low concentrations of blood glucose result in cerebral glucopenia, energy failure, and brain injury.* An elaborate regulatory system has evolved to maintain glucose homeostasis and prevent plasma glucose from falling precipitously to levels that impair brain function. The defense against hypoglycemia includes the autonomic nervous system and hormones that act in concert to enhance glucose production through glycogenolysis and gluconeogenesis, while simultaneously limiting peripheral glucose use, which conserves glucose for cerebral metabolism. With prolonged fasting, fat stores are mobilized via lipolysis, and fatty acid oxidation in the liver results in the generation of ketone bodies, an alternative fuel source for the brain (Fig. 113.1). Hypoglycemia results from a failure in one or several of these fasting mechanisms that normally integrate glucose homeostasis.

DEFINITION

Hypoglycemia is defined as a plasma glucose concentration low enough to cause signs and symptoms of brain dysfunction (Fig. 113.2). However, a numerical value can be difficult to define because the brain responses to hypoglycemia occur across a range of plasma glucose concentrations. In young children, signs and symptoms of hypoglycemia are suggestive but nonspecific; thus the reliance on signs and symptoms to indicate hypoglycemia in this age-group may be problematic (Table 113.1).

In older children, evidence of hypoglycemia is based on **Whipple's triad**: (1) signs and symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration, and (3) resolution of the symptoms with normalization of the plasma glucose concentration.

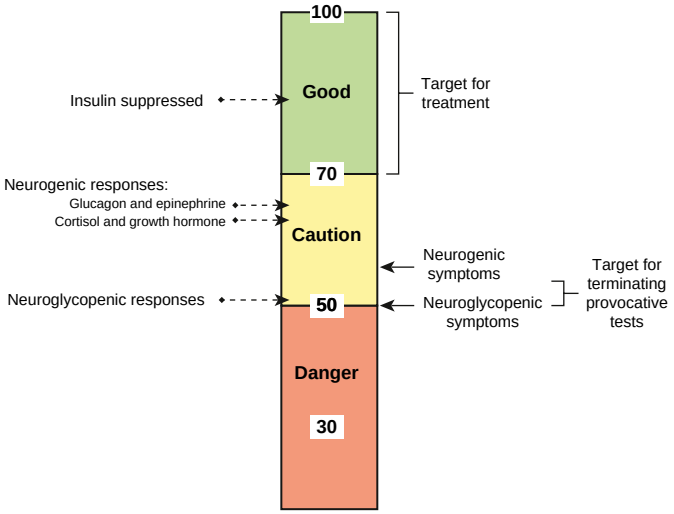

Fig. 113.2 Interpreting glucose levels and glucose treatment targets. Glucose thresholds are shown for suppression of insulin secretion, neurogenic (neuroendocrine hormone-mediated) responses, and neuroglycopenic (impaired cognition) responses. Colors show the normal range *(green)*, the range for symptoms caused by activation of sympathetic nervous system *(yellow)*, and the range for impaired neuronal function *(red)*. (*From Stanescu DL, Stanley CA. Advances in understanding the mechanism of transitional neonatal hypoglycemia and implications for management. Clin Perinatol. 2022;49:55–72, Fig. 2.*)

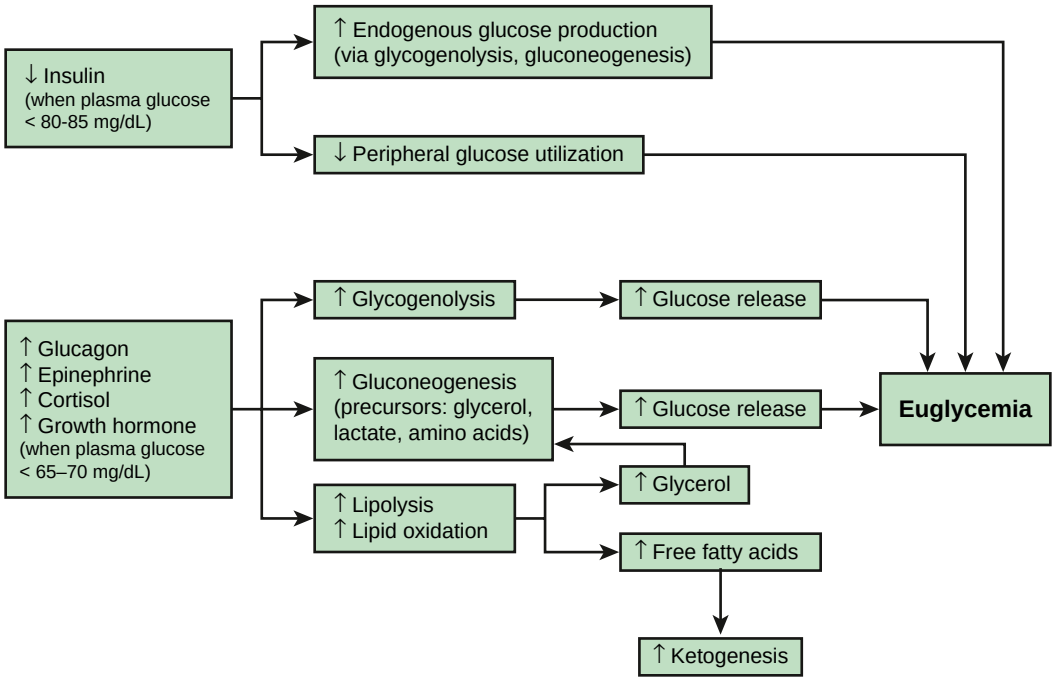

Fig. 113.1 The metabolic response to fasting. With fasting, declining glucose levels result in suppression of insulin and a rise of the counter-regulatory hormones. These changes in hormone levels lead to increased glucose output from the liver via glycogenolysis and gluconeogenesis. With prolonged fasting, counter-regulatory hormones stimulate lipolysis, which results in generation of glycerol (a key precursor in the gluconeogenic pathway) and, through ketogenesis, ketone bodies, a critical alternative fuel.

Table 113.1 Manifestations of Hypoglycemia in Childhood

FEATURES ASSOCIATED WITH ACTIVATION OF AUTONOMIC NERVOUS SYSTEM AND EPINEPHRINE RELEASE*
Anxiety
Perspiration
Palpitation (tachycardia)
Pallor
Tremulousness
Weakness
Hunger
Nausea
Emesis
FEATURES ASSOCIATED WITH CEREBRAL GLUCOPENIA
Headache
Mental confusion
Visual disturbances (↓ acuity, diplopia)
Inability to concentrate
Dysarthria
Staring
Paresthesias
Dizziness
Amnesia
Ataxia
Refusal to feed
Somnolence, lethargy
Seizures
Coma
Stroke, hemiplegia, aphasia
Decerebrate or decorticate posture

*Some of these features will be attenuated if the patient is receiving β-adrenergic blocking agents.

SIGNIFICANCE AND SEQUELAE

Brain metabolism uses the majority of endogenous hepatic glucose production in neonates, infants, and children. Because the brain grows most rapidly in the first year of life and a larger proportion of glucose turnover is used for brain metabolism, hypoglycemia in infants and children can affect brain development and function and can result in developmental delays and learning disabilities. The brain also has the capacity to absorb and oxidize ketone bodies. However, the capacity of the liver to produce ketone bodies is limited in the immediate newborn period. This is especially restricted in the presence of **hyperinsulinism (HI)**, which acutely inhibits hepatic glucose output, lipolysis, and ketogenesis, thereby depriving the brain of any alternative fuel sources. Furthermore, although the brain can metabolize ketones, these alternative fuels cannot completely replace glucose as an essential central nervous system (CNS) fuel. The deprivation of the brain's major energy source during hypoglycemic events has predictable adverse consequences on brain metabolism and growth. These arise from decreased brain oxygen consumption and increased breakdown of endogenous structural brain components, with impairment and loss of functional membrane integrity.

The major long-term sequelae of hypoglycemia are developmental delays, learning disabilities, epilepsy, and behavioral issues. A prospective cohort study of neonates at risk for hypoglycemia found that at 4 years of age, children who had experienced symptomatic hypoglycemia during the neonatal period had a two- to threefold increased risk of low executive and visual-motor function with greater impairment in children with severe or recurrent episodes. Cross-sectional studies in children with HI have found that 26–48% of children with both transient and persistent forms of HI have abnormal neurodevelopment. Children with HI have the highest risk of neurologic damage given the severity of the hypoglycemia in the condition and their inability to generate ketones as an alternative fuel for the brain. In addition, hypoglycemia associated with hypoxic-ischemic encephalopathy increases the risk of CNS sequalae. However, there are no precise data relating the duration or severity of hypoglycemia to subsequent neurologic development of children in a predictable manner. Nonetheless, early detection of hypoglycemia and effective treatment are critical to mitigating the risk of brain damage and developmental delays. Many neonates may have asymptomatic hypoglycemia identified by routine screening or laboratory testing. Although asymptomatic hypoglycemia in an otherwise healthy newborn is usually benign and transient, there remains a risk that if untreated (glucose gel, human milk, formula feedings), the hypoglycemia may become symptomatic. Hypoglycemia in older children may also produce long-term neurologic defects through neuronal death, mediated in part by cerebral excitotoxins released during hypoglycemia.

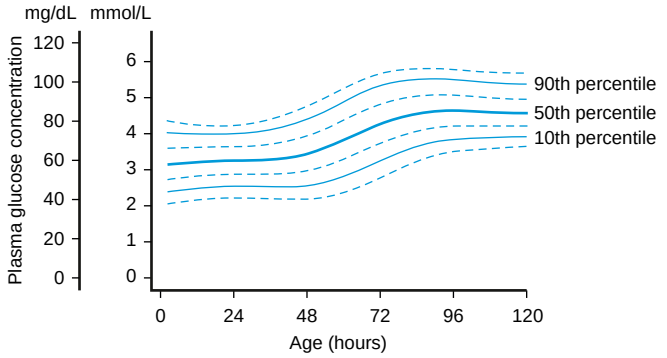

Fig. 113.3 Glucose percentiles in healthy term infants. (*Modified from Harris DL, Weston PJ, Gamble GD, Harding JE. Glucose profiles in healthy term infants in the first 5 days: the Glucose Well Babies (GLOW) study. J Pediatr. 2020;223:34–41, Fig. 2.*)

PHYSIOLOGIC MECHANISMS OF GLUCOSE HOMEOSTASIS

Fetal glucose is derived entirely from the mother through placental-facilitated diffusion; therefore fetal glucose concentration reflects, but is slightly lower than, maternal glucose levels. After birth, plasma glucose decreases, reaching a nadir at about 2 hours of life and remaining below the normal adult range of 70-100 mg/dL for the first 3-4 days of life; this is known as *transitional hypoglycemia*. A study of healthy, full-term infants found a mean plasma glucose concentration of 59 ± 11 mg/dL during the first 48 hours of life, which then increased to 83 ± 13 mg/dL during days 4-5 of life (Fig. 113.3). Transitional asymptomatic hypoglycemia is likely caused by a persistence of fetal pancreatic β-cell fuel metabolism, which allows for the secretion of insulin at lower glucose concentrations to support insulin-mediated fetal growth. Beyond this transitional period, plasma glucose concentration and mechanisms that regulate glucose homeostasis in neonates are the same as in older children and adults.

During fasting, mechanisms responsible for the maintenance of glucose homeostasis include glycogenolysis, gluconeogenesis, lipolysis, and fatty acid oxidation, as well as the hormones that regulate the activation of these processes (see Fig. 113.1). Plasma glucose concentrations are maintained by both metabolism of the nutrients consumed in the immediate postprandial period and then by glycogenolysis and gluconeogenesis starting 2-4 hours after the meal. The liver of a 10-kg child contains 20-25 g of glycogen, which is sufficient to meet normal glucose requirements of 4-6 mg/kg/minute during an overnight fast. Glucose production during this time is augmented by gluconeogenesis (see Fig. 113.1). Defects in glycogenolysis or gluconeogenesis may not be manifested in infants until the frequent feeding pattern at 3- to 4-hour intervals ceases and infants sleep through the night, a situation usually present by 3-6 months of age.

With prolonged fasting, the glycogen stores are depleted, and energy metabolism is more dependent on fatty acid and ketone oxidation. **Lipolysis** generates fatty acids, which undergo β-oxidation in the liver to generate ketone bodies. Peripheral tissues use free fatty acids (FFAs) and ketones, whereas the CNS can use ketones for a

portion of its energy needs. Defects in β-oxidation and ketogenesis may not manifest until fasting exceeds the overnight period or, with illnesses, result in catabolism, fasting, and increased body energy requirements.

Amino acid precursors for gluconeogenesis are derived primarily from muscle protein. The muscle bulk of infants and small children is substantially smaller relative to body mass than that of adults, whereas glucose requirements per unit of body mass are greater in children. Therefore the ability to compensate for glucose deprivation by gluconeogenesis is more limited in infants and young children, as is the ability to withstand fasting for prolonged periods. The ability of muscle to generate alanine, the principal gluconeogenic amino acid, may also be limited.

The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and later gluconeogenesis is governed by hormones, with insulin of central importance (see Fig. 113.1). After a meal, plasma insulin concentrations increase to peak levels of 5- to 10-fold greater than their normal baseline concentration, which serves to lower the plasma glucose through the enhancement of peripheral glucose uptake, activation of glycogen synthesis, and inhibition of gluconeogenesis. In addition, lipogenesis is stimulated, whereas lipolysis and ketogenesis are curtailed. During fasting, plasma insulin concentrations fall, and together with the rise of counter-regulatory hormones, result in maintenance of plasma glucose concentration (see Fig. 113.1).

These **counter-regulatory hormones**—glucagon, growth hormone, cortisol, and epinephrine—act synergistically and in concert to increase plasma glucose concentrations by activating glycogenolytic enzymes (glucagon, epinephrine); inducing gluconeogenic enzymes (glucagon, cortisol); inhibiting glucose uptake by muscle (epinephrine, growth hormone, cortisol); mobilizing amino acids from muscle for gluconeogenesis (cortisol); activating lipolysis and thereby providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, growth hormone, glucagon); and inhibiting insulin release and promoting growth hormone and glucagon secretion (epinephrine).

CLINICAL MANIFESTATIONS

Clinical features of hypoglycemia fall into two categories: (1) symptoms and signs associated with the activation of the autonomic nervous system and epinephrine release **(autonomic symptoms)** and (2) symptoms and signs caused by decreased cerebral glucose use **(neuroglycopenic symptoms)** (see Table 113.1). In newborns and infants, symptoms and signs of hypoglycemia may be subtler and include cyanosis, apnea, hypothermia, hypotonia, irritability, jitteriness, poor feeding, lethargy, and seizures. *It is important to note that neonates and infants are frequently asymptomatic when hypoglycemic.*

DIAGNOSIS

Infants and children with a suspected hypoglycemia disorder require a timely and comprehensive diagnostic workup to establish the underlying cause and to initiate specific treatment, prevent hypoglycemia, and minimize the risk of brain damage and neurologic dysfunction. The Pediatric Endocrine Society provides guidelines that outline which children and adolescents should be evaluated for a hypoglycemia disorder:

- Older children and adolescents who demonstrate Whipple's triad
- Infants and younger children (who cannot communicate symptoms) with plasma glucoses <60 mg/dL on laboratory-quality assays
  - Neonates at high risk of a persistent hypoglycemic disorder
  - Glucose screening is recommended for those born large for gestational age, a history of perinatal stress, premature or postmature delivery, infants of diabetic mothers, family history of hypoglycemia disorder, or a congenital syndrome associated with hypoglycemia.
  - A persistent hypoglycemia disorder should be ruled out in those with severe hypoglycemia (symptomatic or requiring intravenous [IV] dextrose), inability to maintain plasma glucose >50 mg/dL (up to 48 hours of life) or >60 mg/dL (after 48 hours of life), family history of a genetic form of hypoglycemia, and those with a congenital syndrome associated with hypoglycemia.

Table 113.2 Clinical Features of Hypoglycemia Disorders

BIRTH HISTORY	
Large for gestational age	Congenital HI, BWS
Small for gestational age	Perinatal stress HI
Maternal gestational diabetes	Infant of diabetic mother, dominant K_{ATP} -HI
FAMILY HISTORY	
Sudden infant death	Fatty acid oxidation disorder
Diabetes*	HNF4A-HI, HNF1A-HI, dominant K_{ATP} -HI
PHYSICAL EXAM	
Hepatomegaly	Glycogen storage disease
Congenital heart disease	Perinatal stress HI, Kabuki or Turner syndrome
Midline defect	Hypopituitarism
Macroglossia	BWS
Hyperpigmentation	Primary adrenal insufficiency
Short stature	Growth hormone deficiency, glycogen storage disease

*Specifically, non–type 1 diabetes diagnosed at a younger age in lean individuals.
HI, Hyperinsulinism; BWS, Beckwith-Wiedemann syndrome; K_{ATP}, ATP-sensitive potassium channel; HNF, hepatocyte nuclear factor.

The etiology of hypoglycemia varies based on the age of the child, associated clinical and laboratory features, and more detailed diagnostic testing, including gene panels or whole exome sequencing (Tables 113.2, 113.3, 113.4, and 113.5).

A thorough history and physical exam may provide clinical clues to the underlying diagnosis (see Table 113.2). Evaluation for hypoglycemia disorders requires obtaining blood and urine at the time of hypoglycemia, ideally when the plasma glucose is <50 mg/dL. This "**critical sample**" is used to measure hormones, which regulate glucose metabolism, and metabolic fuels (Table 113.6, Fig. 113.4). The critical sample can be obtained during a spontaneous episode of hypoglycemia or during a supervised diagnostic fast. Given the likelihood of hypoglycemia, a **diagnostic fast** should be performed in a hospital setting with close supervision and placement of an IV catheter to facilitate obtaining the critical sample. Point-of-care glucose (and β-hydroxybutyrate if available) should be followed closely, so the samples can be obtained as soon as the plasma glucose falls below 50 mg/dL. The evaluation of neonates should not occur during the first 48-72 hours of life to avoid the period of transitional hypoglycemia.

After the critical sample is obtained and before the child is allowed to eat, a **glucagon stimulation test** should be performed to assess for hyperinsulinism. While the child is still hypoglycemic, 1 mg of glucagon is administered, and glucose is measured by a point-of-care meter every 10 minutes for a total of 40 minutes. A greater than 30-point rise in plasma glucose concentration is consistent with insulin excess or hyperinsulinism. If children do not have an increase in their glucose during the first 20 minutes of the test, the test should be terminated and the child should be given juice or IV dextrose as rescue therapy.

The levels of alternative fuels at the time of hypoglycemia (β-hydroxybutyrate, FFAs, and lactate) allow for the classification of the hypoglycemia disorders into four distinct groups (see Fig. 113.4). The results from the critical sample then allow for narrowing of the differential and guide additional testing. Interpretation of the critical sample results has several important caveats. Low cortisol and growth hormone levels on the critical sample are not diagnostic of a hormone deficiency, and in most cases, the appropriate (specific) stimulation testing is needed if these levels are low. Additionally, a low or undetectable insulin level does not rule out hyperinsulinism. Insulin concentrations can be affected by hemolysis, and assays have variable sensitivity for detecting insulin. Other biomarkers of insulin effect, such as β-hydroxybutyrate (to evaluate ketogenesis), FFAs (to evaluate lipolysis), and the glycemic response to glucagon (to evaluate glycogenolysis), should be used to assess for hyperinsulinism.

Table 113.3 Classification of Hypoglycemia in Infants and Children

NEONATAL TRANSITIONAL (ADAPTIVE) HYPOGLYCEMIA
Associated with inadequate substrate or immature enzyme function in otherwise normal neonates
Prematurity
Small for gestational age
Normal newborn

Transient Neonatal Hyperinsulinism
Infant of diabetic mother
Small for gestational age
Discordant twin
Birth asphyxia
Infant of toxemic mother

NEONATAL, INFANTILE, OR CHILDHOOD PERSISTENT HYPOGLYCEMIA
Hyperinsulinism (see Tables 113.4 and 113.5)
Counter-Regulatory Hormone Deficiency
Panhypopituitarism
Isolated growth hormone deficiency
Adrenocorticotropic hormone deficiency
Addison disease (including congenital adrenal hypoplasia, adrenal leukodystrophy, triple A syndrome, ACTH receptor deficiency, and autoimmune disease complex)
Epinephrine deficiency

Glycogenolysis and Gluconeogenesis Disorders
Glucose-6-phosphatase deficiency (GSD Ia)
Glucose-6-phosphate translocase deficiency (GSD Ib)
Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD III)
Liver phosphorylase deficiency (GSD VI)
Phosphorylase kinase deficiency (GSD IX)
Glycogen synthetase deficiency (GSD 0)
Fructose-1,6-diphosphatase deficiency
Pyruvate carboxylase deficiency
Galactosemia
Hereditary fructose intolerance

Lipolysis Disorders
Fatty Acid Oxidation Disorders
Carnitine transporter deficiency (primary carnitine deficiency)
Carnitine palmitoyltransferase-1deficiency
Carnitine translocase deficiency
Carnitine palmitoyltransferase-2 deficiency
Secondary carnitine deficiencies
Very long-, long-, medium-, and short-chain acyl-CoA dehydrogenase deficiency

OTHER ETIOLOGIES
Substrate-Limited Causes
Ketotic hypoglycemia
Poisoning—drugs
Salicylates
Alcohol
Oral hypoglycemic agents
Insulin
Propranolol
Pentamidine
Quinine
Disopyramide
Ackee fruit (unripe)—hypoglycin
Litchi-associated toxin (toxic hypoglycemic syndrome)
Vacor (rat poison)
Trimethoprim-sulfamethoxazole (with renal failure)
L-Asparaginase and other antileukemic drugs

Liver Disease
Reye syndrome
Hepatitis
Cirrhosis
Hepatoma

AMINO ACID AND ORGANIC ACID DISORDERS
Maple syrup urine disease
Propionic acidemia
Methylmalonic acidemia
Tyrosinosis
Glutaric aciduria
3-Hydroxy-3-methylglutaric aciduria

SYSTEMIC DISORDERS
Sepsis
Carcinoma/sarcoma (secreting—insulin-like growth factor II)
Heart failure
Malnutrition
Malabsorption
Antiinsulin receptor antibodies
Antiinsulin antibodies
Neonatal hyperviscosity
Renal failure
Diarrhea
Burns
Shock
Chiari malformation
Postsurgical complication
Pseudohypoglycemia (leukocytosis, polycythemia)
Excessive insulin therapy of insulin-dependent diabetes mellitus
Factitious disorder
Nissen fundoplication (dumping syndrome)
Falciparum malaria

GSD, Glycogen storage disease; HI, hyperinsulinemia; KATP, regulated potassium channel.

MANAGEMENT

Acute Treatment

A child presenting with hypoglycemia should be rapidly treated with oral carbohydrates or IV dextrose to normalize their plasma glucose (>70 mg/dL). If the child is asymptomatic or has mild symptoms and is capable of oral intake, the hypoglycemia can be treated with 15 grams of rapid-acting carbohydrates, such as 4 ounces of juice or two graham crackers. If a child is symptomatic or unable to tolerate oral intake (risk of aspiration, impending depressed level of consciousness), 2 mL/kg of dextrose 10% water (D10W) should be administered. After administration of the bolus, the child should be placed on an IV dextrose infusion (for infants, a glucose infusion rate of 5-6 mg/kg/minute and for older children 2-3 mg/kg/minute) to prevent recurrent hypoglycemia. Plasma glucose via point-of-care testing should be monitored every 15-20 minutes until it is >70 mg/dL, and then checks may be spaced once stable levels are demonstrated.

In an asymptomatic child with a plasma glucose <50 mg/dL, a critical sample can be obtained if the appropriate supplies and tubes are readily available. Otherwise, treatment of the hypoglycemia should not be delayed.

Table 113.5 Syndromic Forms of Hyperinsulinemic Hypoglycemia*

SYNDROME NAME	GENETIC ETIOLOGY *GENE* (LOCATION)	CLINICAL CHARACTERISTICS
PRENATAL AND POSTNATAL OVERGROWTH (MACROSOMIA)		
Beckwith-Wiedemann	(11p15)	Macroglossia, abdominal wall defects, ear lobe pits/creases, hemihypertrophy, tumor risk; IUGR if associated with placental mesenchymal dysplasia
Sotos	*NSD1* (5q35)	Macrocephaly, frontal bossing, pointed chin, developmental delay, tumor risk
Simpson-Golabi-Behmel	GPC3 (Xq26), GPC4 (Xp22)	Coarse facial features, broad feet, polydactyly, cryptorchidism, hepatomegaly, tumor risk
Perlman	*DIS3L2* (2q37)	Inverted V-shaped upper lip, prominent forehead, developmental delay, hypotonia, tumor risk
POSTNATAL GROWTH FAILURE (SHORT STATURE)		
Kabuki	*KMT2D* (12q13), *KDM6A* (Xp11.3)	Arched eyebrows, long eyelashes, developmental delay, fetal finger pads, scoliosis, heart defects, hypotonia
Costello	*HRAS* (11p15)	Deep palmar/plantar creases, developmental delay, coarse facial features, heart abnormalities, papillomas, tumor risk
CHROMOSOMAL ABNORMALITY		
Mosaic Turner	Loss of X in some cells	Milder Turner syndrome phenotype (short stature, coarctation of aorta, gonadal dysgenesis)
Patau	Trisomy 13	Developmental delay, microphthalmia, heart and neural defects
CONGENITAL DISORDERS OF GLYCOSYLATION		
Types 1a, 1b, and 1d	*PMM2* (16p13.2), *MPI* (15q24.1), *ALG3* (3q27.1)	Developmental delay, hypotonia, growth failure
CONTIGUOUS GENE DELETION AFFECTING THE *ABCC8* GENE		
Usher	11 genes	Hearing loss, visual impairment
ABNORMALITIES IN CALCIUM HOMOEOSTASIS		
Timothy	*CACNA1C* (12p13.33)	Long QT syndrome, syndactyly, developmental delay, immune deficiency
INSULIN RECEPTOR PATHOGENIC VARIANT		
Insulin resistance syndrome (leprechaunism)	*INS* (19p13)	Hypoglycemia and hyperglycemia, prenatal and postnatal growth restriction, elfin-like features, hirsutism
OTHER SYNDROMES		
Congenital central hypoventilation syndrome	*PHOX2B* (4p13)	Central hypoventilation, "box-shaped" face, neurocristopathies (Hirschsprung disease, tumor risk)

IUGR, intrauterine growth restriction.
*Various developmental syndromes have been described with the gene/s linked to the condition and the common clinical features.
Modified from Güemes M, Rahman SA, Kapoor RR, et al. Hyperinsulinemic hypoglycemia in children and adolescents: recent advances in understanding of pathophysiology and management. *Rev Endo Metab Dis.* 2020;21:577–597, Table 2.

Ongoing Management

Treatment goals of hypoglycemia disorders include maintaining euglycemia (plasma glucose >70 mg/dL), promoting normal development, and monitoring for medication side effects. Once the diagnostic evaluation identifies a specific hypoglycemia disorder, tailored treatment should be initiated promptly. Effective treatment allows the child to maintain euglycemia, both while eating an age-appropriate diet and fasting overnight. Continuous or forced feeds should not be used as treatment for hypoglycemia, as they result in long-term oral aversion and excessive weight gain. Additionally, hypoglycemia should not routinely be treated with steroids or cornstarch unless indicated as a treatment for specific disorders, such as adrenal insufficiency or glycogen storage disease. Home glucose monitoring is required for all children with hypoglycemia disorders and is particularly important during times of illnesses, as this may provoke additional hypoglycemia.

Management of individual hypoglycemia disorders is given in more detail in the following sections and in Table 113.7.

DISORDERS OF HYPOGLYCEMIA

Disorders of hypoglycemia can be classified by the metabolic fuel response to fasting (see Fig. 113.4).

Insulin-Mediated Disorders

Insulin-mediated disorders (see Table 113.4) are characterized by low plasma β-hydroxybutyrate and FFAs and a positive glycemic response to glucagon (Table 113.8).

Hyperinsulinism

HI is the most common cause of *persistent hypoglycemia* in infants and children. HI is caused by dysregulated insulin secretion by the pancreatic β-cells, resulting in severe and recurrent hypoglycemia (Fig. 113.5). HI can be categorized into three main forms: (1) perinatal stress-induced, (2) congenital or monogenic (see Table 113.4), and (3) syndromic (see Table 113.5).

Perinatal stress-induced HI (PSHI), the most common form of HI, occurs in the setting of stress on the fetus in utero or during delivery.

Table 113.6 Hypoglycemia Diagnostic Evaluation

"CRITICAL SAMPLE" TO BE OBTAINED WHEN PLASMA GLUCOSE <50 MG/DL	
LABORATORY TEST	INTERPRETATION
Comprehensive metabolic panel	Low HCO_3 suggests elevation of ketones or lactate Elevated liver function tests may indicate GSD
β-hydroxybutyrate	Low levels suggest insulin excess (most commonly HI) or FAO disorder Elevated levels suggest GSD, hormone deficiency, or ketone utilization disorder
Insulin C-peptide	Detectable levels consistent with insulin excess Detectable insulin with undetectable c-peptide is consistent with exogenous insulin
Cortisol Growth hormone	Low levels concerning for hormone deficiency; need stimulation testing to confirm
Lactate	Elevated levels concerning for disorder of gluconeogenesis
Ammonia	Elevation can be seen in forms of HI and in IEM
Acylcarnitine profile Free and total carnitine Urine organic acids	Abnormalities suggestive of FAO disorder
IGF-BP1	Low levels suggest insulin excess
GLUCAGON STIMULATION TEST	
Administer 1 mg of glucagon IV or IM when plasma glucose <50 mg/dL Check point-of-care glucose every 10 min for 40 min If glucose does not increase 20 points in 20 min, terminate test and feed child Interpretation: Increase in glucose by 30 points is consistent with insulin excess	

HCO_3, Bicarbonate; GSD, glycogen storage disorder; HI, hyperinsulinism; FAO, fatty acid oxidation; IEM, inborn errors of metabolism.

In a study of 514 neonates at risk of hypoglycemia, 19% of late-preterm and small-for-gestational-age (SGA) infants had recurrent hypoglycemia, which is concerning for PSHI. Common causes of PSHI include intrauterine growth restriction, being born SGA, maternal preeclampsia, birth asphyxia, and congenital heart disease. *Most infants with PSHI respond to diazoxide, although a subset, particularly those with liver dysfunction and hypoxic ischemic encephalopathy, may fail to respond.* PSHI typically resolves within the first 3-6 months of life.

Congenital HI is the result of genetic defects in the insulin secretory pathways of the β-cell. It is estimated to occur in 1:28,000-50,000 live births but may be as high as 1:3,000 in populations with a high frequency of consanguinity. The most common and severe type of congenital HI is caused by inactivating pathogenic variants of *ABCC8* and *KCNJ11,* which encode the ATP-sensitive potassium (K_{ATP}) channel of the β-cell. Infants born with K_{ATP}-HI are commonly large for gestation age and have high glucose requirements (glucose infusion rate [GIR] >10 mg/kg/min) (see Fig. 113.5). However, the spectrum of presentation is wide, and some infants have normal birthweights and lower glucose requirements. In addition to fasting hypoglycemia, children with this type of HI have protein-induced hypoglycemia, in which isolated protein ingestion leads to increased insulin secretion and low plasma glucose. K_{ATP}-HI is most frequently unresponsive to treatment with diazoxide, the only approved drug for HI, which acts on the K_{ATP} channel.

K_{ATP}-HI has two distinct histologic forms: a **diffuse form**, in which β-cells throughout the pancreas show evidence of hyperactivity, and a focal form, characterized by a localized area of β-cell overgrowth or adenomatosis. The diffuse form is caused by biallelic recessive pathogenic variants in *ABCC8* or *KCNJ11* or, less commonly, monoallelic dominant pathogenic variants of these genes. **Focal HI** occurs as a result of a "two-hit" mechanism: a paternally inherited recessive pathogenic variant in *ABCC8* or *KCNJ11* combined with somatic loss of the maternal 11p15 region, resulting in paternal uniparental isodisomy. Infants with the focal form are cured with resection of the focal lesion. In contrast, those with the diffuse form may require a palliative near-total pancreatectomy if intensive medical therapy fails to control the hypoglycemia (Fig. 113.6). Given the different treatment approaches and outcomes for the diffuse and focal forms of K_{ATP}-HI, distinguishing between the two is critical and is best done through genetic testing. A paternally inherited recessive pathogenic variant in *ABCC8* or *KCNJ11* has a 94% positive predictive value for focal K_{ATP}-HI.

In children with genetic testing consistent with the focal form, an 18-fluoro L-3,4-dihydroxyphenylalanine positron emission tomography (^{18}F-DOPA PET) scan is used before surgery to localize the focal lesion (see Fig. 113.6). Frozen section evaluation of biopsies taken during surgery is used to confirm the presence of the focal lesion and guides the extent of the resection. Children with the focal form of HI should receive care at specialized centers with ^{18}F-DOPA PET access and a multidisciplinary team of endocrinologists, surgeons, pathologists, and radiologists with expertise in HI. Children with the diffuse form also benefit from care at these centers because their management and the decision to pursue intensive medical therapy or a near-total pancreatectomy are complex.

The second most common form of congenital HI is caused by **dominant activating pathogenic variants of *GLUD1***, which encodes **glutamate dehydrogenase** (GDH). This protein regulates the first step of amino acid–stimulated insulin secretion in the β-cell. Children with GDH-HI or hyperinsulinism-hyperammonemia syndrome (HI/HA) have fasting hypoglycemia, significant protein-induced hypoglycemia, and elevated plasma ammonia concentration. Seizures, attention-deficit disorder, and learning disabilities also occur in this form of HI, and these neurologic issues do not seem to correlate with the degree of hypoglycemia or ammonia elevation. *This form of HI responds well to diazoxide.*

Activating pathogenic variants of *GCK*, which encodes **glucokinase**, cause an autosomal dominant form of congenital HI. Glucokinase is the key enzyme triggering glucose-mediated insulin secretion. Children with GCK-HI have fasting hypoglycemia of variable severity and diazoxide responsiveness. Severe cases may require a near-total pancreatectomy.

Pathogenic variants in *HNF4A* and *HNF1A,* which encode the transcription factors hepatic nuclear factors 4-alpha and 1-alpha, cause a dominant form of diazoxide-responsive HI. These infants may be large for gestational age and have high GIR requirements at birth. The HI resolves within the first several years of life. However, some individuals experience progressive β-cell failure and progress to an early-onset diabetes, known as *maturity-onset diabetes of the young (MODY).*

Syndromes associated with HI are increasingly being recognized (see Table 113.5). Beckwith-Wiedemann syndrome (BWS), an imprinting disorder, is characterized by macroglossia, lateralized overgrowth, omphalocele, and a predisposition to embryonal tumors (Fig. 113.7). Hyperinsulinism occurs in approximately 50% of infants with BWS, although most cases are mild and resolve within the first several weeks of life. These cases are typically responsive to diazoxide. Children with BWS caused by paternal uniparental isodisomy of 11p can have severe and persistent HI, which does not respond to diazoxide and may

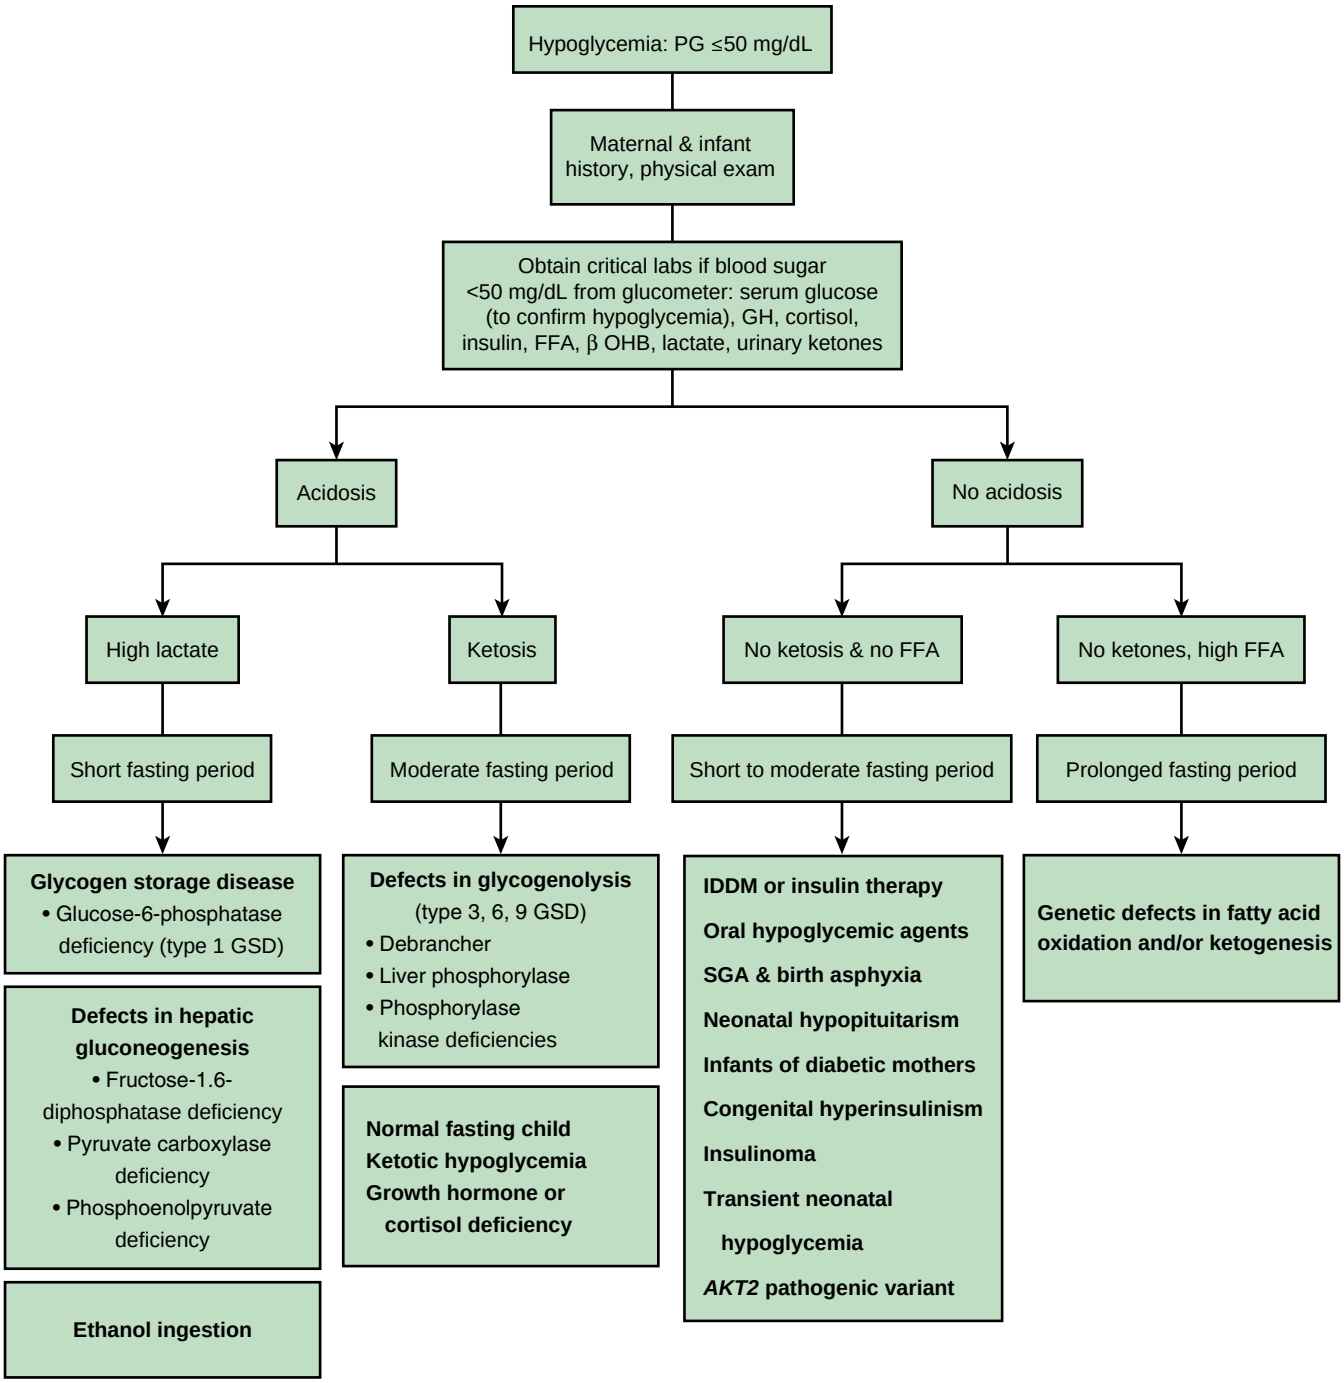

Fig. 113.4 Diagnostic algorithm for determining the etiology of hypoglycemia in children. OHB, Hydroxybutyrate; FFA, free fatty acid; GH, growth hormone, GSD, glycogen storage disease; PG, plasma glucose; IDDM, insulin-dependent diabetes mellitus. (*Modified from Melmed S, Auchus RJ, Goldfine AB, Koenig RJ, Rosen CJ. Williams Textbook of Endocrinology. 14th ed. Elsevier; 2020:1547, Fig. 38.14.*)

require a pancreatectomy. Other syndromes known to be associated with HI include Kabuki, Turner, and Rubinstein-Taybi. HI in these syndromes presents with variable degrees of severity and responsiveness to diazoxide.

After establishing a diagnosis of HI, a trial of diazoxide, the first-line agent for the treatment of HI, should be undertaken (Fig. 113.8). Diazoxide opens the K_{ATP} channel, inhibiting insulin secretion. Children are considered responsive to diazoxide if the cardinal feature of HI, hypoketotic hypoglycemia, is corrected. This is assessed by demonstrating that the child can maintain plasma glucose >70 mg/dL both while feeding and during an overnight fast and/or plasma β-hydroxybutyrate concentration increases to >2 mmol/L before plasma glucose decreases below 50-60 mg/dL during fasting. *Failure to respond to diazoxide strongly suggests K_{ATP}-HI, and those children require expedited genetic testing for ABCC8 and KCNJ11 to determine their risk for focal HI.* Thus the assessment of the response to diazoxide has important therapeutic and diagnostic implications.

Somatostatin analogs are used off-label as second-line agents for the treatment of diazoxide-unresponsive diffuse HI. Octreotide requires multiple daily injections, and its effectiveness is limited by

Table 113.7 Treatments for Hypoglycemia Disorders

DRUG/THERAPY	INDICATION	DOSE (ROUTE OF ADMINISTRATION)	SIDE EFFECTS/COMMENTS
Diazoxide	HI	5-15 mg/kg/day every 12 hr (PO)	Hypertrichosis, fluid overload* neutropenia, thrombocytopenia, respiratory distress, hyperglycemia
Octreotide	HI	2-20 mcg/kg/day every 6 hr (SQ)	Gallstones, transaminitis, malabsorption, suppression of thyroid and growth hormones
Lanreotide	HI	60-90 mg every 28 days (SQ)	Gallstones, transaminitis, malabsorption, suppression of thyroid and growth hormones
Enteral D20	HI	Up to 10 mg/kg/min continuously (via gastrostomy or nasogastric tube)	Vomiting, diarrhea, fluid overload
Cornstarch	GSD, rarely FAOD, IKH	1-2 g/kg per dose (PO)	Diarrhea in infants
Growth hormone	Growth hormone deficiency	0.3 mg/kg/wk daily or every 12 hr (infants) (SQ)	Pseudotumor cerebri, edema, slipped capital femoral epiphysis, hyperglycemia
Hydrocortisone	Adrenal insufficiency	8-12 mg/m^2/day (PO)	High doses: Immunosuppression, hyperglycemia, hypertension, obesity
Acarbose	Postprandial hypoglycemia	12.5-50 mg with meals	Transaminitis, diarrhea, abdominal pain
PANCREATECTOMY			
Partial	Focal HI Insulinoma		>50% pancreatectomy increases risk of diabetes and exocrine insufficiency later in life
Near-total (98%)	Severe diffuse HI		Insulin-dependent diabetes, exocrine insufficiency

*Concomitant use of diuretics is strongly recommended in neonates and infants; older children may require this as well.
HI, Hyperinsulinism; GSD, glycogen storage disease; FAOD, fatty acid oxidation disorder; IKH, idiopathic ketotic hypoglycemia.

Table 113.8 Criteria for Diagnosing Hyperinsulinism and Other Forms of Insulin Excess

DRAWN AT A TIME OF FASTING HYPOGLYCEMIA: PLASMA GLUCOSE <50 MG/DL
Detectable insulin or c-peptide (plasma insulin ≥2 μU/mL or plasma C-peptide ≥0.5 ng/mL)*
Hypofattyacidemia (plasma free fatty acids <1.7 mmol/L)
Hypoketonemia (plasma β-hydroxybutyrate <1.8 mmol/L)
Inappropriate glycemic response to glucagon (increase in glucose >30 mg/dL)

*Depends on sensitivity of insulin assay. Detectable insulin and C-peptide is not necessary to make a diagnosis of HI.

tachyphylaxis. A long-acting analog, lanreotide, is administrated monthly in children greater than 1 year old and can be an effective and more convenient alternative to octreotide. Somatostatin analogs should not be used in neonates or infants less than 2 months old because they are associated with fulminant necrotizing enterocolitis. Continuous intragastric dextrose administered via gastrostomy tube is used in combination with a somatostatin analog and allows for an age-appropriate feeding schedule.

Infants Born to Diabetic Mothers

See Chapter 147.1.

Gestational diabetes affects approximately 2% of pregnant women, and 1 in 1,000 pregnant women have insulin-dependent diabetes. Infants born to mothers with poorly controlled diabetes are born large for gestational age and with severe hypoglycemia resulting from a transient hyperinsulinemic state. Exposed to high glucose concentrations, the fetal islets compensate with increased insulin secretion that, during intrauterine life, leads to overgrowth and, after birth, results in hypoglycemia. The hypoglycemia resolves within the first 3-7 days of life. Mothers whose diabetes has been well controlled during pregnancy, labor, and delivery generally have infants near normal size who are less likely to develop hypoglycemia.

Insulinoma

Older children and adolescents presenting with insulin-mediated hypoglycemia should be evaluated for an **insulinoma**, a rare islet cell tumor. These tumors may be insidious, slow growing, and difficult to localize with conventional imaging modalities. Surgical resection is curative. Children diagnosed with an insulinoma should undergo genetic testing for the tumor predisposition syndrome, multiple endocrine neoplasia type 1 (MEN1).

Factitious Hypoglycemia

Surreptitious administration of insulin presents with abrupt onset and erratic hypoglycemia. In a younger child, a parent or guardian may provoke hypoglycemia (factitious disorder imposed on another: Munchhausen by proxy), but an adolescent may be self-administering insulin. The biochemical hallmark of exogenous insulin administration is a detectable insulin level with undetectable c-peptide. However, specialized assays may be needed to detect the analog insulins, such as aspart or glargine. Intentional or accidental ingestion of sulfonylureas also presents with hypoglycemia. In these cases, both insulin and c-peptide are detectable, and sulfonylurea blood levels are required for confirmation.

Defects of Fatty Acid Oxidation

Fatty acid oxidation disorders are characterized by low plasma β-hydroxybutyrate and high plasma FFAs. See Chapter 106.1.

Multiple enzymatic deficiencies in the mitochondria pathway of fatty acid oxidation cause defective carnitine or fatty acid metabolism. These disorders are characterized by fasting hypoglycemia, hepatomegaly, cardiomyopathy, and hypotonia, although the spectrum of severity is wide. Infants may present with a Reye-like syndrome (see

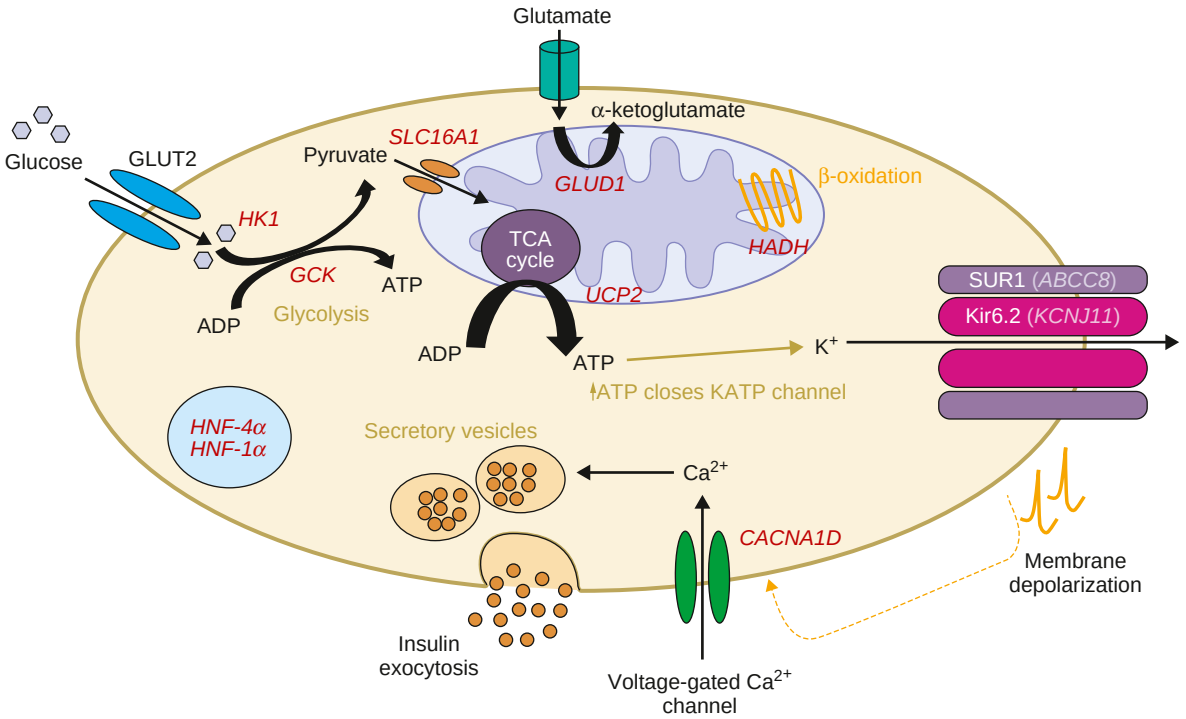

Fig. 113.5 Diagrammatic representation of β-cell function. Genetic defects associated with congenital HI are included in *red*. Postprandial glucose is taken into the β-cells via the glucose transporter 2 (GLUT-2). Glucose then enters the glycolysis pathway followed by the mitochondrial citric acid cycle (TCA), yielding the high-energy molecule, adenosine triphosphate (ATP). ATP molecules travel to and inhibit the potassium-dependent ATP channels (K_{ATP}), which prevents influx of potassium resulting in membrane depolarization. This triggers voltage-gated calcium channels to open, and influx of calcium (Ca^{2+}) occurs. The Ca^{2+} activates the enzyme phospholipase C (PLC) to produce inositol 1,3,5 triphosphate (IP3) and diacylglycerol (DAG) from phosphatidyl 1,3 bisphosphate (PIP2). The IP3 molecule binds to the protein receptor on the endoplasmic reticulum (ER) to promote a release of Ca^{2+} from the ER. This subsequent increase in cytoplasmic Ca^{2+} promotes exocytosis of the prepackaged mature insulin and active C-peptide, which are released into circulation. GLUT2: Glucose transporter 2; Glucokinase (GCK) encoded by GCK gene; ADP: Adenosine diphosphate; ATP: Adenosine triphosphate; Monocarboxylate transporter (MCT1) encoded by *SLC16A1* gene; Glutamate dehydrogenase (GDH) encoded by *GLUD1* gene; Uncoupling protein 2 (UCP2) encoded by *UCP2* gene; L-3hydroxyacyl-coenzyme A dehydrogenase (HADH) encoded by *HADH* gene; SUR1 subunit of the K_{ATP} channel encoded by the *ABCC8* gene; Kir6.2 subunit of the K_{ATP} channel encoded by *KCNJ11* gene; Hepatocyte nuclear factor 4α (HNF4α) encoded by *HNF4A* gene; Hepatocyte nuclear factor 1α (HNF1α) encoded by *HNF1A* gene; HK1: Hexokinase 1 encoded by the gene *HK1*; CACNA1D: calcium voltage-gated channel subunit alpha1 D. Gene variants in forkhead box protein A2 (FOXA2), phosphoglucomutase 1 (PGM1), and phosphomannomutase 2 (PMM2) are not included in the drawing. (*From Güemes M, Rahman SA, Kapoor RR, et al. Hyperinsulinemic hypoglycemia in children and adolescents: recent advances in understanding of pathophysiology and management. Rev Endo Metab Dis. 2020;21:577–597, Fig. 1.*)

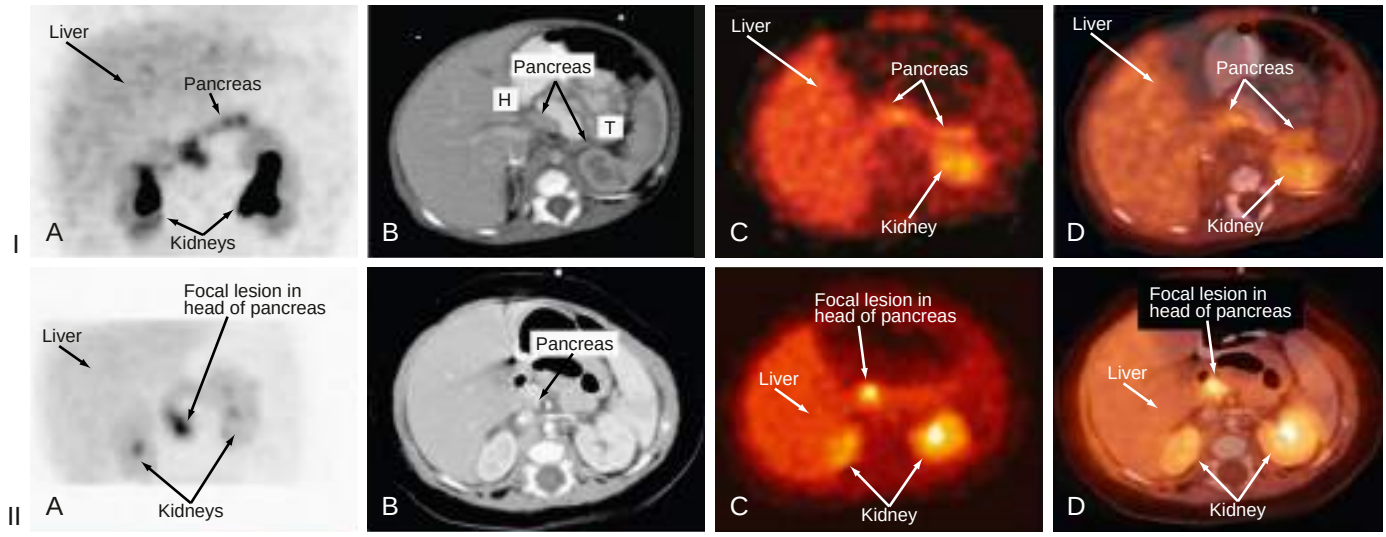

Fig. 113.6 Imaging of congenital hyperinsulinism. I Panels *(diffuse)*: 18-fluoro L-3,4-dihydroxyphenylalanine positron emission tomography (^{18}F-DOPA PET) of a patient with a diffuse form of congenital hyperinsulinism. **A,** Diffuse uptake of ^{18}F-DOPAa is visualized throughout the pancreas. Transverse views show **(B)** normal pancreatic tissue on abdominal CT, **(C)** diffuse uptake of ^{18}F-DOPA in the pancreas, and **(D)** confirmation of pancreatic uptake of ^{18}F-DOPA with co-registration. H, Head of pancreas; T, tail of pancreas. II Panels *(focal)*: ^{18}F-DOPA PET of a patient with a focal form of congenital hyperinsulinism. **(A)** Discrete area of increased ^{18}F-DOPA uptake is visualized in the head of the pancreas. The intensity of this area is greater than that observed in the liver and neighboring normal pancreatic tissue. Transverse views show **(B)** normal pancreatic tissue on abdominal CT, **(C)** focal uptake of ^{18}F-DOPA in the pancreatic head, and **(D)** confirmation of ^{18}F-DOPA uptake in the pancreatic head with co-registration. Chapter 409) and recurrent episodes of fasting hypoglycemia, cardiorespiratory arrest, and coma, whereas older children with less severe forms may only develop symptoms with illness. Most cases are detected via newborn screening and confirmed with genetic testing. Abnormalities are seen in the acylcarnitine and urine organic acid profiles in children who are not identified through newborn screening. Treatment typically involves avoidance of fasting and administration of dextrose-containing fluids with illness.

Interference with fatty acid metabolism also underlies the fasting hypoglycemia associated with Jamaican vomiting sickness. In **Jamaican vomiting sickness**, the unripe ackee fruit contains a water-soluble toxin, hypoglycin, which produces vomiting, CNS depression, and severe hypoglycemia. The hypoglycemic activity of hypoglycin derives from its inhibition of gluconeogenesis secondary to its interference with the acyl-CoA and carnitine metabolism essential for the oxidation of long-chain fatty acids. The disease is almost totally confined to Jamaica, where ackee forms a staple of the diet. The ripe ackee fruit no longer contains this toxin. A similar illness noted in India, **acute toxic encephalopathy-hypoglycemic syndrome**, may be caused by litchi consumption. Litchi contains hypoglycin A and/or methylenecyclopropylglycine, which may inhibit fatty acid oxidation or gluconeogenesis.

KETOTIC HYPOGLYCEMIC DISORDERS

These disorders are characterized by elevated levels of plasma β-hydroxybutyrate (>2.5 mmol/L) (Table 113.9).

Glycogen Storage Disorders

See Chapter 107.1.

The **hepatic glycogen storage disorders** (GSDs; 0, I, III, VI, and IX) result from genetic defects in the enzymes that regulate the synthesis, breakdown, and release of glycogen in the liver. GSD type I also affects gluconeogenesis. GSDs are characterized by fasting ketotic hypoglycemia and various degrees of hepatomegaly, liver function abnormalities, hyperlipidemia, and

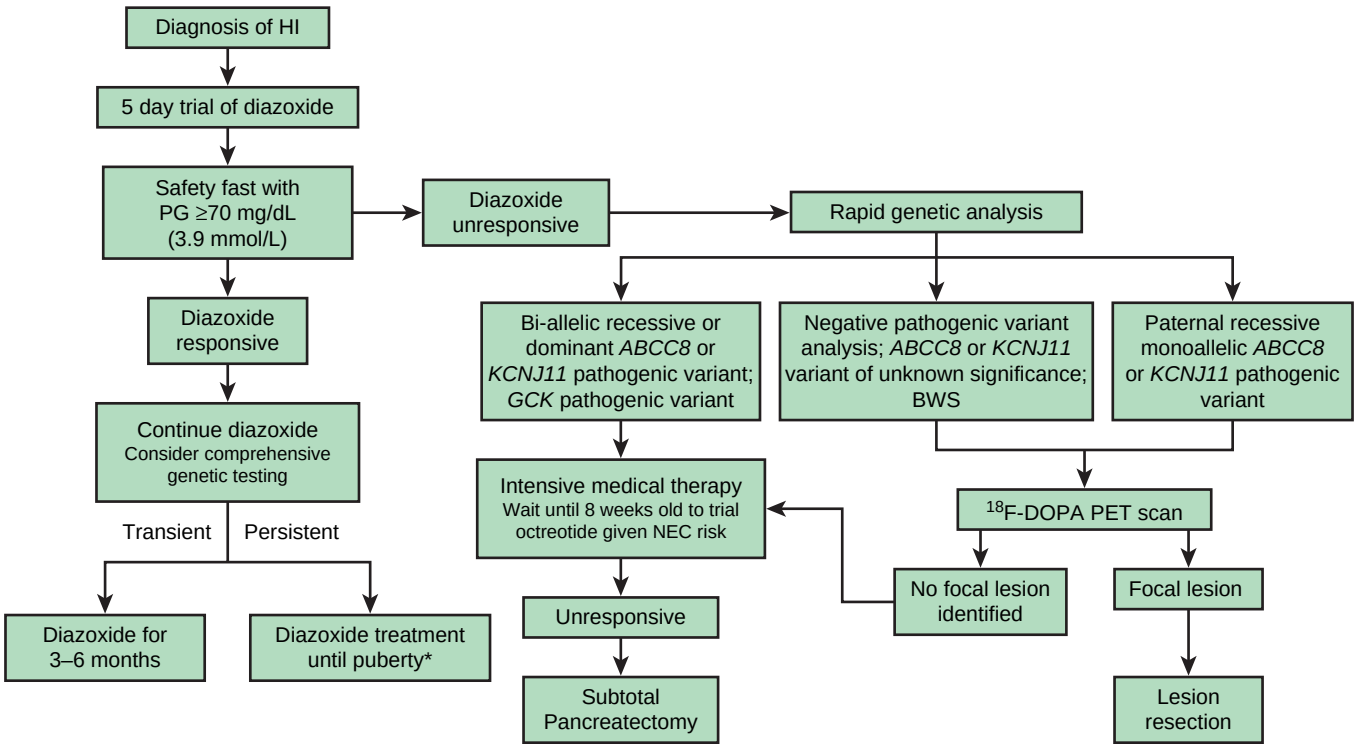

Fig. 113.8 Management algorithm for hyperinsulinism. HI, Hyperinsulinism; BWS, Beckwith-Wiedemann syndrome. *Some individuals may require diazoxide treatment into adulthood and possibly lifelong.

Table 113.9 Causes of Ketotic Hypoglycemia in Children

	GENE OR CHROMOSOME	INHERITANCE
HORMONAL		
Growth hormone deficiency or resistance	Genetic or acquired	Variable
ACTH deficiency or resistance; cortisol deficiency	Genetic or acquired	Variable
Glucagon deficiency*	*GCG, DBH*	N/D
Dopamine β-hydroxylase deficiency*	*GCG, DBH*	N/D
METABOLIC		
Glycogen storage disease (GSD)		
GSD 0; glycogen synthase deficiency	*GYS2*	AR
GSD III; glycogen debranching enzyme deficiency	*AGL*	AR
GSD VI; glycogen phosphorylase deficiency	*PYGL*	AR
GSD IX; phosphorylase kinase subunit deficiencies	*PHKA2, PHKB, PHKG2*	X-linked, AR
GLUCOSE METABOLISM AND TRANSPORT		
Phosphoglucomutase I deficiency	*PMG1*	AR
Pyruvate carboxylase deficiency	*PC*	AR
ORGANIC ACIDEMIAS		
Maple syrup urine disease, propionic aciduria, methylmalonic aciduria	Multiple genes	AR
Ketone body transport and metabolism		
Monocarboxylase transporter 1 defect	*SLC16A1 (MCT1)*	AR, AD
Ketolysis		
Succinyl CoA oxoacid transferase deficiency	*SCOT*	AR
Mitochondrial acetoacetyl-CoA thiolase (β-ketothiolase) deficiency	*ACAT1*	AR
SYNDROMES		
Silver-Russel syndrome	11p15 or 7**	Mostly sporadic
Prader-Willi syndrome	15q11-q13***	Mostly sporadic
Fanconi-Bickel syndrome	*SLC2A2 (GLUT2)*	AR
KH secondary to chronic malnutrition, severe malaria, other chronic diseases	—	—
Idiopathic ketotic hypoglycemia		
Physiologic KH in prolonged fasting or acute illness	—	—
Pathologic KH	—	—
IGF2BP1 deficiency*	*IGF2BP1*	N/D
Sodium glucose co-transporter 2 defect*	*SLC5A2*	N/D
PEP carboxykinase 1 and G-6P catalytic transcriptional induction*	*NCOR1*	N/D
Mitosis gene A-related kinase 11 defect*	*NEK11*	N/D

*Suggested, not well-established, causes of KH.
**Several mechanisms, rare other mechanisms, or unknown.
***Paternal deletion, maternal uniparental disomy, or imprinting defect.
AD, Autosomal dominant; AR, autosomal recessive; N/D, no data; PEP, phosphoenolpyruvate; G-6P, glucose 6-phosphate. The list is not fully inclusive.
From Drachmann D, Hoffman E, Carrigg A, et al. Towards enhanced understanding of idiopathic ketotic hypoglycemia: a literature review and introduction of the patient organization, Ketotic Hypoglycemia International. *Orphanet J Rare Dis*. 2021;16:173, Table 1.

failure to thrive. Muscle involvement is a feature of GSD type III, resulting in proximal muscle weakness and risk of cardiomyopathy. GSD types 0, VI, and IX present with less severe hypoglycemia compared with type I and III. The diagnosis of GSD is suspected in patients presenting with ketotic hypoglycemia, hepatomegaly, and liver enzyme abnormalities and is confirmed through genetic testing. The treatment of GSDs consists of uncooked cornstarch therapy, protein supplementation, and limited fasting.

Hormone Deficiencies

Deficiencies of cortisol or growth hormone can result in ketotic hypoglycemia, as these counter-regulatory hormones play a role in mobilizing glucose production by the liver. Hypoglycemia occurs in both primary or secondary (central) **adrenal insufficiency** and is commonly seen during an adrenal crisis. **Growth hormone deficiency** results in hypoglycemia mainly during infancy and early toddlerhood. Combined hormone deficiencies, known as hypopituitarism, can also result in hypoglycemia and are commonly caused by structural abnormalities of the pituitary gland. A clinical clue to the diagnosis of hypopituitarism is the presence of midline defects, cleft lip or palate, or in males, a microphallus. In the neonatal period, hypopituitarism presents with a hypoketotic hypoglycemia pattern that is indistinguishable from the pattern seen in neonates with HI. Thus in neonates with features suggestive of hypopituitarism, it is important to rule out hormone deficiencies before making a diagnosis of HI.

Low cortisol and growth hormone levels on a critical-sample laboratory result are suggestive of hormone deficiencies but not diagnostic. To confirm these diagnoses in a child presenting with hypoglycemia, appropriate hormone stimulation testing is recommended. A child diagnosed with central adrenal insufficiency, growth hormone deficiency, or hypopituitarism requires magnetic resonance imaging of their pituitary gland to assess for structural abnormalities or lesions. Hormone replacement with either hydrocortisone or growth hormone

resolves the hypoglycemia. Neonates and infants require twice-a-day growth hormone dosing to prevent ongoing hypoglycemia.

Idiopathic Ketotic Hypoglycemia

Idiopathic ketotic hypoglycemia (IKH) commonly occurs during the first 1-4 years of life and typically resolves by age 6-8 years old. Children present with hypoglycemia and elevated β-hydroxybutyrate (>2-3 mmol/L), frequently in the setting of illness, and demonstrate shortened fasting tolerance on a diagnostic fast. IKH is a diagnosis of exclusion, and it is important to rule out other causes of ketotic hypoglycemia, such as GSDs or hormone deficiencies, before making this diagnosis. IKH is likely the result of the lower energy stores in toddlers and young children and is not caused by an underlying metabolic defect, as evidenced by its spontaneous resolution (see Table 113.9). Treatment typically consists of limited fasting time and home glucose monitoring during times of illness. IV dextrose infusion may be required with illness if children are unable to tolerate oral feeds.

Disorders of Gluconeogenesis

Disorders of gluconeogenesis are characterized by elevated plasma lactate levels during hypoglycemia.

Glycogen Storage Disease Type I

See Chapter 107.1.

Glucose-6-phosphatase regulates the terminal step of gluconeogenesis and glycogenolysis, and deficiency of this enzyme results in GSD type I. Children with this condition experience hypoglycemia within 2-3 hours after a meal and significant elevations of lactate, uric acid, and triglycerides because of shunting of gluconeogenic precursors to alternative pathways in the liver. The diagnosis should be suspected in an infant with hypoglycemia, hepatomegaly, and the characteristic metabolic abnormalities. Sequencing of *G6PC* (type Ia) or *SLC37A4* (type Ib) confirms the diagnosis. Treatment includes frequent meals or feeds and after the first 6-12 months of life, uncooked cornstarch administered every 3-4 hours. Fasting beyond 4-6 hours can provoke life-threatening lactic acidosis.

Fructose-1,6-Bisphosphatase Deficiency

See Chapter 107.3.

A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-bisphosphate. Features are similar to GSD type I with fasting hypoglycemia, severe lactic acidosis, and elevations of uric acid and triglycerides. However, glycogenolysis remains intact, so patients do not have significant hepatomegaly or transaminitis. The diagnosis is confirmed through genetic testing of *FBP1*. Similar to GSD type I, treatment involves frequent meals, cornstarch, and avoidance of prolonged fasting.

OTHER CAUSES OF HYPOGLYCEMIA

Postprandial Hypoglycemia

Up to 30% of infants and children with **Nissen fundoplication**, a procedure used to ameliorate gastroesophageal reflux, develop **postprandial hypoglycemia**, or "late dumping syndrome." Characteristic features include hyperglycemia followed by severe hypoglycemia (average 32 mg/dL in one series) 1.5-3 hours later. The early hyperglycemia phase is associated with brisk and excessive insulin release that causes the resultant hypoglycemia. A role for exaggerated GLP-1 secretion has been proposed as being responsible for the excessive insulin release. Treatment consists of feed modifications for formula- or tube-fed children, such as the use of complex formulas or prolonged feeds. Acarbose has been successfully used in some orally fed children.

Acute Alcohol Intoxication

The generation of reducing equivalents during the oxidation of ethanol in the liver inhibits several gluconeogenic enzymes, resulting in hypoglycemia if glycogen stores are depleted by starvation or by preexisting abnormalities in glycogen metabolism. There is no correlation between blood ethanol levels and the occurrence of hypoglycemia. In toddlers who have been fasting for some time, even the consumption of small quantities of alcohol can precipitate hypoglycemia. *Alcohol-induced hypoglycemia promptly responds to IV dextrose*. However, if there is an associated alcohol toxicity, the patient may not show clinical signs of improvement despite now having a normal blood glucose level. A careful history allows the diagnosis to be made and may avoid additional workup.

β Blockers

β-Adrenergic stimulation enhances glucagon secretion and increases glycogenolysis and gluconeogenesis. β blockers impair the counterregulatory response to hypoglycemia and blunt the autonomic symptoms described earlier. Children at highest risk of hypoglycemia from β blockers include those with insulin-dependent diabetes and infants and toddlers in the setting of prolonged fasting or illness. Despite increased use of propranolol for infantile hemangiomas, the prevalence of hypoglycemia in this population appears to be low (0.9%). Propranolol has also been safely used in children with underlying hypoglycemia disorders, although close monitoring of glucose is needed during illness.

Salicylate Intoxication

See Chapter 94.

Both hyperglycemia and hypoglycemia occur in children with salicylate intoxication. Accelerated use of glucose, resulting from augmentation of insulin secretion by salicylates, and possible interference with gluconeogenesis may contribute to hypoglycemia. Infants are more susceptible than older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood. Ketosis may occur.

Systemic Disorders

Several systemic disorders are associated with hypoglycemia in infants and children. Children with acute liver failure develop hypoglycemia because of loss of gluconeogenesis. Sepsis, particularly in neonates, may result in hypoglycemia. Falciparum malaria is also associated with hypoglycemia, which is thought to be the result of increased glucose use and impaired gluconeogenesis.

Aneuploidy screening is offered to pregnant persons in the first trimester or at midgestation to evaluate the risk for common aneuploidies such as Down syndrome (trisomy 21), trisomy 18, trisomy 13, and congenital malformations (e.g., abdominal wall or NTDs) known to cause elevations of various markers. A combination of these biochemical markers (including AFP, inhibin A, estriol, pregnancy-associated plasma protein A, β-human chorionic gonadotropin [β-hCG]) and US increases the positive predictive value (PPV) of these screening tests. Fetal DNA in maternal plasma and fetal cells circulating in maternal blood are potential noninvasive sources of material for prenatal genetic testing. This testing, however, is not diagnostic, and a positive test requires either amniocentesis or postnatal analysis to confirm the diagnosis. Nonetheless, fetal karyotyping by analysis of fetal DNA in maternal plasma is another screening test that is very sensitive for the detection of Down syndrome, with a higher PPV than any other prenatal screening test for Down syndrome. Currently, however, the use of this technology is only advocated in pregnancies deemed at high risk for aneuploidy.

117.7 Treatment and Prevention of Fetal Disease

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

See also Chapter 118.

Management of a fetal disease depends on coordinated advances in diagnostic accuracy and knowledge of the disease's natural history; an understanding of fetal nutrition, pharmacology, immunology, and pathophysiology; the availability of specific active drugs that cross the placenta; and therapeutic procedures. Progress in providing specific treatments for accurately diagnosed diseases has improved with the advent of real-time ultrasonography, amniocentesis, and cordocentesis (see Tables 117.1 and 117.9).

The incidence of sensitization of Rh-negative women by Rh-positive fetuses has been reduced by prophylactic administration of Rh(D) immunoglobulin to mothers early in pregnancy and after each delivery or abortion, thus reducing the frequency of hemolytic disease in their subsequent offspring. **Fetal erythroblastosis** (see Chapter 140) may be accurately detected by fetal Doppler assessment of the peak systolic velocity of the middle cerebral artery and treated with intrauterine transfusions of packed Rh-negative blood cells via the intraperitoneal or, more often, intraumbilical vein approach.

Pharmacologic approaches to fetal immaturity mostly revolve around the administration of antenatal corticosteroids to the mother to promote fetal production of surfactant with a resultant decrease in the incidence of **respiratory distress syndrome** (see Chapter 126). Tocolytic agents have been demonstrated to prolong pregnancy to allow the administration of antenatal corticosteroids (48 hours); however, there is no proven benefit beyond this time frame. Maternal administration of magnesium sulfate for fetal/neonatal neuroprotection is recommended in pregnancies deemed to be at risk of imminent delivery before 32 weeks' gestation in light of evidence demonstrating a reduction in frequency of cerebral palsy compared with those who did not receive this treatment.

Management of definitively diagnosed fetal genetic disease or congenital anomalies consists of multidisciplinary parental counseling. Rarely, high-dose **vitamin therapy** for a responsive inborn error of metabolism (e.g., biotin-dependent disorders) or fetal transfusion (with red blood cells or platelets) may be indicated. **Fetal surgery** is well-established treatment for certain conditions but remains a largely experimental approach to therapy for other conditions and is available only in a few, highly specialized perinatal centers (see Table 117.9 and Chapter 118). The nature of the defect and its consequences must be considered, as well as ethical implications for the fetus and the parents. **Termination of pregnancy** is also an option that should be discussed during the initial phases of counseling.

Folic acid supplementation decreases the incidence and recurrence of NTDs. Because the neural tube closes within the first 28 days of conception, periconceptional supplementation is needed for prevention. It is recommended that women without a prior history of a NTD ingest 400 μg/day of folic acid throughout their reproductive years. Women with a history of a prior pregnancy complicated by an NTD or a first-degree relative with an NTD should have preconceptional counseling and should ingest 4 mg/day of supplemental folic acid beginning at least 1 month before conception. Fortification of cereal-grain flour with folic acid is established policy in the United States and some other countries. The optimal concentration of folic acid in enriched grains is somewhat controversial. The incidence of NTD in the United States and other countries has decreased significantly since these public health initiatives were implemented. Use of some antiepileptic drugs (valproate, carbamazepine) during pregnancy is associated with an increased risk of NTD. Women taking these medications should ingest 1-5 mg of folic acid daily in the preconception period.

Chapter 118

Fetal Intervention and Surgery

Natalie E. Rintoul, Emily A. Partridge, and Holly L. Hedrick

Congenital anomalies have always been recognized as a therapeutic challenge. Numerous diagnoses have been evaluated for the possibility of fetal intervention (Tables 118.1 and 118.2). Some have proved beneficial to the developing infant, some have been abandoned, and some remain under investigation.

FETAL THERAPY ETHICS

With the development of advanced fetal ultrasound (US), ultrafast fetal MRI, and fetal echocardiography, the ability to accurately diagnose fetal disease has improved substantially over the past 3 decades. The first prenatal therapeutic intervention was reported in 1963 with the successful treatment of erythroblastosis fetalis by fetal intraperitoneal infusion. Other innovations, though groundbreaking, brought to light the high morbidity (fetal and maternal) and mortality associated with open fetal interventions, and it would take greater experience and techniques before open fetal surgery would be safer and therapeutic.

OBSTRUCTIVE UROPATHY

Obstructive uropathy is a diverse set of diseases affecting the bladder neck or urethra and affects between 2.2 and 3.3 per 10,000 live births. It is most frequently caused by **posterior urethral valves (PUVs)** but can be caused by a variety of other defects, including urethral atresia, persistent cloaca, caudal regression, and megacystis–microcolon–intestinal hypoperistalsis syndrome (see Chapters 577 and 578). Although male fetuses are more commonly affected, females are more commonly associated with severe pathologic variants, and 30% of survivors will require renal replacement therapy or transplantation before age 5. Congenital obstructive uropathy

Table 118.1 Fetal Diagnoses Evaluated and Treated in Fetal Centers

Amniotic band syndrome (ABS)	Gastroschisis
Anomalies in monochorionic twins	Hydrocephalus
Aortic stenosis	Hydronephrosis
Arachnoid cyst	Hypoplastic left heart syndrome (HLHS)
Bladder exstrophy	Imperforate anus
Bladder outlet obstruction	Intraabdominal cyst
Bronchopulmonary sequestration (BPS)	Lymphangioma
Cervical teratoma	Mediastinal teratoma
Cloaca	Myelomeningocele, spina bifida
Cloaca exstrophy	Neuroblastoma
Complete heart block	Obstructive uropathy
Congenital pulmonary airway malformation (CPAM)	Omphalocele
Congenital diaphragmatic hernia (CDH)	Pentalogy of Cantrell
Congenital high airway obstruction syndrome (CHAOS)	Pericardial teratoma
EXIT to airway procedure for CHAOS	Pleural effusions
Conjoined twins	Pulmonary agenesis
Dandy-Walker malformation	Pulmonary atresia with intact ventricular septum
Duodenal atresia	Sacrococcygeal teratoma (SCT)
Encephalocele	Twin reversed arterial perfusion (TRAP) sequence
Enteric duplication atresia	Twin-to-twin transfusion syndrome (TTTS)
Esophageal atresia	Vein of Galen aneurysm

EXIT, Ex utero intrapartum treatment.

Table 118.2 Indications and Rationales for In Utero Surgery on the Fetus, Placenta, Cord, or Membranes

FETAL SURGERY	PATHOPHYSIOLOGY	RATIONALE FOR IN UTERO INTERVENTION
SURGERY ON THE FETUS		
1. Congenital diaphragmatic hernia	Pulmonary hypoplasia and anatomic substrate for pulmonary hypertension	Reversal of pulmonary hypoplasia and reduced degree of pulmonary hypertension Repair of actual defect delayed until after birth
2. Lower urinary tract obstruction	Progressive renal damage due to obstructive uropathy Pulmonary hypoplasia due to oligohydramnios	Prevention of renal failure and pulmonary hypoplasia by anatomic correction or urinary deviation
3. Sacrococcygeal teratoma	High-output cardiac failure due to AV shunting and/or bleeding Direct anatomic effects of the tumoral mass Polyhydramnios-related preterm labor	Reduction of functional impact of tumor by ablation of tumor or (part of) its vasculature Reduction of anatomic effects by drainage of cysts or bladder Amnioreduction preventing obstetric complications
4. Thoracic space-occupying lesions	Pulmonary hypoplasia (space-occupying mass) Hydrops due to impaired venous return (mediastinal compression)	Creation of space for lung development Reversal of the process of cardiac failure
5. Neural tube defects	Damage to exposed neural tube Chronic CSF leak, leading to Arnold-Chiari malformation and hydrocephalus	Prevention of exposure of the spinal cord to amniotic fluid Restoration of CSF pressure correcting Arnold-Chiari malformation
6. Cardiac malformations	Critical lesions causing irreversible hypoplasia or damage to developing heart	Reversal of process by anatomic correction of restrictive pathology
SURGERY ON THE PLACENTA, CORD, OR MEMBRANES		
7. Chorioangioma	High-output cardiac failure due to AV shunting Effects of polyhydramnios	Reversal of process of cardiac failure and hydrops fetoplacentalis by ablation or reduction of flow
8. Amniotic bands	Progressive constrictions causing irreversible neurologic or vascular damage	Prevention of amniotic band syndrome leading to deformities and function loss
9. Abnormal monochorionic twinning: twin-to-twin transfusion; fetus acardius, and discordant anomalies	Twin-twin transfusion leading to oligopolyhydramnios sequence, hemodynamic changes; preterm labor, and rupture of membranes; in utero damage to brain, heart, or other organs In utero fetal death may cause damage to co-twin Cardiac failure of pump twin and consequences of polyhydramnios Serious anomaly raising the question of termination of pregnancy Selective feticide	Arrest of intertwin transfusion Prevention/reversal of cardiac failure and/or neurologic damage, including at in utero death Prolongation of gestation Selective feticide to arrest parasitic relationship, to prevent consequences of in utero fetal death, and to avoid termination of entire pregnancy

AV, Arteriovenous; CSF, cerebrospinal fluid.
From Deprest J, Hodges R, Gratacos E, Lewi L. Invasive fetal therapy. In: Creasy RK, Resnik R, Iams JD, et al., eds. *Creasy & Resnik's Maternal-Fetal Medicine*. 7th ed. Philadelphia: Elsevier; 2014. Table 35-1.

causes hydronephrosis and renal dysplasia of variable severity. Although the mechanism of renal injury is debated, hypotheses include cyst formation secondary to urinary retention and subsequent disruption of nephrogenesis versus obstruction-associated apoptosis of renal tubular cells.

Obstructive uropathy usually presents on fetal US with an enlarged bladder, bilateral hydroureteronephrosis, and oligohydramnios in the second and third trimester. Mild forms of obstructive uropathy may lead to minimal short- or long-term clinical sequelae. However, reduced fetal urine output resulting in oligohydramnios or anhydramnios in more severe forms can cause significant pulmonary hypoplasia, which is associated with death shortly after delivery in >80% of infants. Pulmonary survivors remain subject to high mortality and chronic morbidity resulting from renal dysplasia, renal failure, and the need for chronic renal replacement therapy. Workup of congenital obstructive uropathy includes genetic and structural evaluation, with additional imaging and fetal urinalysis aiding in prognostication. For example, a fetal urine sodium <100 mEq/L, chloride <90 mEq/L, and urine osmolality >210 mEq/L at a mean gestational age of 23.8 weeks predicts "good outcome," as reflected by the presence of nondysplastic kidneys at autopsy or biopsy, or normal renal and pulmonary function at birth. Fetuses with salvageable renal function should have downtrending values of urine sodium, chloride, calcium, total protein and β_2-microglobulin on repeat vesicocentesis. Fetal bladder filling time [(fetal bladder volume 48 hours post-vesicocentesis – fetal bladder volume prior to vesicocentesis)/fetal bladder volume prior to vesicocentesis)], fetal MRI, and three-dimensional fetal cystoscopy have also been shown to have utility in predicting postnatal renal function.

The primary objective of fetal intervention in fetuses with obstructive uropathy is restoration of amniotic fluid volume to prevent pulmonary hypoplasia. Although prevention of ongoing renal injury is also desired, the efficacy of fetal intervention in achieving this goal is uncertain. Therefore fetal intervention for obstructive uropathy is currently limited to fetuses in whom the obstruction is sufficient to cause oligohydramnios or anhydramnios.

For fetuses that still have adequate renal function and can produce urine, treatment options include vesicoamniotic shunting, valve ablation via cystoscopy, and vesicostomy. **Vesicoamniotic shunting** is the most common and involves percutaneous, US-guided placement of a double-pigtailed shunt from the fetal bladder to the amniotic space, allowing decompression of the obstructed bladder and restoration of the amniotic fluid volume (Figs. 118.1 and 118.2). Although simple in concept, bladder decompression may not always occur, and many catheters will become dislodged as the fetus develops; a fetus typically requires three catheter replacements before completion of pregnancy. Vesicoamniotic shunting may improve perinatal survival, but at the expense of poor long-term renal function. In a systematic review of over 250 fetuses, increased prenatal survival is present in the shunted population, but there is no difference in the 12- and 24-month survival.

Fig. 118.1 Ultrasound image showing fetoscopic placement of a transurethral vesicoamniotic shunt in a patient with posterior urethral valves. *(Courtesy Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)*

Fetal **cystoscopy** is more technically challenging than vesicoamniotic shunt placement, more invasive, and requires more sedation, but this option holds some important advantages. Cystoscopy allows for direct visualization of the obstruction and does not require amnioinfusion. Moreover, when the obstruction is visualized and the diagnosis of PUV confirmed, the valves can be treated, restoring urine flow to the amniotic space, and eliminating the need for repeated fetal interventions in most patients. Creation of a vesicostomy (direct opening from bladder through fetal abdominal wall) by open fetal surgery has improved perinatal survival (Fig. 118.3). However, the current dataset evaluating this approach is still limited, and direct comparisons to shunting suggest no significant difference between these interventions.

NONOBSTRUCTIVE RENAL DISEASE

Nonobstructive fetal renal disease can result from renal hypoplasia/dysplasia and from genetic diseases such as autosomal recessive polycystic kidney disease. Similar to obstructive uropathy, fetal therapy is focused on restoring amniotic fluid volume in patients with oligohydramnios or anhydramnios. However, restoration of amniotic fluid volume in nonobstructive renal disease requires external sources of amniotic fluid. Current treatment options include serial percutaneous **amnioinfusion** and infusion of fluid by amnioport. Serial amnioinfusions are less invasive as a single procedure, but most pregnancies will require weekly infusions to maintain adequate amniotic fluid volume. Amnioinfusion through an amnioport involves open surgical placement of a catheter into the amniotic space that is connected to an ex utero subcutaneous port. This allows repeated fluid infusion into the amniotic space. The amnioport is more challenging and invasive as an individual procedure but provides more reliable access to the amniotic space for the duration of the pregnancy. Small studies suggest both these procedures improve pulmonary outcomes and perinatal survival in infants with renal disease, but these infants will require dialysis and then renal transplant when the infant is large enough (2-3 years of age). The Renal Anhydramnios Fetal Therapy (RAFT) is a multi-site clinical trial to determine the feasibility, safety and success rate of serial **amnioinfusions** for early pregnancy renal anhydramnios (EPRA). The trial originally included EPRA caused both by congenital bilateral **renal agenesis** (CoBRA) and by fetal renal failure

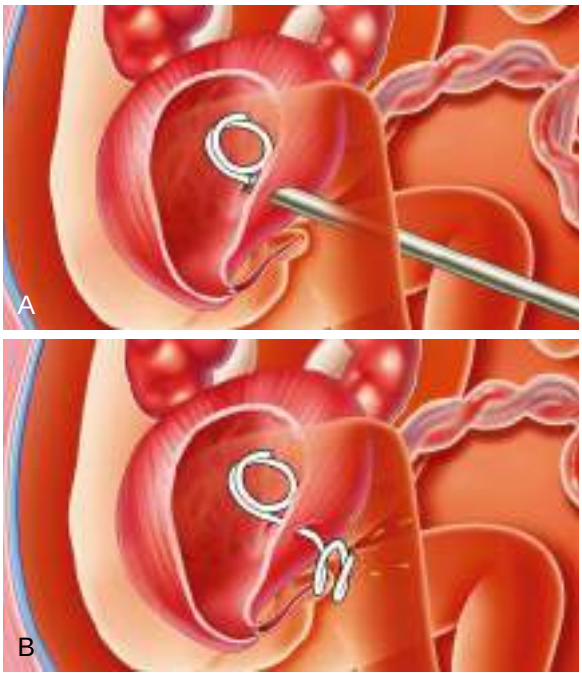

Fig. 118.2 Vesicoamniotic shunt placement. **A**, The shunt is loaded into the trocar, passed into the bladder, and recoils to a pigtail shape. **B**, The other end of the shunt recoils to a pigtail outside the abdominal wall, releasing urine into the amniotic fluid space around the fetus. *(Copyright 2021, The Children's Hospital of Philadelphia.)*

Fig. 118.3 Creation of a fetal vesicostomy. The uterine opening is stapled to prevent bleeding, and a catheter is inserted to replace amniotic fluid and maintain uterine volume. The fetus is positioned with the legs to the lower part of the field and the umbilical cord to the upper part of the field. A vesicostomy is created through the bladder and the abdominal wall to allow drainage of the obstructed bladder and restoration of amniotic fluid volume. *(Courtesy Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)*

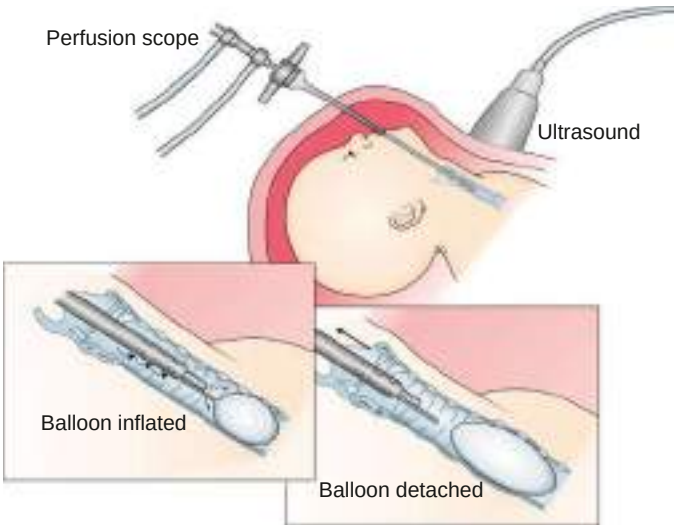

Fig. 118.4 Technique for fetoscopic tracheal occlusion using a balloon. *(Modified from Hirose S, Harrison MR. Fetal therapy. In Holcomb GW III, Murphy JP, eds. Ashcraft's Pediatric Surgery. 5th ed. St Louis: Elsevier; 2010. Fig. 10.1.)*

(FRF) with kidney tissue present. At the time of this publication, the CoBRA arm is no longer recruiting. The primary objective of this trial is to determine the proportion of neonates surviving to successful dialysis after serial amnioinfusions.

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is a structural birth defect in which the diaphragm fails to fully close during development resulting in herniation of the abdominal contents into the thorax and inhibition of fetal lung growth (see Chapter 131). CDH occurs in 1,500 live births in the United States annually and is the leading cause of in-hospital neonatal deaths as well as the costliest noncardiac birth defect. Although the pathophysiology of CDH remains unclear, most patients are affected by some degree of pulmonary hypoplasia and persistent pulmonary hypertension. A dual-hit hypothesis has been suggested to characterize lung injury in CDH, with an initial injury occurring during organogenesis resulting in bilateral pulmonary hypoplasia and a secondary insult of the ipsilateral lung due to compression by the herniated abdominal viscera. Fetal breathing and fluidic lung distension are features of normal lung development, which are mechanically compromised by the diaphragmatic defect, resulting in not only reduced parenchymal volume but also decreased vascular density. Compensatory vascular remodeling results in hypermuscularization of the arteriolar bed, increased vascular resistance, and ultimately pulmonary hypertension. It is the severity of pulmonary hypoplasia and persistent pulmonary hypertension that represents the greatest determinant of morbidity and mortality.

In mild cases of CDH, surgical repair of the diaphragm is typically performed in the first few days of life after respiratory and hemodynamic stabilization. Although these infants are affected by pulmonary hypoplasia and close monitoring is required during the first years of life, long-term outcomes are excellent in the majority of survivors of mild CDH. In cases of *severe* CDH, pulmonary hypertension leads to right ventricular dysfunction and right-to-left shunting across the patent foramen ovale and ductus arteriosus, which can result in left ventricular dysfunction and cardiac failure necessitating extracorporeal membrane oxygenation (ECMO) in the perinatal period. Mortality is high in severely affected infants, and survivors often have significant impairments in long-term respiratory, feeding, and neurodevelopmental outcomes.

More than half of all CDH cases are identified on routine second trimester anatomy US, whereas delayed diagnosis may occur secondary to small defects, technical limitations, or unavailability of prenatal care. In 50–70% of cases the lesion is isolated, whereas *syndromic* or *complex* CDH may be associated with additional anomalies warranting further imaging and genetic studies. Fetal echocardiography and ultrafast MRI should be included in comprehensive fetal diagnosis, permitting calculation of fetal lung volumes as well as ruling out major structural cardiac anomalies.

The first reports of attempted *in utero repair* of CDH noted impairment of umbilical blood flow after reduction of the liver resulting in fetal demise in a number of cases. Although the procedure proved to be technically feasible in fetuses without liver herniation, comparative analysis revealed higher rates of preterm delivery (32 vs 38 weeks' gestation) and similar rates of survival (75% fetal repair vs 86% postnatal repair), leading to abandonment of prenatal attempts at surgical repair.

Given the disappointing results after attempted open fetal surgical repair of **CDH**, researchers turned to the fetal lamb model to assess the impact of tracheal ligation on pulmonary development. By blocking the efflux of fetal lung fluid into the amniotic space, pulmonary distension results in increased lung volumes. To mitigate the risks associated with open tracheal ligation, a **fetoscopic endoluminal tracheal occlusion (FETO)** approach with balloon tracheal occlusion was developed (Fig. 118.4). In a study of 210 fetuses with *severe* hypoplasia due to isolated CDH, the use of FETO had an acceptable safety profile in the mother with improved neonatal survival but increased risk of preterm birth. In this trial the balloon was inserted at approximately 28 weeks of gestation and removal at 34 weeks, with this timing based on the hypothesis that tracheal occlusion will promote lung expansion while removal of the balloon before delivery will promote alveolar type II cell maturation. The multicenter prospective randomized Tracheal Occlusion to Accelerate Lung Growth (TOTAL) study results had inclusion criteria of gestational age less than 29 weeks 6 days at randomization, isolated left-sided CDH with no other major structural or chromosomal defects, and severe pulmonary hypoplasia defined as observed-to-expected lung-to-head ratios of less than 25%. Forty percent of infants with severe CDH in the FETO group survived to discharge compared to 15% in the expectant care group, with survival to 6 months identical to survival at discharge and increased rate of preterm rupture of membranes (47% vs 11%) and preterm birth (75% vs 29%).

CONGENITAL PULMONARY AIRWAY MALFORMATION

Congenital pulmonary airway malformations (CPAM), or fetal lung lesions, are a group of rare congenital pulmonary neoplasms including congenital cystic adenomatoid malformations (CCAMs), bronchopulmonary sequestrations (BPSs), congenital lobar emphysema, and bronchogenic cysts (Fig. 118.5). The reported incidence of CPAM is 9 per 100,000 live births, with prenatal diagnosis by fetal US most commonly coinciding with the 18–20-week anatomy scan. CCAMs are caused by abnormal branching and hamartomatous growth of the terminal respiratory structures, resulting in cystic and adenomatoid malformations (see Chapter 444), and are the most common congenital lung lesion. CCAMs

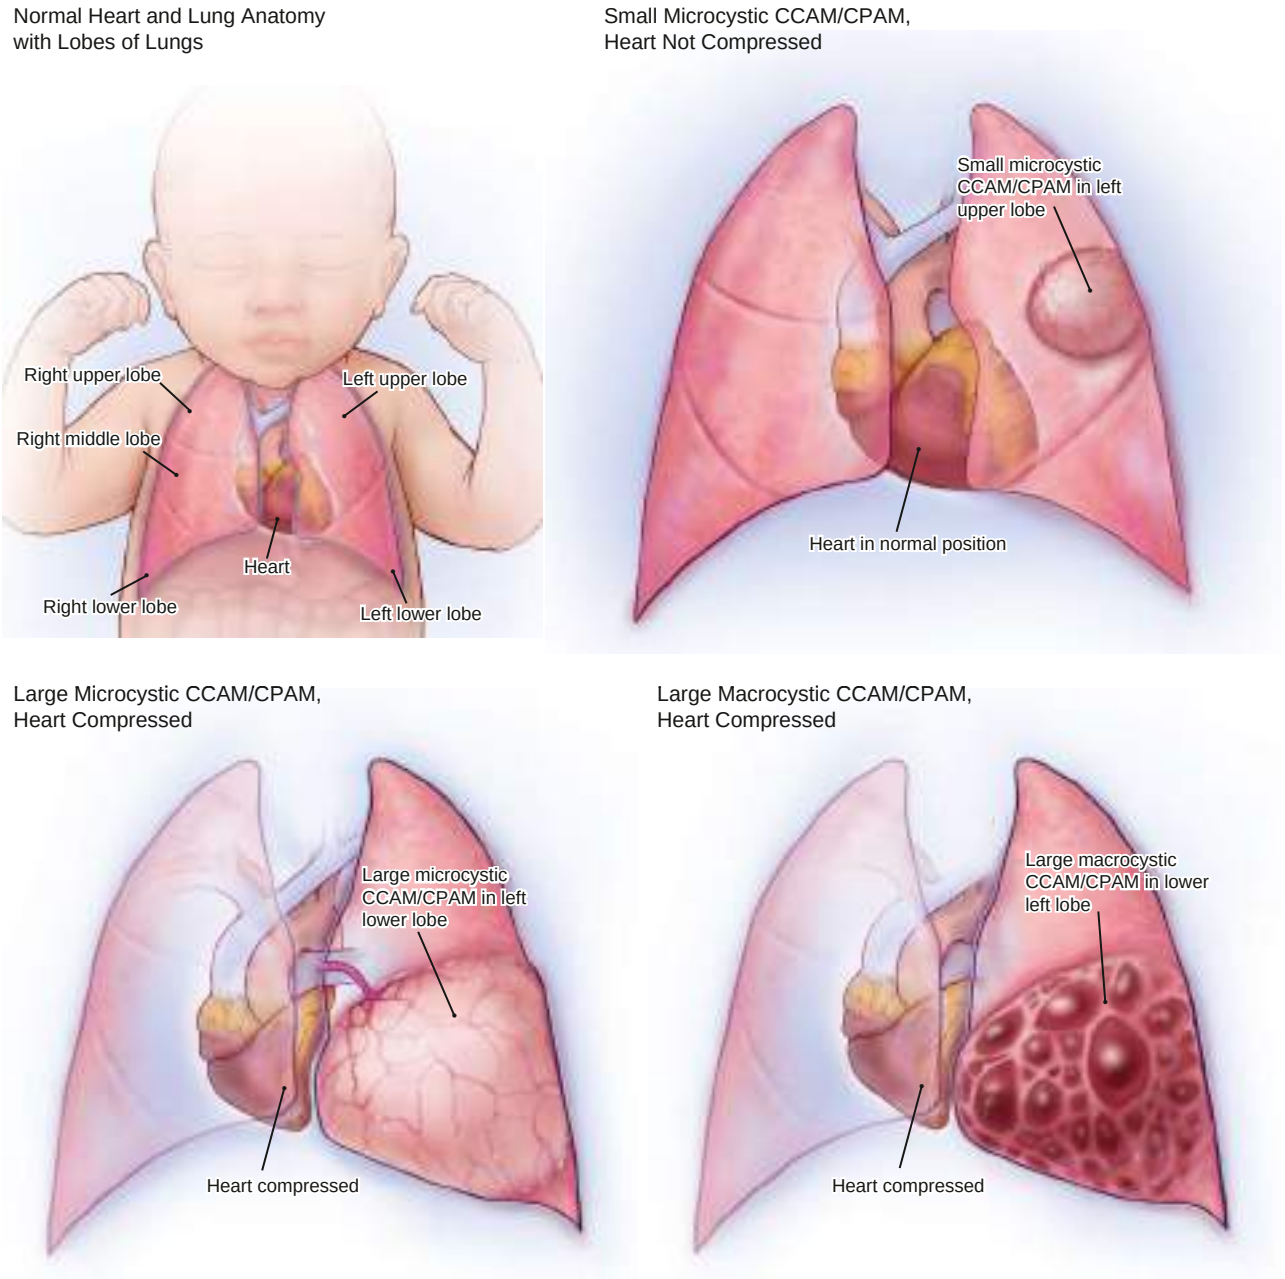

Fig. 118.5 Different types of congenital cystic adenomatoid malformation (CCAM)/congenital pulmonary airway malformation (CPAM), and how the different sizes and presentations of lung lesions can impact the heart and lungs. *(Copyright 2021, The Children's Hospital of Philadelphia.)*

have been classified as microcystic (maximal cyst diameter <5 mm) vs macrocystic (≥5 mm), and prognosis is correlated with lesion size as well as presence of macrocysts (see Fig. 118.5). In contrast, BPSs appear as echogenic homogeneous masses on US and can be distinguished from CCAM by US evidence of systemic aortic arterial blood supply.

Large CPAMs may cause significant pulmonary hypoplasia and polyhydramnios due to decreased fetal swallowing secondary to esophageal compression. In severe cases, hydrops fetalis may result due to compression of the heart and great vessels. Hydrops with concomitant placentomegaly may result in maternal mirror syndrome, which is postulated to result from the release of vasoactive substances from the inflamed and edematous placenta. Due to the variable natural history of these lesions, a prenatal prognostic parameter, the CPAM volume ratio (CVR), is followed. The CVR is an index that compares the volume of the CPAM to the fetal head circumference. Most studies indicate >95% survival in CPAM patients with no hydrops and CVR <1.6, with greater risk for hydrops and need for closer surveillance in patients with a CVR >1.6.

Management of pregnancies complicated by prenatal diagnosis of a fetal lung lesion requires a plan for safe delivery. In the absence of mediastinal shift or flattening, small microcystic lesions will typically meet criteria for community delivery with a plan for close postnatal follow-up. Due to the risk of recurrent infection and malignant transformation, elective postnatal resection is anticipated; a CT angiogram (CTA) is performed at 4-6 weeks of age with surgical intervention following a few weeks later, when the potential for compensatory growth of the remaining lobe(s) is maximized. In the example of large macrocystic lesions with concern for respiratory compromise, delivery at an experienced center with access to ECMO and advanced emergent resection approaches is critical. For large lesions with CVR >1.6 or associated hydrops, the presence of macrocysts permits fetal thoracentesis and eventual thoracoamniotic shunt placement, which may reverse hydrops and allow continuation of the pregnancy without open fetal surgical intervention. Irrespective of the presence of drainable cysts, large lesions with threatened hydrops are treated with maternal betamethasone, which has been shown to reduce lesion size and reverse hydrops and may be given in multiple courses

to maximize therapeutic impact. Lesions not responsive to steroids or amenable to drainage may require open fetal surgery if the gestational age is less than 32 weeks; beyond 32 weeks' gestation, early delivery by C-section or ex utero intrapartum therapy (EXIT) with planned immediate resection is recommended.

CONGENITAL HIGH AIRWAY OBSTRUCTION SYNDROME

Congenital high airway obstruction syndrome (CHAOS) is secondary to partial or complete intrinsic fetal upper airway obstruction. Most often due to laryngeal or tracheal atresia, CHAOS prevents lung fluid efflux resulting in dilated distal pulmonary airways and enlargement of the fetal lungs with potential for cardiac compression and the development of fetal hydrops. The diagnosis is confirmed by fetal MRI (Fig. 118.6).

In addition to CHAOS, extrinsic compression of the airway may be secondary to mass lesions (lymphangioma, teratoma, goiter) making respiratory efforts after birth difficult.

EXIT (ex utero intrapartum treatment) is a procedure to secure an airway during elective delivery (while the umbilical cord is patent and connected to the placenta), by C-section, before the onset of labor and before the fetus attempts to breathe (Fig. 118.7). The EXIT to airway procedure may be performed by direct laryngoscopy and

endotracheal intubation or, if needed, rigid bronchoscopy, fiberoptic intubation, or tracheostomy (see Fig. 118.6).

SACROCOCCYGEAL TERATOMA

Sacrococcygeal teratoma (SCT) is one of the most common solid tumors of the newborn, with an incidence of 4.8 per 100,000 live births. This germline tumor has a female predominance (4:1) and is rarely associated with other congenital anomalies including nervous, skeletal, and cardiac abnormalities.

The high morbidity and mortality associated with SCT is multifactorial and is associated with both high rates of preterm delivery as well as hemodynamic sequelae. The mechanism of preterm delivery in SCT is believed to be a result of polyhydramnios-associated uterine irritability and premature rupture of membranes. Rupture of the tumor itself is rare but is most often fatal. The vascular composition of the tumor has hemodynamic implications for the fetus/newborn as high-output cardiac failure results from arteriovenous shunting causing vascular steal away from the placenta and the fetus to the SCT and compromised perfusion. Hydropic fetuses with placentomegaly may develop maternal mirror syndrome mandating immediate delivery. Prenatal diagnosis relies on US to identify the lesion and subsequent fetal MRI and echocardiography to assess for placental size, hydrops, and cardiac output physiology. Specific echocardiographic and Doppler US measurements of prognostic utility include cardiac output, cardiac/thoracic ratio, placental thickness, amniotic fluid index, and markers of hydrops including ascites as well as skin and scalp edema.

Given the morbidity and mortality associated with open fetal resection, prenatal intervention is limited to fetuses with mostly external masses manifesting hydrops and fetal cardiac insufficiency. The fetal approach to SCT debulking involves incision of the fetal skin circumferentially around the base of the tumor, application of a Rummel tourniquet, and debulking of the mass with a tissue stapler or energy device to interrupt the high output state (Fig. 118.8). Completion resection of the tumor and coccyx is performed postnatally. More often in the setting of early signs of evolving hydrops in the third trimester, early delivery (28-29 weeks' gestation) and debulking are considered with a similar strategy of staged debulking followed by completion resection when the neonate has stabilized. Resection of the coccyx is critical to avoid recurrence.

Reports of noninvasive interruption of blood flow with laser ablation, radiofrequency ablation, or vascular coiling are tempting but have been complicated by the inability to control the energy source leading to destructive tissue injury and injury to adjacent structures.

MYELOMENINGOCELE

Myelomeningocele (MMC) is the most common neural tube defect with an incidence of 1-2 per 1,000 live births. The disease is characterized by an abnormal outgrowth of the nerve root through the meninges with a concomitant vertebral bone and skin defect resulting in neural tissue exposure to the amniotic fluid. Associated defects include Chiari II malformation, characterized by descent of the cerebellar vermis through the foramen magnum, medullary kinking, and obliteration of the cistern magna leading to brainstem herniation. Hydrocephalus complicates up to 85% of MMC patients and is a major source of long-term morbidity, with high rates of shunting of cerebrospinal fluid required in survivors. Dermoid cysts are also common and may require intervention. Developmental and cognitive impairment is prevalent and profound, and current estimates suggest rates between 60% and 70% of pregnancies complicated by a prenatal diagnosis of MMC end in termination or demise. The etiology of MMC is likely multifactorial, with folic acid deficiency as well as use of folic acid antagonists associated with the development of neural tube defects. Screening for neural tube defects includes measurement of maternal serum α-fetoprotein (MSAFP) and US. Expectant mothers with screening concerns for MMC should be evaluated at a specialized center with further anatomic US, genetic screening, and ultrafast fetal MRI. In addition to identification of the neural tube defect, expert US can assess lower extremity function, and fetal MRI can define the extent of hindbrain herniation and ventricular size.

Before the introduction of fetal repair of MMC, fetal surgery was limited to life-threatening anomalies with high predictive mortality for the fetus or infant without intervention. However, a growing body of data suggested that the neurologic outcome in MMC was directly related to progressive injury from ongoing damage to the exposed spinal cord during pregnancy (see Chapter 631.3) (Fig. 118.9). A large multicenter National Institutes of Health–sponsored Management of Myelomeningocele Study (MOMS) comparing the safety and efficacy of prenatal repair of MMC with that of standard postnatal repair was performed and determined a clear advantage for prenatal surgery before 26 weeks' gestation. The MOMS trial demonstrated a significant reduction in the need for ventriculoperitoneal (VP) shunt at 12 months in the fetal repair group (40% vs 82% in postnatal repair group) with reduced hindbrain herniation and improved mental development and motor function at 30 months. Furthermore, the need for shunting was independent of lesion level and degree of hindbrain herniation. The 1-year neurosurgical outcomes for the complete cohort showed that prenatal surgery did not decrease the need for shunting in those fetuses with a cerebral ventricular size of ≥15 mm at initial screening. Prenatal surgery was associated with an increased risk for earlier gestational age at birth. Delivery occurred before 30 weeks of gestation in 11% of neonates that had fetal MMC repair. Adverse pulmonary sequelae were rare in the prenatal surgery group despite an increased rate of oligohydramnios. The benefits of prenatal surgery outweigh the complications of prematurity.

Open fetal repair of MMC has been a paradigm-shifting advance in fetal surgery and has led to the formation of the North American Fetal Therapy Network (NAFTNet) registry of fetal MMC patients, with follow-up studies continuing to demonstrate the benefits

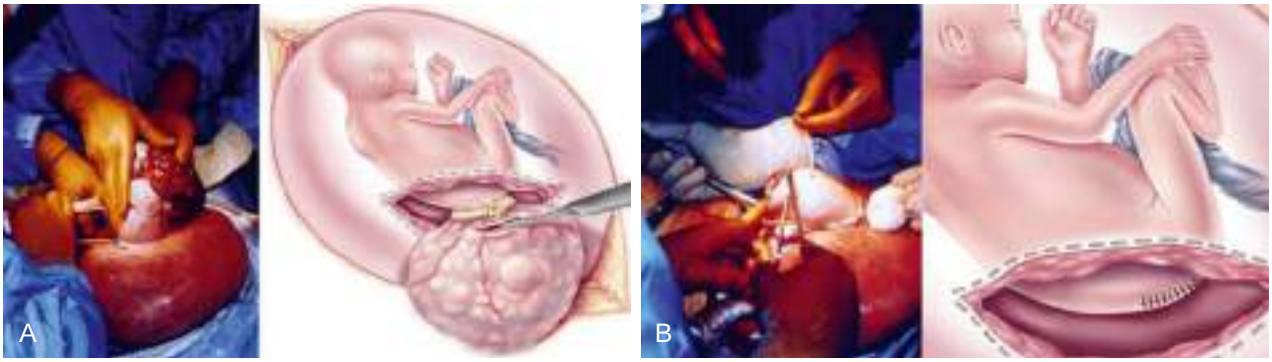

Fig. 118.8 A, Exposure of 26-week fetus through hysterotomy revealing sacrococcygeal teratoma (SCT). B, Closure of skin flaps after resection. *(Copyright 2021, The Children's Hospital of Philadelphia.)*

Fig. 118.10 In twin-to-twin transfusion syndrome (TTTS), blood flow through vascular connections on the surface of the placenta is unequal. One twin ("donor twin") pumps blood to the other twin ("recipient"). This unequal blood flow between twins results in the recipient twin *(right)* having too much amniotic fluid, and donor twin *(left)* with little or no amniotic fluid. *(Copyright 2021, The Children's Hospital of Philadelphia.)*

observed in the MOMS trial in subsequent series. The risk of prematurity and requirement for cesarean section deliveries for all future pregnancies remain significant considerations for this procedure. The less invasive *fetoscopic* MMC repair approach, which is being developed at a limited number of centers, may reduce maternal morbidity and prematurity rates associated with open fetal MMC repair, but this remains a question of active ongoing investigation. At this time, fetoscopic fetal MMC repair is recommended in an investigational setting according to the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine.

TWIN-TO-TWIN TRANSFUSION SYNDROME

Twin-to-twin transfusion syndrome (TTTS) is a condition that affects approximately 10–15% of *monochorionic diamniotic identical twin* pregnancies. In these cases, shared fetoplacental circulation can lead to unbalanced blood flow between the two fetuses which, left untreated, results in perinatal loss of one or both fetuses in approximately 80% of cases (Fig. 118.10). Unlike dichorionic twins, which do not have any vascular connections between the placentas, monochorionic twins have vascular anastomoses within the shared fetoplacental circulation. Unbalanced deep arteriovenous anastomoses without proper compensation from the superficial bidirectional vessels results in discordant blood supply, with the "donor" fetus presenting with oligohydramnios and intrauterine growth restriction while the "recipient" fetus develops polyhydramnios, heart failure, and hydrops due to hypervolemia. Neurodevelopmental delay is commonly observed in long-term survivors.

TTTS is usually a gradual process that is usually observed in the second trimester. Diagnosis is performed via US in the second trimester. The Quintero classification system is used to stratify TTTS into five stages.

- Stage I: Abnormal amniotic fluid levels (oligo- and polyhydramnios) with bladder filling in the donor twin
- Stage II: Features of stage I with collapsed bladder in the donor twin
- Stage III: New abnormal flow through the umbilical artery or ductus venosus in either the donor or recipient twin with stage II features present
- Stage IV: Hydrops in either the donor or recipient twin
- Stage V: Intrauterine demise of either the donor or recipient twin

Several therapies have been proposed for the treatment of TTTS. Amnioreduction is performed to remove excess fluid from the sac with polyhydramnios and can be done serially to help prevent preterm later. Endoscopic or fetoscopic laser ablation of the superficial vascular anastomoses is another therapeutic option. Under local or regional anesthesia, a trocar is placed under US guidance and an endoscope passed, through which superficial anastomoses are then identified and coagulated, followed by amnioreduction. The procedure is performed only once during the pregnancy, usually prior to 26 weeks. Several observational studies have noted perinatal survival approximating 60% with both amnioreduction and laser coagulation. A multicenter randomized trial demonstrated a survival and neurologic advantage after laser coagulation therapy vs amnioreduction; although after 26 weeks, amnioreduction is often still recommended for technical reasons. Other surgical therapies include septostomy (disrupting the membrane between the twins) and selective umbilical cord coagulation in severe cases. Like amnioreduction, septostomy does not alter the underlying pathophysiology. All cases should be referred to tertiary care centers with extensive experience in the treatment of TTTS.

OTHER INDICATIONS

Antenatal intervention for **cardiac defects**, such as aortic stenosis, pulmonic stenosis, and hypoplastic left heart syndrome (HLHS), have been used to dilate, with balloon valvuloplasty, stenotic valves (aortic stenosis) to prevent further development of HLHS (creating biventricular physiology) (Fig. 118.11) (see Chapter 480.10).

Laser therapy has been used to treat TTTS (Chapter 119.1) and amniotic bands (Fig. 118.12).

FETAL CENTERS

The value of fetal surgical program centers extends beyond fetal intervention itself. Often, families will present to a fetal center with a new diagnosis and little understanding of the implications for their baby and family. Prenatal counseling by the fetal team provides the opportunity to confirm the diagnosis, investigate for other anomalies and genetic susceptibilities, and provide detailed counseling to achieve understanding of both the diagnosis and

LEVEL OF CERTAINTY	DIAGNOSIS
DIAGNOSTIC CERTAINTY/PROGNOSTIC CERTAINTY	
Genetic problems	Trisomy 13, 15, or 18 Triploidy
Central nervous system abnormalities	Anencephaly/acrania Holoprosencephaly Large encephaloceles
Heart problems	Acardia Inoperable heart anomalies
Kidney problems	Potter syndrome/renal agenesis Multicystic/dysplastic kidneys Polycystic kidney disease
DIAGNOSTIC UNCERTAINTY/PROGNOSTIC CERTAINTY	
Genetic problems	Thanatophoric dwarfism or lethal forms of osteogenesis imperfecta
Early oligo/anhydramnios and pulmonary hypoplasia	Potter syndrome with unknown etiology
Central nervous system abnormalities	Hydranencephaly
	Congenital severe hydrocephalus with absent or minimal brain growth
Prematurity	<23 weeks' gestation
PROGNOSTIC UNCERTAINTY/BEST INTEREST	
Genetic problems	Errors of metabolism that are expected to be lethal even with available therapy
Mid oligo/anhydramnios	Renal failure requiring dialysis
Central nervous system abnormalities	Complex or severe cases of meningomyelocele Neurodegenerative diseases, such as spinal muscular atrophy
Heart problems	Some cases of hypoplastic left heart syndrome Pentalogy of Cantrell (ectopia cordis)
Other structural anomalies	Some cases of giant omphalocele Severe congenital diaphragmatic hernia with hypoplastic lungs Idiopathic nonimmune hydrops Inoperable conjoined twins Multiple severe anomalies
Prematurity	23-24 weeks' gestation

From Leuthner SR. Fetal palliative care. *Clin Perinatol* 2004;31:649–665. Table 1.

all available treatment options. This collaborative and multidisciplinary family-centered approach allows for the development of a management plan that may include fetal surgery or intervention, enhanced monitoring of the fetus and mother, and coordination of complex deliveries involving multidisciplinary delivery teams and specialized equipment as required for EXIT to ECMO, EXIT to airway, EXIT to tumor resection, delivery to cardiac catheterization, and procedures on placental support.

In some highly specialized fetal centers, delivery may be facilitated with the neonatal intensivists, perinatal anesthesiologist, and pediatric surgical care teams present in the same location to permit expert stabilization and resuscitation of the neonate. The benefits range from the psychological benefits of avoiding maternal-infant separation as well as improved outcomes in diagnoses such as CDH, in which early stabilization of the neonate is critical to minimize pulmonary hypertensive crisis.

Finally, but equally importantly, not all severely affected fetuses will have available therapies in utero or after birth. In these lethal situations, fetal care planning will provide support for the family and a plan for delivery room or nursery palliative care (Table 118.3) (see Chapter 8).

Chapter 119

The High-Risk Infant

Erik Brandsma, Lori A. Christ, and Andrea F. Duncan

The term *high-risk infant* designates an infant at greater risk for neonatal morbidity and mortality; many factors can contribute to an infant being high risk (Table 119.1). There are four broad categories of high-risk infants: the preterm infant, infants with special healthcare needs or dependence on technology, infants at risk because of family issues, and infants with anticipated early death.

Table 119.1 Factors in Considering Infants as High Risk for Morbidity or Mortality in the Neonatal Period

BIRTH PARENT DEMOGRAPHIC FACTORS
Maternal age <16 yr or >40 yr
Environmental, economic, social disadvantage, racial discrimination
BIRTH PARENT MEDICAL HISTORY
Genetic disorders
Diabetes mellitus
Hypertension
Asymptomatic bacteriuria
Rheumatologic illness (systemic lupus erythematosus)
Immune-mediated diseases
Long-term medication (see Chapters 117.4 and 117.5)
PREVIOUS PREGNANCY
Intrauterine fetal demise
Neonatal death
Prematurity
Intrauterine growth restriction
Congenital malformation
Incompetent cervix
Blood group sensitization, neonatal jaundice
Neonatal thrombocytopenia
Hydrops
Inborn errors of metabolism
PRESENT PREGNANCY
Vaginal bleeding (abruptio placentae, placenta previa)
Sexually transmitted infections (colonization: herpes simplex, group B streptococcus, chlamydia, syphilis, hepatitis B, HIV)
Multiple gestation
Preeclampsia
Premature rupture of membranes
Short interpregnancy time
Poly-/oligohydramnios
Acute medical or surgical illness
Familial or acquired hypercoagulable states
Abnormal fetal ultrasonographic findings
Treatment of infertility
Inadequate prenatal care
Substance use disorder
LABOR AND DELIVERY
Premature labor (<37 wk)
Postdates pregnancy (≥42 wk)
Fetal distress
Breech presentation
Meconium-stained fluid
Nuchal cord
Cesarean delivery
Forceps or vacuum assisted delivery
Apgar score <4 at 5 min
NEONATE
Birthweight <2,500 g or >4,000 g
Birth <37 wk or ≥42 wk of gestation
Small or large for gestational age
Respiratory distress, cyanosis
Congenital malformation
Pallor, plethora, petechiae

All high-risk infants require closer evaluation and/or treatment by experienced physicians and nurses. This often starts before delivery and continues in the delivery room and through a neonatal intensive care unit (NICU) stay (see Chapter 121). Regionalized care for infants is based on the acuity of care that can be provided at hospitals with different levels of care and whether transport should be undertaken (see Chapter 120). It is important to note that additional care does not stop at time of NICU discharge, and that many high-risk infants also benefit from additional resources and follow-up after discharge from the hospital (see Chapter 119.5).

Twins and higher-order multiples are at increased risk for morbidity and mortality and are discussed in Chapter 119.1, whereas other infants deemed high risk are discussed throughout this textbook. Preterm infants comprise the majority of high-risk infants. Approximately 15 million infants are born preterm (before 37 weeks' gestational age) each year worldwide, accounting for about 1 in every 10 babies born. The World Health Organization (WHO) defines infants born before 28 weeks' gestational age as *extremely preterm* infants, infants born between 28 and 31 6/7 weeks as *very preterm* (see Chapter 119.2), and infants born between 32 and 36 6/7 weeks as *moderate to late preterm* infants (see Chapter 119.3). Risk of both morbidity and mortality increases with earlier gestational age. Gestational age, birthweight, and gender are all important factors that impact neonatal mortality (Fig. 119.1). The **highest risk** of neonatal and infant mortality occurs in infants with birthweight <1,000 g and/or with gestational age <28 weeks. The **lowest risk** of neonatal mortality occurs in infants with birthweight of 3,000-4,000 g and a gestational age of 39-41 weeks. As birthweight increases

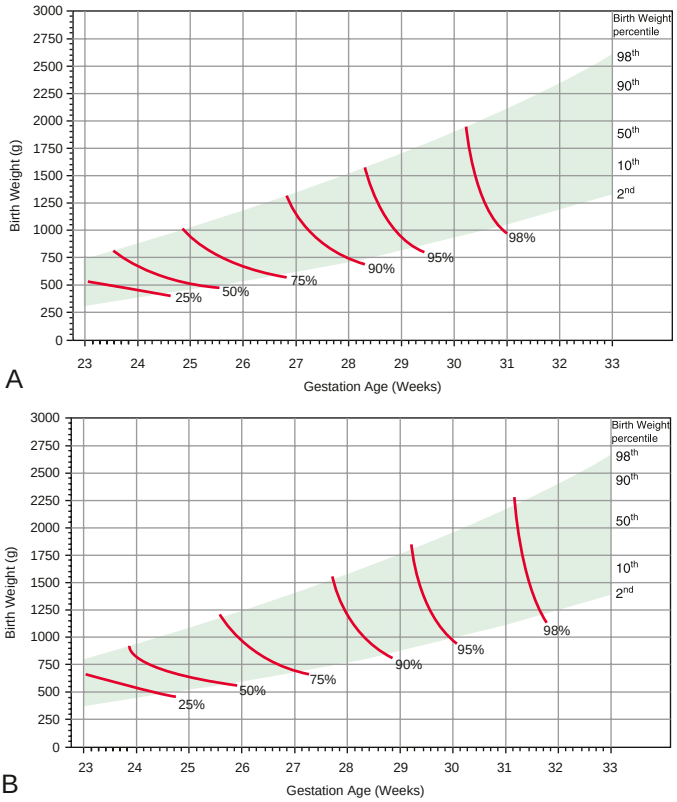

Fig. 119.1 Contour plot of predicted survival according to gestational age, birthweight, and gender. **A**, Female. **B**, Male. The contour lines join combinations of gestational age and birthweight of equal estimated probability of survival. Birthweight percentiles are shown for information. Data based on singleton infants born in the United Kingdom between January 2008 and December 2010 who survived to NICU admission. *(From Manktelow BN, Seaton SE, Fields DJ, et al. Population-based estimates of in-unit survival for very preterm infants. Pediatrics. 2013;131:e425e432. Fig. 2.)*

from 400 to 3,000 g and gestational age increases from 23 to 39 weeks, a logarithmic decrease in neonatal mortality occurs. Once birthweight exceeds 4,000 g and/or gestational age exceeds 42 weeks, the incidence of neonatal morbidities and mortality increases (see Chapter 119.4).

119.1 Multiple-Gestation Pregnancies

Lori A. Christ

CLASSIFICATION OF TWINS

Monozygotic vs Dizygotic Twins

Traditionally, twins have been classified as either **monozygotic** (originating from one ovum fertilized by one sperm in a single fertilization event that then results in postzygotic division of the conceptus into two embryos) or **dizygotic** (originating from two fertilization events each occurring when a single ovum is fertilized by a single sperm). Identifying twins as monozygotic or dizygotic is useful in determining the relative influence of heredity and environment on human development and disease. Detailed blood typing, gene analysis, or tissue (human leukocyte antigen) typing can be used for zygosity testing (an exception being blood typing in cases of **chimeric** twins, where one or both twins contain distinct cell lines from multiple zygotes). While often referred to as "identical" twins, physical and cognitive differences may still exist between monozygotic twins due to differences in the in utero environment, the mitochondrial genome, in posttranslational gene product modification, or in the epigenetic modification of nuclear genes in response to environmental factors.

Chorionicity and Amnionicity

Twins can also be classified by the number of chorions and amnions in the pregnancy. Dizygotic twins largely result in **dichorionic, diamniotic** pregnancies, although rarely may result in atypical twinning (see later). The chorionicity and amnionicity of monozygotic twins depends on the timing of fission of the zygote. One-third of monozygotic twins are dichorionic and diamniotic, and result from splitting on embryonic day 1-3. **Monochorionic**, diamniotic twins result from splitting on embryonic day 3-8, and monochorionic, **monoamniotic** twins result from splitting on day 8-13. Determination of amnionicity and chorionicity are not reliable ways of determining zygosity. An apparently single placenta may be present with either monozygotic or dizygotic twins, but inspection of a dizygotic placenta usually reveals that each twin has a separate chorion that crosses the placenta between the attachments of the cords and two amnions. Separate or fused dichorionic placentas may be disproportionate in size, resulting in growth restriction or malformation of the fetus attached to the smaller placenta or the smaller portion of the placenta.

Incidence

Differences in the incidence of twins worldwide mainly involve dizygotic twins, as monozygotic twinning appears to be independent of heritable factors. In 2019 the U.S. final natality report recorded a twin rate of 32.1 per 1,000 live births, which has continued to decline after an all-time high in 2014. Increases in monozygotic and dizygotic twinning had been associated with advanced maternal age (AMA) and the use of assisted reproductive technologies (ARTs). The rate of triplets and higher-order multiple births was 87.7 per 100,000 live births in the United States and has continued to decline since 1998. The use of single-embryo transfer in ART has decreased the numbers of triplet births and higher-order multiples.

ETIOLOGY

Dizygotic twins result from polyovulation, or the release of more than one ovum at a single ovulation. Polyovular pregnancies are more frequent after the second pregnancy, with increasing maternal age, and in families with a history of dizygotic twins. They may result from simultaneous maturation of multiple ovarian follicles, but follicles containing two ova have also been described as a genetic trait leading to twin pregnancies. Twin-prone women have higher levels of gonadotropin. Polyovular pregnancies occur in many women treated for infertility with ovarian stimulants such as clomiphene or gonadotropins.

The etiology of monozygotic twinning is unknown, but there are two prevailing theories. In the classic **fission theory**, twinning results from the splitting of a single conceptus, with the timing of splitting resulting in differing amnionicity and chorionicity (i.e., the earlier the fission occurs, the more likely the twins are to be diamniotic dichorionic) (Fig. 119.2). However, this theory fails to account for several forms of atypical twinning, including the occurrence of **diamniotic dichorionic monozygotic** twinning after single-embryo transfer in the

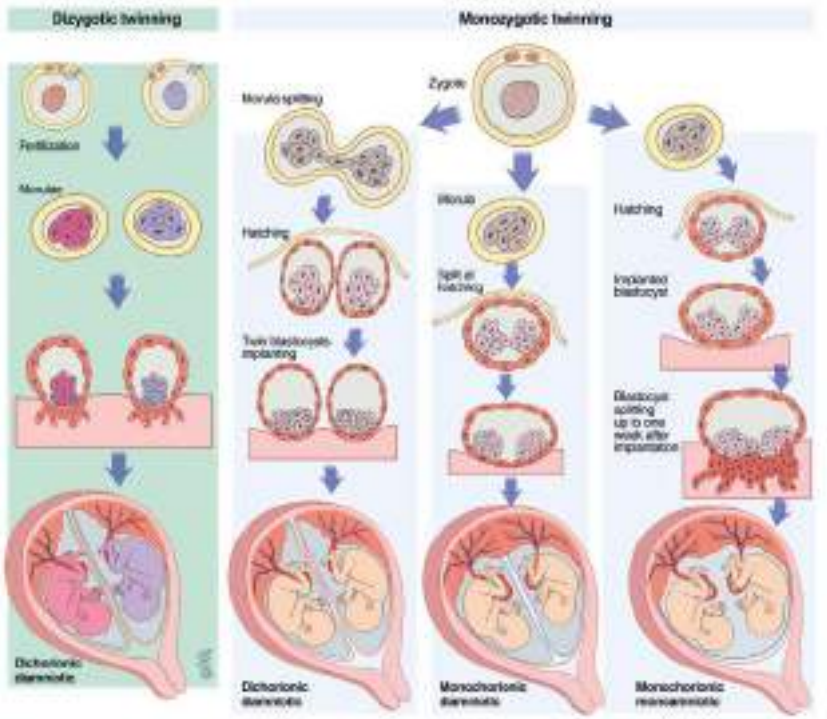

Fig. 119.2 Classical fission theory of twinning. Dizygotic twins result from two distinct fertilization events, with dichorionic diamniotic twins each developing to become a genetically distinct individual. Monozygotic twins result from postzygotic splitting of the product of a single fertilization event. Splitting on days 1-3 (up to the morula stage) results in dichorionic diamniotic twins, on days 3-8 (during which blastocyst hatching occurs) in monochorionic diamniotic twins, on days 8-13 in monochorionic monoamniotic twins. *(Illustration copyright LeventEfe, CMI. www.leventefe.com.au.)*

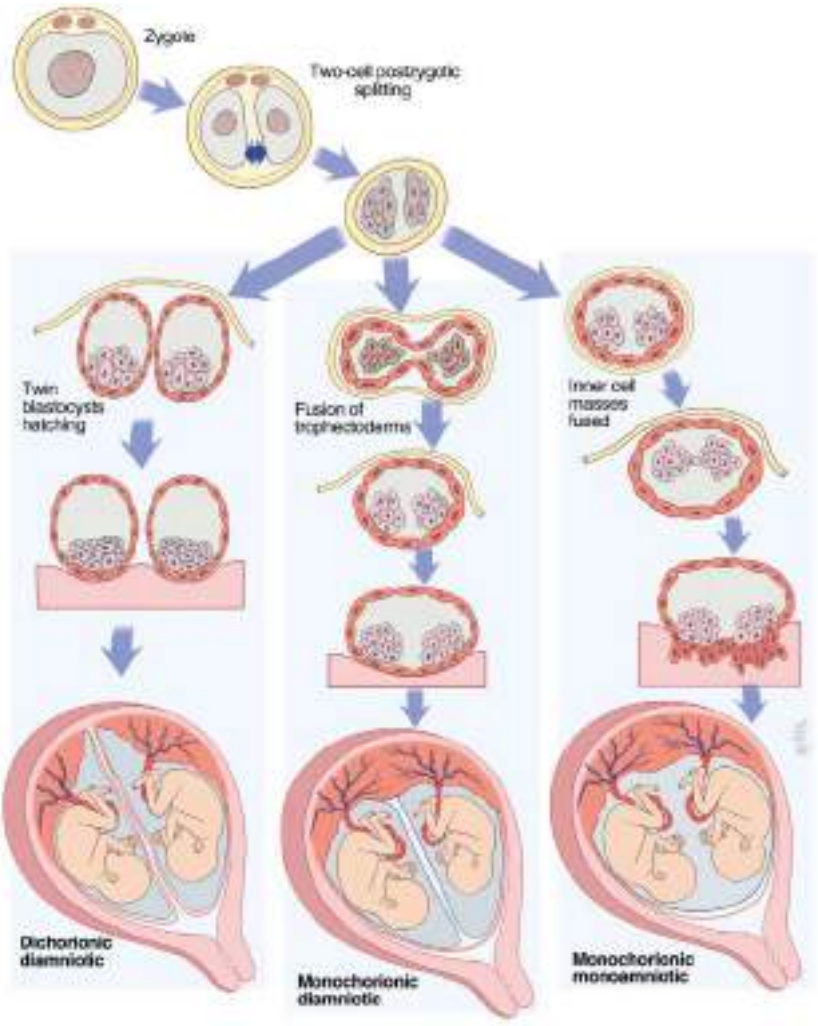

Fig. 119.3 Fusion theory of monozygotic twinning. Splitting occurs at the postzygotic two-cell stage, with each cell forming a distinct individual. If twin blastocysts hatch from the zona pellucida together, dichorionic diamniotic twins will result. If the two trophectoderms fuse before hatching and the inner cell masses are separated within the shared trophectoderm, monochorionic diamniotic twins will result. If the inner cell masses are fused and separated later, monochorionic monoamniotic twins will result. *(Illustration copyright LeventEfe, CMI. www.leventefe.com.au)*

late blastocyst state, phenotypically discordant monozygotic twins, and asymmetrically attached conjoined twins. An alternate **fusion theory** of twinning has been proposed to account for this discrepancy, in which the inner cell masses of trophectoderm fuse after the initial two-cell splitting stage (Fig. 119.3).

Atypical Twinning

Conjoined twins occur in 1 in 50,000 pregnancies and 1 in 250,000 live births. Theoretically, they result from later fission of a single zygote (10-14 days) or from fusion of two zygotes (as proposed for asymmetrically attached conjoined twins). Most conjoined twins are female. The prognosis for symmetrically conjoined twins depends on the possibility of surgical separation, which in turn depends on the extent to which vital organs are shared. The site of connections varies, as follows: thoracoomphalopagus (28% of conjoined twins), thoracopagus (18%), omphalopagus (10%), craniopagus (6%), and incomplete duplication (10%). The term *parasitic twin* has historically been used to describe the smaller and less completely developed member of a pair of conjoined twins; this twin has typically had embryonic demise but remains vascularized by the surviving *independent* twin (the **autocyte**). For asymmetrically attached conjoined twins in whom one twin is dependent on the cardiovascular system of the intact autocyte (**exoparasitic twins**, 1 in 1 million live births) survival of the autocyte depends on the feasibility of excising the *exoparasitic* twin. For **endoparasitic twins** (*fetus in fetu,* 1 in 500,000 live births) in whom one (or more) fetus exists as a benign mass in the autocyte, survival of the autocyte is unaffected. **Superfecundation,** or fertilization of an ovum by an insemination that takes place after one ovum has already been fertilized, and **superfetation**, or fertilization and subsequent development of an embryo when a fetus is already present in the uterus, have been proposed as explanations for differences in size and appearance of certain twins at birth.

Diagnosis

A prenatal diagnosis of pregnancy with twins is suggested by a uterine size that is greater than that expected for gestational age, auscultation of two fetal heartbeats, and/or elevated maternal serum α-fetoprotein (AFP) or human chorionic gonadotropin (hCG) levels. It is confirmed by ultrasonography. Physical examination of twins is necessary but not sufficient to determine zygosity of twins. In the event that congenital anomalies are present or there are transfusion or transplantation considerations, genetic testing of zygosity should be performed. Although noninvasive prenatal testing (NIPT) is becoming more common, the results should be interpreted with caution in multiple-gestation pregnancies until normative values are better established.

Complications

Twin and higher-order pregnancies are associated with poorer neonatal and perinatal outcomes compared with singleton pregnancies of the same gestation. Severe maternal morbidities and death are also

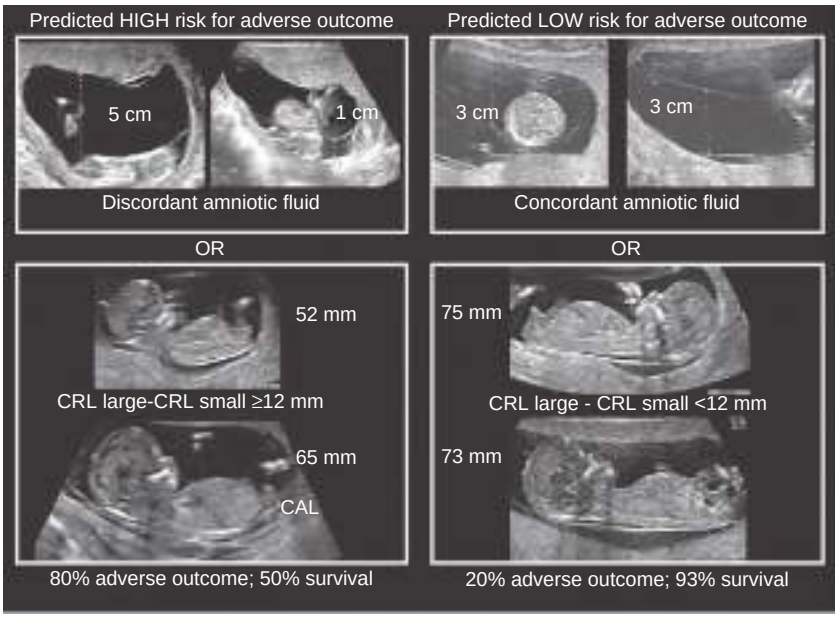

Fig. 119.4 Representation of first-trimester risk assessment for the development of discordant growth, twin-twin transfusion syndrome (TTTS), or intrauterine demise. Discordant amniotic fluid in the first trimester generally corresponded with deepest vertical pockets ≤3 cm in one sac and ≥6.5 cm in the other. Discordance in crown-rump length (CRL) was present if the difference was ≥12 mm. *(From Lewi L, Gucciardo L, Van Mieghem T, et al. Monochorionic diamniotic twin pregnancies: natural history and risk stratification. Fetal Diagn Ther. 2010;27:121–133.)*

twice as likely in twin pregnancies worldwide compared with singleton pregnancies.

Most twins are born prematurely, which contributes to additional neonatal and childhood morbidity and mortality. Spontaneous single intrauterine demise occurs at a rate of about 6% of all twin pregnancies. Twin-twin transfusion syndrome (TTTS) and early-onset discordant growth are associated with an overall worse prognosis (see Chapter 118). The perinatal mortality of twins is about four times that of singletons, with **monochorionic** twins being particularly at risk. **Monochorionic** twins have an increased risk of a demised twin in utero. The surviving twin has a greater risk for cerebral palsy and other neurodevelopmental sequelae. **Monoamniotic** twins have an increased likelihood of cord entanglement, which may lead to asphyxia. Twins are at greater risk for congenital malformations, with up to 25% of monozygotic twins being affected. Theoretically, the twin delivered second is at higher risk of anoxia than the first because the placenta may separate after birth of the first twin and before birth of the second. In addition, delivery of the second twin may be difficult because it may be in an abnormal presentation (breech, entangled), uterine tone may be decreased, or the cervix may begin to close after the first twin's birth.

Triplet or higher-order births are associated with an increased risk of death or neurodevelopmental impairment compared with extremely low birthweight (ELBW) singleton and twin infants after controlling for gestational age. The mortality for multiple gestations with ≥4 fetuses is excessively high for each fetus. Because of this poor prognosis, selective fetal reduction has been offered as a treatment option.

Twin-Twin Transfusion Syndromes

Placental vascular anastomoses occur with high frequency in **monochorionic** twins (see Chapter 118). In monochorionic placentas, the fetal vasculature is usually joined, sometimes in a very complex manner. They are usually balanced and neither twin is appreciably affected. Artery-to-artery communications cross over placental veins, and when anastomoses are present, blood can readily be stroked from one fetal vascular bed to the other. Vein-to-vein communications are similarly recognized but are less common. A combination of artery-to-artery and vein-to-vein anastomoses is associated with the condition of **acardiac fetus**. This rare lethal anomaly (1 in 35,000) is secondary to the **twin reversed arterial perfusion (TRAP) syndrome**. In utero radiofrequency or laser ablation of the anastomosis or cord occlusion can be used to treat heart failure in the surviving twin. However, death of the autocyte is reported in up to 75% of cases. In rare cases, one umbilical cord may arise from the other after leaving the placenta, and the twin attached to the secondary cord usually is malformed or dies in utero.

Table 119.2 Characteristic Changes in Monochorionic Twins with Uncompensated Placental Arteriovenous Shunts

TWIN ON:	
ARTERIAL SIDE—DONOR	**VENOUS SIDE—RECIPIENT**
Prematurity	Prematurity
Oligohydramnios	Polyhydramnios
Intrauterine growth restriction	Hydrops
Pale	Plethoric
Anemic	Polycythemic
Hypovolemic	Hypervolemic
Hypoglycemic	Cardiac hypertrophy
Microcardia	Myocardial dysfunction
Glomeruli small or normal	Glomeruli large Tricuspid valve regurgitation Right ventricular outflow obstruction
Arterioles thin walled	Arterioles thick walled

In **twin-twin transfusion syndrome (TTTS)**, an artery from one twin acutely or chronically delivers blood that is drained into the vein of the other. The latter develops polyhydramnios and polycythemia, and the former has oligohydramnios, anemia, and growth restriction (Fig. 119.4). TTTS is more common in monozygotic twins and affects up to 30% of monochorionic twins. Death of the donor twin in utero may result in generalized fibrin thrombi in the smaller arterioles of the recipient twin, possibly as the result of transfusion of thromboplastin-rich blood from the macerating donor fetus. Disseminated intravascular coagulation (DIC) may develop in the surviving twin. Table 119.2 lists the more frequent changes associated with a large shunt. Preterm birth and/or death of the surviving twin is also highly likely. **Treatment** of this highly lethal problem includes aggressive amnioreduction for polyhydramnios, selective twin termination, and most often, laser or fetoscopic ablation of anastomosis (Fig. 119.5).

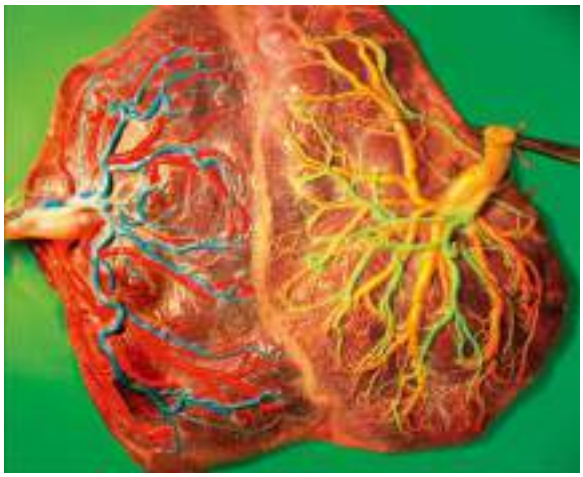

Fig. 119.5 Color-dye-stained twin-to-twin transfusion syndrome placenta that was treated using the Solomon technique. Blue and green dye are used to stain the arteries, and pink and yellow dye are used to stain the veins. After identification and coagulation of each individual anastomosis, the complete vascular equator is coagulated from one placental margin to the other. *(From Slaghekke F, Lopriore E, Lewi L, et al. Fetoscopic laser coagulation of the vascular equator versus selective coagulation for twin-to-twin transfusion syndrome: an open-label randomized controlled trial, Lancet. 2014;383:2144–2150. Fig. 3.)*

Fig. 119.6 Total and singleton low birthweight rates: United States, 2019 and 2020. *Numbers do not add to total du to rounding. *(From Osterman M, Hamilton B, Martin JA, Driscoll AK, Valenzuela CP. Births: Final Data for 2020. Natl Vital Stat Rep. 2021;70[17]:1–50. Fig. 3.)*

Management

Prenatal detection of a multiple gestation pregnancy enables the obstetrician and pediatrician to anticipate complications. The risk of multiple-gestation pregnancies due to ART may be reduced by elective single-embryo transfers. Asymptomatic early cervical dilation may be managed with cerclage, which is 50% effective in preventing delivery before 28 weeks' gestation. Elective delivery of twins at 37 weeks (or earlier for **monochorionic**, **monoamniotic** twins) reduces the complication rate for the fetuses and the birth parent. Furthermore, in twin pregnancies between 32 and 39 weeks' gestation, planned vaginal delivery is preferred if the first twin is in the cephalic presentation. Close observation and attendance by a pediatric team are indicated in the immediate neonatal period so that prompt treatment of asphyxia or fetal transfusion syndrome can be initiated. The decision to perform an immediate blood transfusion in a severely anemic "donor" twin or a partial exchange transfusion of either twin due to anemia in the "donor" or polycythemia in the "recipient" twin must be based on clinical judgment.

119.2 Extremely and Very Preterm Infants

Lori A. Christ and Erik Brandsma

Traditionally, the delivery date is determined 280 days after the last menstrual period (LMP). However, only 4% of pregnant women deliver at 280 days, and only 70% deliver within 10 days of the estimated delivery date.

Infants born before 37 weeks from the first day of the LMP are termed *premature* by WHO. Infants born before 28 weeks' gestation are **extremely preterm,** also referred to as **extremely low gestational age newborns (ELGANs)**; whereas infants born between 28 and 31 weeks and 6 days' gestation are **very preterm**. Moderate and late preterm infants (born between 32 and 36 week 6 days' gestation) are discussed in Chapter 119.3.

In addition to classification by gestational age, classification is also based on birthweight. **ELBW** is used to describe infants with a birthweight <1,000 g, **very low birthweight (VLBW)** describes infants 1,000-1,500 g, and **low birthweight (LBW)** describes infants <2,500 g at birth. Birthweight, in general, is a proxy for gestational age, but in the cases of intrauterine growth restriction (IUGR) and small-for-gestational-age (SGA) infants, birthweight can sometimes be misleading for true gestational age and is an additional risk factor for comorbidities of prematurity (see Chapter 119.4).

INCIDENCE

Preterm birth, or birth before 37 weeks of gestation, occurs at a rate of approximately 11% worldwide, adding up to a total of 15 million preterm births annually. Significant variations in preterm birthrates exist between countries, with an approximate rate of 10% in the United States. The U.S. preterm birthrate declined 1% in 2020 to 10.09%. Most of this decline is due to a decrease in rate of late preterm births (7.40% of all births in 2020) and in preterm births less than 34 weeks' gestation (2.70%). These results are reflected in birthweight-specific categories (Fig. 119.6). Disparities in preterm birthrates continue to exist, ranging from a high of 14.39% of babies born to non-Hispanic black mothers to a low of 8.72% of babies born to non-Hispanic Asian mothers.

ETIOLOGY

The etiology of preterm birth is multifactorial and involves complex interactions between fetal, placental, uterine, and maternal factors. In the setting of maternal or fetal conditions that prompt early delivery, as well as placental and uterine pathology, causes of preterm birth can sometimes be identified (Table 119.3). Most preterm births are *spontaneous* without an identifiable cause. AMA, maternal health conditions, history of previous preterm delivery, short interpregnancy interval, and lower socioeconomic status (SES) have all been associated with preterm birth. Racial disparities also exist and can only be partially predicted when factoring in education and income level. Large population studies have found associations between maternal genetics and epigenetics and preterm birth. Gestational duration and actual preterm birth have been noted with genetic variants in the maternal genome. Many of these genes have roles in regulation of the estrogen receptor, uterine development, maternal nutrition, or vascular reactivity.

ASSESSMENT OF GESTATIONAL AGE

Ultrasound measurement of fetal crown-rump length at 11-14 weeks' gestation remains the most accurate method of gestational age estimation. Estimates based on ultrasound at later gestation are less accurate, but may be improved with newer methods and likely superior to postnatal assessment. With insufficient prenatal care or discrepancies between birthweight and predicted gestational age at birth, it remains helpful to be able to assess infants for an estimated gestational age. With a careful physical exam, one may be able to distinguish SGA and IUGR infants

Table 119.3 Identifiable Risk Factors for Preterm Birth

FETAL

New Ballard score, expanded to include extremely premature infants. J Pediatr. 1991;119:417–423.)*

from preterm infants. Compared with a premature infant of appropriate weight, an infant with IUGR has a reduced birthweight and may appear to have a disproportionately larger head relative to body size; infants in both groups lack subcutaneous fat. Neurologic maturity (nerve conduction velocity) in the absence of asphyxia correlates with gestational age despite reduced fetal weight. Physical signs may be useful in estimating gestational age at birth. The commonly used **Ballard scoring system** is accurate to within 2 weeks of actual gestational age (Figs. 119.7-119.9).

NURSERY CARE

At birth, the general measures needed to clear the airway, initiate breathing, care for the umbilical cord and eyes, and administer vitamin K are the same for premature infants as for those of normal weight and maturity (see Chapter 123). Additional considerations are the need for (1) thermal control and monitoring of the heart rate and respiration, (2) advanced respiratory support, and (3) special attention to the details of fluid requirements and nutrition that may in turn lead to considerations of IV access. Preterm infants are at an increased risk of early and late-onset neonatal sepsis compared with their term counterparts. Routine procedures that disturb these infants may result in hypoxia and stress. The benefits of regular and active participation by the parents in the infant's care in the nursery and the question of prognosis for later growth and development require special consideration.

Thermal Control

Avoidance of hypothermia and hyperthermia decreases the risk of morbidity and mortality in ELBW and VLBW infants. Neonates in general, and ELBW and VLBW infants to an even greater extent, are at increased risk of heat loss compared with older children due to an

increased body surface/weight ratio, decreased epidermal and dermal skin thickness, minimal subcutaneous fat, and an immature nervous system.

Preterm infants should be kept in a **neutral thermal environment**. This environment comprises a set of thermal conditions, including air and radiating surface temperatures, relative humidity, and airflow, at which heat production (measured experimentally as oxygen consumption) is minimal and the infant's core temperature is within the normal range. The neutral thermal environment is a function of the size and postnatal age of an infant; larger, older infants require lower environmental temperatures than smaller, younger infants. Incubators or radiant warmers can be used to maintain body temperature. Body heat is conserved through provision of a warm environment and humidity, while minimizing heat loss through conduction, convection, radiation, and evaporation. The optimal environmental temperature for minimal heat loss and oxygen consumption for an unclothed infant is one that maintains the infant's core temperature at 36.5–37.0°C (97.7–98.6°F). The smaller and less mature the infant, the higher is the environmental temperature required. Infant warmth can be maintained by heating the air to a desired temperature or by servo-control. Continuous monitoring of the infant's temperature is required to maintain optimal body temperature. **Kangaroo care,** especially in LBW infants, with direct skin-to-skin contact between infant and parent, with a hat and blanket covering the infant, is to be encouraged (and not delayed), without untoward effects on thermoregulation.

Maintaining increased relative humidity for preterm infants in the first weeks of life aids in stabilizing body temperature by reducing heat loss at lower environmental temperatures. The ideal humidity and duration of increased humidity at a specific gestational age is not known, but typically is maintained between 60% and 80% for a week. Humidification of inspired air for infants requiring respiratory support prevents drying and irritation of the lining of respiratory passages and aids in thinning viscid secretions and reducing insensible water loss. Humidification should be gradually weaned after the first week of life to promote skin barrier formation and to reduce the risk of microbial growth associated with prolonged excessive humidity. The infant should also be weaned and then removed from the incubator or radiant warmer when the gradual change to the atmosphere of the nursery does not result in a significant change in the infant's temperature, color, activity, vital signs, or rate of weight gain.

Oxygen Administration

Administering oxygen to reduce the risk of injury from hypoxia and circulatory insufficiency (risk of cerebral palsy, death) must be balanced against the risk of hyperoxia to the eyes **(retinopathy of prematurity [ROP])** and injury to the lungs due to generation of free radicals. For ELBW infants at birth, guidelines should be followed to determine need for supplemental oxygen during resuscitation to maintain goal O_2 saturation limits (see Chapter 123).

After the initial resuscitation period, ideal target O_2 saturation limits for ELBW infants should be within the range of 90–95% for most infants.

Nutrition for the High-Risk Infant

In the absence of early parenteral and enteral nutritional support, deficits in protein, energy, and micronutrients will quickly accrue, placing the infant at risk for poor growth and neurodevelopmental outcomes. The goals of early nutritional support for extremely premature infants include approximating the rate and composition of growth for a normal fetus at the same postmenstrual age. Achieving this goal requires an understanding of the intrauterine growth rate to be targeted as well as the unique nutrient requirements of premature infants. Strategies to prevent growth failure include a combined approach of early parenteral and enteral nutrition, fortification of human milk, and the use of standardized feeding guidelines. Careful monitoring of weight gain, length, and head circumference using appropriate growth curves and timely biochemical assessment of bone health and potential nutritional deficiencies is paramount. Consultation with an experienced neonatal dietitian is important to achieve optimal outcomes.

Early Parenteral Nutrition

In the absence of IV amino acids, extremely premature infants lose 1–2% of body protein stores per day. IV amino acids and dextrose should be started immediately after birth. Many units use a *starter* or *stock* solution of amino acids and dextrose to accomplish this goal in infants weighing <1,500 g. Ideally at least 2 g/kg of amino acids should be given in the first 24 hours after birth, with a goal of at least 3 g/kg within 24-48 hours after birth. To meet total energy requirements, up to 3 g/kg of IV lipids will also be needed.

Benefits of Human Milk

Maternal milk is the preferred source of enteral nutrition for premature infants and is associated with decreased in-hospital morbidity, including lower rates of necrotizing enterocolitis (NEC), late-onset sepsis, bronchopulmonary dysplasia (BPD), and severe ROP. Maternal milk feeding is also associated with superior neurodevelopmental outcomes at 18- and 30-months corrected age compared to infants fed premature formula. Donor human milk is increasingly being used when maternal milk is not available, but it is typically lower in protein and energy content than preterm maternal milk and may result in suboptimal growth unless adequately fortified. Although donor human milk has been associated with a reduction in NEC, the impact of donor human milk on neurodevelopmental outcomes remains unclear.

Enteral Nutrition

Early enteral feedings are recommended in ELBW and VLBW infants, typically beginning between 6 and 48 hours of life with some period of trophic/minimal enteral feeding volume. Feedings are typically advanced slowly (15-30 mL/kg/day) with a target goal of delivering approximately 110-135 kcal/kg/day and 3.5-4.5 g protein/kg/day. To accomplish these goals, human milk must be fortified, or a premature formula can be given. Additional supplements such as vitamins, iron, or other micronutrients may be required and should be based on ongoing assessment and in consultation with a neonatal dietitian.

Standardized Feeding Guidelines

Standardized feeding guidelines should be developed incorporating evidence-based strategies for the provision of parenteral and enteral nutrition in ELBW and VLBW infants, including a plan to manage feeding intolerance. Regardless of the specific protocol, having a feeding guideline leads to improved outcomes (e.g., time to regain birthweight, time to reach full enteral nutrition), decreased rates of late-onset sepsis and NEC, improved growth at 36 weeks' postmenstrual age, and reduced length of hospital stay.

Transitioning to Discharge Nutrition

The earlier an infant is born before expected, the greater the likelihood that not all nutritional deficits will be resolved before hospital discharge. Regardless of weight gain during the initial hospital stay, there is strong evidence for improved bone mineralization with the use of higher concentrations of calcium and phosphorus after discharge. Fortified human milk or preterm formula with higher concentrations of protein, minerals, and trace elements is often recommended after discharge. An individualized approach to postdischarge nutrition should be developed to transition from the NICU and communicated with the outpatient pediatrician who will be caring for the infant.

Prevention of Infection

Extremely preterm infants have an increased susceptibility to infection; thus meticulous attention to infection control is required. Prevention strategies include strict compliance with handwashing and universal precautions, minimizing the risk of catheter contamination and duration, meticulous skin care, encouraging early appropriate advancement of enteral feeding, education and feedback to staff, and surveillance of nosocomial infection rates in the nursery. Although no one with an active infection should be permitted in the nursery, the risks of infection must be balanced against the disadvantages of limiting the infant's contact with the family. Early and frequent participation by parents in the nursery care of their infant does not increase the risk of infection when preventive precautions are maintained.

Preventing transmission of infection from infant to infant is difficult because often neither term nor premature newborn infants have clear clinical evidence of an infection early in their course. When epidemics occur within a nursery, cohort nursing and isolation rooms should be used. **Hand hygiene** is of upmost importance. Because premature infants have immature immune functions, some will develop nosocomial infection even when all precautions are followed.

Awareness of overutilization of antibiotics may mitigate associated complications both at the population level (cost and antibiotics resistance) and for the individual patient (alteration of the microbiome).

Routine **immunizations** should be given on the regular schedule based on chronological age at standard doses.

Transfusion Medicine

Premature infants are at increased risk of anemia due to impaired erythropoiesis and iatrogenesis due to frequent laboratory sampling. Most infants with a birthweight less than 1,000 g admitted to the NICU receive at least one blood transfusion during their stay. The need for repeated transfusion can be minimized by a thoughtful approach to laboratory sampling and establishing set hemoglobin thresholds for transfusions. A multicenter randomized controlled trial in infants 22 weeks 0 days to 28 weeks 6 days found that a lower transfusion threshold resulted in fewer transfusions per infant without an impact on neurodevelopment at 22 to 26 months' corrected gestational age. The need for transfusions depends in part on the cardiopulmonary stability of the patient, postnatal age, birthweight, and the etiology of the anemia. For severe cardiopulmonary disease, transfusions are recommended to maintain the hematocrit between 40% and 45%. For asymptomatic stable neonates with anemia of prematurity, maintaining the hematocrit at ~25% is acceptable.

Transfusion of platelets is another common practice in the NICU. Premature infants are at high risk for intraventricular hemorrhage in the first week of life, which historically prompted platelet transfusion at thresholds now considered safe. Additionally, preterm infants may also develop thrombocytopenia in the setting of severe bleeding or infection. A multicenter randomized controlled trial found that infants randomized to a higher platelet transfusion threshold ($50{,}000/m^3$) paradoxically had a higher rate of death or severe bleeding that infants randomized to a lower threshold ($25{,}000/m^3$).

IMMATURITY OF DRUG METABOLISM

Great care must be taken when prescribing and dosing medications for premature infants (Table 119.4). Renal clearance of almost all substances excreted in the urine is diminished in newborn infants, and to even a greater extent in premature infants. The glomerular filtration rate rises with increasing gestational age; therefore drug dosing recommendations vary with age. For drugs primarily excreted by the kidneys, longer intervals between dosages are often needed with increasing degree of prematurity. Drugs that are detoxified in the liver or require chemical conjugation before renal excretion should also be given with caution and in doses smaller than usual.

Many drugs apparently safe for adults on the basis of toxicity studies may be harmful to newborns, especially premature infants. Oxygen and a number of drugs have proved toxic to premature infants in amounts not harmful to term infants. Thus, administering any drug, particularly in high doses, that has not undergone pharmacologic testing in premature infants should be undertaken carefully after risks have been weighed against benefits.

Table 119.4 Potential Adverse Reactions to Drugs Administered to Premature Infants

DRUG	REACTION(S)
Oxygen	Retinopathy of prematurity, bronchopulmonary dysplasia
Sulfisoxazole	Kernicterus
Chloramphenicol	Gray baby syndrome—shock, bone marrow suppression
Novobiocin	Jaundice
Hexachlorophene	Encephalopathy
Benzyl alcohol	Acidosis, collapse, intraventricular bleeding
Intravenous vitamin E	Ascites, shock
Phenolic detergents	Jaundice
$NaHCO_3$	Intraventricular hemorrhage
Amphotericin	Anuric renal failure, hypokalemia, hypomagnesemia
Indomethacin	Oliguria, hyponatremia, intestinal perforation
Cisapride	Prolonged QTc interval
Tetracycline	Enamel hypoplasia
Tolazoline	Hypotension, gastrointestinal bleeding
Calcium salts	Subcutaneous necrosis
Aminoglycosides	Deafness, renal toxicity
Prostaglandins	Seizures, diarrhea, apnea, hyperostosis, pyloric stenosis
Phenobarbital	Altered state, drowsiness
Morphine	Hypotension, urine retention, withdrawal
Pancuronium	Edema, hypovolemia, hypotension, tachycardia
Iodine antiseptics	Hypothyroidism, goiter
Fentanyl	Seizures, chest wall rigidity, withdrawal
Dexamethasone	Gastrointestinal bleeding, hypertension, infection, hyperglycemia, cardiomyopathy, reduced growth
Furosemide	Deafness, hyponatremia, hypokalemia, hypochloremia, nephrocalcinosis, biliary stones
Heparin (*not* low-dose prophylactic use)	Bleeding, intraventricular hemorrhage, thrombocytopenia
Erythromycin	Pyloric stenosis

MORBIDITY AND MORTALITY

Rates of neonatal morbidity and mortality are high in extremely preterm infants, and risks increase with decreasing gestational age and lower birthweight (Table 119.5). Data on extremely preterm infants born between 2003 and 2007 found that 42% of VLBW infants developed BPD, 12% developed ROP requiring treatment, 11% NEC, 36% late-onset sepsis, 16% grade III or IV intraventricular hemorrhage, and 3% periventricular leukomalacia (PVL). Mortality increased with lower gestational age, with a 94% mortality in infants born at 22 weeks and 8% mortality at 28 weeks. The group of extremely preterm infants had a 28% mortality rate, with 37% surviving without a significant neonatal morbidity.

Another study found that morbidity and mortality among VLBW infants decreased between 2000 and 2009. This study was limited to liveborn infants with birthweights of 500-1,500 g. For infants born in 2009, this study found a 12.4% mortality rate; 28% of infants developed BPD, 7% severe ROP, 5% NEC, 15% late-onset sepsis, 6% grade III or IV IVH, and 3% PVL; 51% survived without significant neonatal morbidity.

Outcomes are improving with time; survival among infants born at 22-24 weeks' gestation is ~50–80% in units providing active management. The percentage surviving without neurodevelopmental impairment has also increased. Factors that reduce morbidity and mortality in extremely preterm infants include higher birthweight and gestational age, receipt of antenatal corticosteroids, female sex, singleton pregnancy, and active

resuscitation planned at delivery. With improvement in neonatal care, a growing number of centers offer a trial of resuscitation starting at 22 0/7 weeks if that is consistent with parental goals. Outcome prediction tools such as those based on data from the United States (NICHD-VON) or UK (BAPM) and the latter organization's framework to guide management are resources for the clinician that can be used for parental counseling. The prediction tools underscore that extreme prematurity is still associated with significant risk of both mortality and major neonatal morbidities. For infants who survive to discharge, prematurity, as well as neonatal morbidities, put them at increased risk for developmental delays and impairment as they age (see Chapter 119.5). Perinatal centers should develop consensus guidelines regarding an approach to periviable birth to ensure a consistent approach to both maternal and neonatal care. Balanced and unbiased antenatal counseling that includes shared decision-making between neonatologists, obstetricians, and families is imperative.

119.3 Moderate and Late Preterm Infants

Erik Brandsma

Whereas the American Academy of Pediatrics (AAP), the American College of Obstetricians and Gynecologists (ACOG), and the WHO have precise definitions for preterm, term, and postterm births, there has been some debate on defining subcategories of preterm infants. Because outcomes vary widely within broad gestational age range groups, consensus on definitions of subcategories is important. Based on a now widely adopted recommendation from a 2005 National Institutes of Health (NIH) sponsored workshop, infants born at 34 0/7 through 36 6/7 weeks' gestation are considered late preterm. The WHO defines **moderate to late preterm** birth as infants born at 32 0/7 through 36 6/7 weeks' gestation. Therefore most define **moderate preterm** infants as those born at 32 0/7 through 33 6/7 weeks' gestation.

The initial effect of the NIH-sponsored workshop and the resulting 2007 AAP Clinical Report from the Committee on Fetus and Newborn on late preterm infants was encouraging. The report continues to be a resource for pediatricians caring for late preterm infants, listing recommended minimum criteria for their discharge. A 2019 update from the Committee on Fetus and Newborn addresses the concern of the increasing incidence of late preterm birth since 2015.

The risk of morbidity in the individual infant born moderate or late preterm is lower than infants born before 32 weeks of gestation. Because late and moderate preterm births account for approximately 75% and 11.5% of preterm births in the United States, respectively, morbidities in this group continue to be a significant burden on the healthcare system. Etiology of preterm birth is discussed elsewhere (see Chapter 117.2). The majority of moderate and late preterm births are associated with spontaneous preterm labor, preterm premature rupture of membranes (PPROM), and multiple gestation.

MODERATE PRETERM INFANT

Moderate preterm infants are at increased risk for postnatal morbidities, although to a lesser extent and severity than very preterm infants. The most common morbidities associated with preterm birth at this gestational age are temperature instability, respiratory distress, apnea, sepsis, hypoglycemia, feeding difficulties, and hyperbilirubinemia. Moderate preterm infants with birthweight >1,500 g and an unremarkable NICU course are thought to be at minimal risk for IVH and do not routinely need a head ultrasound. Similarly, the AAP does not recommend universal screening for ROP at this gestational age, unless birthweight is below 1,500 g or in select cases for infants with a history of significant cardiopulmonary compromise. Little research has examined moderate preterm infants as an isolated group; more often these infants are grouped with very preterm infants when assessing complications and outcomes. A cohort of approximately 7,000 infants born between 29 and 33 weeks' gestational age were found in a recent study to have a mean hospital stay of 33.3 days. Moderate and late preterm infants are at increased risk of mortality as well. The increased risk of mortality is modest, approximately 10-fold for moderate preterm infants and fourfold for late preterm infants compared to term infants (22 and 8.2 per 1,000 live births, respectively), but because these infants comprise close to 90% of preterm infants overall, this group as a whole contributes significantly to infant mortality.

LATE PRETERM INFANT

As described previously, the overall rate of prematurity has increased gradually since 2015. Most of the increase in overall preterm birthrate can be contributed to infants born late preterm. These infants account for approximately 7.5% of all births and almost three fourths of all preterm births in the United States. Historically, late preterm infants were referred to as *near-term infants,* and the approach to their care was similar to that of term infants. It has been increasingly recognized that late preterm infants have significantly increased morbidity, as well as mortality, compared with their term counterparts. Overall, compared to their term counterparts, late preterm infants have approximately a sevenfold risk of morbidities and fourfold risk of mortality. There is an increased incidence of congenital anomalies in preterm infants, but even when these infants are excluded, late preterm infants continue to have significantly more morbidities. Immediately after birth, there is an increased risk of requiring resuscitation, as well as increased incidence of hypoglycemia, respiratory distress due to respiratory distress syndrome (RDS) or transient tachypnea of the newborn (TTN) apnea, and

difficulty with thermoregulation. Their average birth hospital length of stay is approximately 9 days compared to 2 days for term infants. Additional concerns during this initial hospital stay include feeding difficulties and jaundice. They have a higher rehospitalization rate compared to their term peers and an increased risk of long-term morbidities and even mortality (e.g., sudden infant death syndrome [SIDS]). Some studies suggest a higher risk of lower school readiness at kindergarten and increased risk of academic difficulties in childhood when comparing late preterm infants with term peers.

In addition to universal routine newborn care, the potential morbidities associated with preterm birth need to be addressed. This starts before birth with possible interventions to prevent preterm birth or a course of betamethasone for the pregnant women at risk for preterm birth within 7 days as recommended by ACOG and continues in the delivery room, where measures should be in place to prevent and treat common preterm birth associated morbidities such as hypothermia and hypoglycemia. Whether infants are taken care of in a NICU or in a well-baby nursery, continued vigilance is required to address the potential consequences of physiologic immaturity, such as poor feeding, dehydration, and hyperbilirubinemia. Follow-up visits should occur early and additional visits may be required to ensure the infant thrives. Because of ongoing health risks that the preterm infant faces in infancy and childhood, awareness and documentation of the child's birth history is important. It is paramount that all interventions are implemented equitably, with particular attention to non-Hispanic black and Hispanic women and children, who are currently disproportionally affected by preterm birth and account for the largest increase in late preterm birth.

119.4 Term and Postterm Infants

Andrea F. Duncan

The ACOG further divides term infants into subgroups: **early term** (37-38 6/7 weeks), **full term** (39-40 6/7 weeks), and **late term** (41-41 6/7 weeks). Many risk factors for term infants put them at higher risk for complications, such as meconium aspiration syndrome (see Chapter 129.1), hemolytic disease of the newborn (see Chapter 140), infant of a diabetic mother (see Chapter 147), and neonatal abstinence syndrome (see Chapter 145). Both SGA and large-for-gestational-age (LGA) are associated with increased morbidities.

SMALL FOR GESTATIONAL AGE AND IUGR

There is an important distinction between the terms **small for gestational age (SGA)** and **intrauterine growth restriction (IUGR)**. SGA is based on physical evaluation of an infant at birth, usually by a pediatrician or neonatologist. If the infant's weight is <10th percentile, the infant is SGA. The diagnosis of SGA does not differentiate between normal biologic growth potential and a pathologic or growth-restricted state in utero. In contrast, IUGR is a prenatal diagnosis to describe a fetus who fails to reach in utero growth potential, often diagnosed by the obstetrician using intrauterine growth curves and measures of compromise (e.g., abnormal Doppler flow measurements) (Fig. 119.10). This measure is independent of growth centile at birth. Therefore not all infants with IUGR are SGA, and, similarly, not all infants who are SGA have IUGR.

Although it is important to understand the difference between SGA and IUGR, many studies evaluate postnatal outcomes based on a diagnosis of either SGA or IUGR.

Fig. 119.10 This is a 36-week male neonate with a birthweight of 1,600 g who was born to a mother with severe preeclampsia. This baby was noted to have asymmetric intrauterine growth restriction (IUGR). Note the loss of fat over the body, visible rib cage, excessive skin folds noted over the whole body, and relatively large head compared to the body. *(From Sharma D, Shastri S, Sharma P. Intrauterine growth restriction: antenatal and postnatal aspects. Clin Med Insights Pediatr. 2016;10:67–83.)*

Table 119.6 Factors Often Associated with Intrauterine Growth Restriction

FETAL
Chromosomal (trisomies, microdeletions, copy number variants) and monogenetic disorders
Chronic fetal infections (cytomegalic inclusion disease, congenital rubella, syphilis)
Congenital anomalies—syndrome complexes
Irradiation
Multiple gestation
Pancreatic hypoplasia
Insulin deficiency (production or action of insulin)
Insulin-like growth factor type I deficiency
PLACENTAL
Decreased placental weight, cellularity, or both
Decrease in surface area
Villous placentitis (bacterial, viral, parasitic)
Infarction
Tumor (chorioangioma, hydatidiform mole)
Placental separation
Placental mesenchymal dysplasia
Twin transfusion syndrome
MATERNAL/PATERNAL
Preeclampsia
Hypertension or renal disease, or both
Hypoxemia (high altitude, cyanotic cardiac or pulmonary disease)
Malnutrition (micronutrient or macronutrient deficiencies)
Chronic illness
Sickle cell anemia
Drugs (opiates, alcohol, cigarettes, cocaine, prescribed medications, antimetabolites)

Table 119.7 Characteristics of Symmetric vs Asymmetric IUGR

CHARACTERISTICS	SYMMETRIC IUGR	ASYMMETRIC IUGR
Typical period of insult and presentation	Earlier gestation (often second trimester)	Later gestation (often detected in the third trimester)
Percentage of all IUGR cases	20–30%	70–80%
Etiology	Genetic disorders Congenital infections	Placental insufficiency
Antenatal scan	Proportionately decreased head circumference (HC), abdominal circumference (AC), biparietal diameter, and femur length	Only abdominal circumference decreased
Cell number	Decreased	Normal
Cell size	Normal	Decreased
Postnatal anthropometry	All parameters (HC, length, and weight) reduced	Reduced weight, HC normal, length low to normal
Features of malnutrition	Less pronounced	More pronounced

IUGR, Intrauterine growth restriction.
Adapted from Sharma D, Shastri S, Sharma P. Intrauterine growth restriction: –part 2. *J Matern Fetal Neonatal Med.* 2016 Mar 15:1–12.

IUGR is indicative of compromise in utero and is associated with medical conditions that interfere with the circulation and efficiency of the placenta, with the development or growth of the fetus, or with the general health and nutrition of the mother (Table 119.6). Many factors are common to both prematurely born and LBW infants with IUGR. IUGR is associated with decreased insulin production or insulin-like growth factor (IGF) action at the receptor level. Infants with IGF-1 receptor defects, pancreatic hypoplasia, or transient neonatal diabetes have IUGR. Genetic mutations affecting the glucose-sensing mechanisms of the pancreatic islet cells result in decreased insulin release (loss of function of the glucose-sensing glucokinase gene) and give rise to IUGR.

IUGR may be a normal fetal response to nutritional or oxygen deprivation; therefore the issue is not the IUGR but rather the ongoing risk of fetal malnutrition or hypoxia. IUGR is often classified as *reduced growth* that is *symmetric* (head circumference, length, and weight equally affected) or *asymmetric* (with relative sparing of head growth) (Table 119.7). **Symmetric IUGR** often has an earlier onset in the first trimester of pregnancy and is associated with diseases that seriously affect fetal cell number, such as conditions with chromosomal, genetic, malformation, teratogenic, infectious, or severe maternal hypertensive etiologies. It is important to assess gestational age carefully in infants suspected to have symmetric IUGR because incorrect overestimation of gestational age may lead to the diagnosis of symmetric IUGR. It is also important to assess carefully for dysmorphic features in infants with symmetric IUGR. **Asymmetric IUGR** is often of late onset in the second half of pregnancy, demonstrates preservation of Doppler waveform velocity to the carotid vessels, and is associated with poor maternal nutrition or with late onset or exacerbation of maternal vascular disease (preeclampsia, chronic hypertension).

Table 119.8 lists common problems of infants with IUGR. In addition, in both preterm and term infants, IUGR is associated with increased risk of cardiovascular disease across the life span, and both SGA and IUGR are associated with an increased risk of neurodevelopmental impairment. To properly manage infants born IUGR and SGA, clinicians must prepare for the possible perinatal morbidities (e.g., hypoglycemia, hypothermia, pulmonary hypertension, feeding intolerance), perform any diagnostic testing needed to determine the etiology, and monitor closely for long-term deficits (e.g., growth, neurodevelopment, cardiovascular).

Table 119.8 Problems of Infants Small for Gestational Age or with Intrauterine Growth Restriction*

PROBLEM	PATHOGENESIS
Intrauterine fetal demise	Hypoxia, acidosis, infection, lethal anomaly
Perinatal asphyxia	↓ Uteroplacental perfusion during labor ± chronic fetal hypoxia-acidosis; meconium aspiration syndrome
Hypoglycemia	↓ Tissue glycogen stores, ↓ gluconeogenesis, hyperinsulinism, ↑ glucose needs of hypoxia, hypothermia, large brain
Polycythemia-hyperviscosity	Fetal hypoxia with ↑ erythropoietin production
Reduced oxygen consumption/hypothermia	Hypoxia, hypoglycemia, starvation effect, poor subcutaneous fat stores
Dysmorphology	Syndrome anomalads, chromosomal-genetic disorders, oligohydramnios-induced deformation, TORCH†

*Other problems include pulmonary hemorrhage and those common to the gestational age–related risks of prematurity if born at <37 wk.
†TORCH, Toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex infection.
↓, Decreased; ↑, increased.

LARGE-FOR-GESTATIONAL-AGE INFANTS

Infants with birthweight >90th percentile for gestational age are called **large for gestational age (LGA)**. Neonatal mortality rates decrease with increasing birthweight until approximately 4,000 g, after which they increase. These oversized infants are usually born at term, but

preterm infants with high weights for gestational age also have a significantly higher mortality than infants of the same size born at term; maternal diabetes and obesity are predisposing factors. Some infants are constitutionally large because of large parental size. LGA infants, regardless of their gestational age, have a higher incidence of shoulder dystocia and birth injuries, such as cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face. LGA infants are also at increased risk for hypoglycemia and polycythemia.

The incidence of congenital anomalies, particularly congenital heart disease, is also higher in LGA infants than in term infants of normal weight.

POSTTERM INFANTS

Postterm infants are those born after 42 weeks (294 days) of gestation, as calculated from the mother's LMP. Historically, approximately 12% of pregnancies resulted in delivery after 42 weeks. However, with current evidence demonstrating significantly increased maternal, fetal and neonatal risks after 42 weeks' gestation, obstetric interventions to induce labor often occur before 42 weeks, resulting in a decreasing rate of postterm births. The cause of true postterm birth or postmaturity is unknown, though some have been attributed to genetic influences and defects in fetal production of parturition hormones. Postterm infants are often dysmature, with normal length and head circumference but may have decreased weight, indicating impaired nutritional supply from placental insufficiency. Infants born postterm in association with presumed placental insufficiency may have various physical signs. Desquamation, long nails, abundant hair, pale skin, alert faces, and loose skin, especially around the thighs and buttocks, give them the appearance of having recently lost weight; meconium-stained nails, skin, vernix, umbilical cord, and placental membranes may also be noted. Common complications of postmaturity include perinatal depression, meconium aspiration syndrome, persistent pulmonary hypertension, hypoglycemia, hypocalcemia, and polycythemia.

Perinatal mortality is 5.8% for infants born at ≥42 weeks' gestational age, compared to 0.7% for those born at term. Mortality may be due to placental insufficiency or umbilical cord compression resulting in hypoxemia and asphyxia. Mortality has been greatly reduced through improved obstetric management. Data suggest that elective delivery between the 39th and 41st week of gestation for both nulliparous and multiparous women is associated with decreased maternal and neonatal complications compared with those who were expectantly managed.

Careful obstetric monitoring, including nonstress testing (NST), biophysical profile (BPP), or Doppler velocimetry, usually provides a rational basis for choosing one of three courses: nonintervention, induction of labor, or cesarean delivery. Induction of labor or cesarean birth may be indicated in older primigravidas >2 weeks beyond term, particularly if evidence of fetal distress is present. Medical problems in the newborn are treated if they arise.

119.5 Follow-Up of High-Risk Infants After Discharge

Andrea F. Duncan

DISCHARGE FROM THE HOSPITAL

Numerous criteria need to be met before a high-risk infant is ready for discharge from the hospital (Table 119.9). Before discharge, infants should be taking most or all nutrition by nipple, either bottle or breast. Some medically fragile infants may require discharge while receiving gavage feedings or after placement of a gastrostomy tube, after the parents have received appropriate training and education. Growth should be occurring at steady increments, with a goal weight gain of approximately 30 g/day. Temperature should be stable and normal in an open crib. Infants should have had no recent episodes of apnea or bradycardia requiring intervention for at least 5-7 days before discharge. Stable infants recovering from BPD may be discharged on a regimen of home oxygen given by nasal cannula as long as careful follow-up is arranged with home pulse oximetry monitoring and outpatient visits. Some children may require discharge on higher ventilatory support in partnership with pulmonology. All infants with birthweight <1,500 g or gestational age <30 weeks at birth should undergo an eye examination to screen for ROP. If born preterm, hemoglobin or hematocrit should be determined to evaluate for possible anemia of prematurity. Every infant should have a hearing test before discharge. Routine vaccinations should be given based on chronological age before discharge. In addition, palivizumab (Synagis) should be given to eligible infants during respiratory syncytial virus (RSV) season immediately before discharge for prophylaxis against RSV, with continued monthly doses arranged as an outpatient as appropriate.

If all major medical problems have resolved and the home setting is adequate, premature infants may then be discharged when their weight approaches 1,800-2,000 g, they are >34-35 weeks postmenstrual age (PMA), and all the above criteria are met. Parental education, close follow-up, and healthcare provider accessibility are all essential for early discharge protocols. The primary caregivers for the infant should have a chance to provide infant care in the hospital with nursing supervision and support before discharge home. All high-risk infants should follow up with their primary care provider within a few days of discharge and should

Table 119.9 Readiness for Discharge of High-Risk Infants Criteria

Resolution of acute life-threatening illnesses
Ongoing follow-up for chronic but stable problems:
Bronchopulmonary dysplasia
Intraventricular hemorrhage
Necrotizing enterocolitis after surgery or recovery
Ventricular septal defect, other cardiac lesions
Anemia
Retinopathy of prematurity
Hearing problems
Apnea
Cholestasis
Stable temperature regulation
Gain of weight with enteral feedings:
Breastfeeding
Bottle feeding
Gastric tube feeding
Free of significant apnea
Appropriate immunizations and planning for respiratory syncytial virus prophylaxis if indicated
Hearing screenings
Ophthalmologic examination if <30 wk of gestation or <1,500 g at birth
Parental knowledge, skill, and confidence documented in:
Administration of medications (diuretics, methylxanthines, aerosols, etc.)
Use of oxygen, apnea monitors, oximeters
Nutritional support:
Timing
Volume
Mixing concentrated formulas
Recognition of illness and deterioration
Basic cardiopulmonary resuscitation
Infant safety
Scheduling of referrals:
Primary care provider
Neonatal follow-up clinic
Occupational therapy/physical therapy
Imaging (head ultrasound)
Assessment of and solution to social risks

Data from American Academy of Pediatrics, American College of Obstetricians: *Guidelines for Perinatal Care*. 7th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2013.

Table 119.10 Sequelae of Prematurity

IMMEDIATE	LATE
Hypoxia, ischemia	Intellectual disability, spastic diplegia, microcephaly, seizures, poor school performance
Intraventricular hemorrhage	Intellectual disability, spasticity, seizures, post hemorrhagic hydrocephalus
Sensorineural injury	Hearing and visual impairment, retinopathy of prematurity, strabismus, myopia
Respiratory failure	Bronchopulmonary dysplasia, pulmonary hypertension, bronchospasm, malnutrition, subglottic stenosis
Necrotizing enterocolitis	Short-bowel syndrome, malabsorption, malnutrition
Cholestatic liver disease	Cirrhosis, hepatic failure, malnutrition
Nutrient deficiency	Osteopenia, fractures, anemia, growth failure
Social stress	Child abuse or neglect, failure to thrive, divorce
Other sequelae	Sudden infant death syndrome, infections, inguinal hernia, cutaneous scars (chest tube, patent ductus arteriosus ligation, intravenous infiltration), gastroesophageal reflux, hypertension, craniosynostosis, cholelithiasis, nephrocalcinosis, cutaneous hemangiomas

be followed in a follow-up program that tracks medical and neurodevelopmental outcomes.

POSTDISCHARGE FOLLOW-UP

Medical Follow-Up

Even after discharge from the hospital, high-risk infants need very close medical follow-up. They continue to be at increased risk for poor weight gain and failure to thrive. In the setting of viral illness, premature infants are at increased risk for significant respiratory distress. Infants who are sent home on oxygen need very close medical follow-up with frequent visits and assessments, often with pulmonology. Table 119.10 lists common sequelae of prematurity.

Medically complex infants can go home with a multitude of subspecialty appointments to help manage existing morbidities secondary to prematurity, for example, cardiology for management of a patent ductus arteriosus or pulmonary hypertension, pulmonary for BPD, nephrology for hypertension, ophthalmology for ROP, neurosurgery for hydrocephalus, and neurology for history of seizures. The extensive follow-up requirements can be overwhelming and daunting for families. It is very important that these infants have a primary provider who serves as their "medical home" to help coordinate and assimilate the care from all these providers for families. This may be their primary care provider or subspecialty program provider.

Developmental Follow-Up

Premature infants are at much greater risk for neurodevelopmental delays than their term counterparts; the more preterm, the greater the risk of delay. In addition, certain postnatal morbidities (severe BPD, grade III or IV intraventricular hemorrhage, severe ROP, seizures) are associated with significantly increased risk of developmental delays. It is very important that these infants, particularly those born preterm, are followed and assessed for developmental delay, so that if delays are detected targeted interventions can be instituted as early as possible.

It is recommended that developmental follow-up be available for infants born <32 weeks' PMA, or at a minimum <28 weeks' PMA and/or <1 kg birthweight. Developmental follow-up in the United States is most often provided in a neonatal follow-up program for the first 2-3 years of life, and in some cases, until school age. Assessments focus on five main developmental domains: cognitive development, language development, fine and gross motor skills, social development, and emotional development. Although many assessments exist, the most widely used assessment in the United States is the *Bayley Scales of Infant and Toddler Development, 4th Edition.*

It is important to note that for at least the first 2 years of life, a child's corrected age should be used in determining whether a delay exists. Corrected age is calculated by subtracting the weeks born premature from a child's chronological age. In doing so, a corrected age accounts for a child's prematurity. There is some debate whether corrected age should continue to be used after age 2 years.

If it is determined that a delay exists, a child should be referred for appropriate therapy immediately to help minimize the delay as the child ages. Federal law under the Individuals with Disabilities Act requires states to provide *early intervention* services to children <3 years old with developmental delay. States vary greatly in how delay is defined and what services are offered. Early intervention is associated with improved cognitive outcomes in infancy and preschool age, but not lasting into school age. Motor outcomes are improved in infancy for children who receive early intervention, but this has not been shown to be a lasting effect into preschool and school age. However, these findings are difficult to interpret, given the heterogeneity of early interventions included in the reviews. With *targeted* interventions for specific delays, functional outcomes are improved.

Premature infants, especially those with a history of grade III or IV intraventricular hemorrhage or PVL seen on head imaging, are also at increased risk of motor impairments. Cerebral palsy is a *nonprogressive* but *permanent* disorder of movement and posture caused by disturbance to the developing immature brain. Historically, cerebral palsy had not been diagnosed until 18-24 months of age, but it can be diagnosed within the first 6 months of life. Early detection is critical to leveraging the neuroplasticity present in the very early years of life for improved function. International guidelines for early assessment and diagnosis of cerebral palsy and standardized assessments such as the General Movements Assessment (GMA) and the Hammersmith Infant Neurological Examination (HINE) are recommended in the guidelines to help identify children at high risk for or with cerebral palsy within the first few months to a year of life. This enables these children to access early intervention services and therapy at an earlier age, as well as undergo more frequent surveillance as needed.

Children with a history of prematurity who do not show significant developmental delays in the first few years of life are still at risk of later developing learning disabilities, attention problems, and decreased school achievement. Continued screening by their primary care provider is needed as these children age. More subtle deficits may not be recognized until school age; therefore continued surveillance is critical.

Chapter 120

Transport of the Critically Ill Newborn

David A. Munson

REGIONALIZED CARE OF NEWBORNS

The concept of regionalized care for neonates emphasizes the importance of providing regionalized care for infants in facilities with adequate personnel and equipment for an infant's severity of illness. Ideally, pregnant people should give birth to infants at a facility with the appropriate level of expertise and resources to care for the degree of prematurity and illness of the infant. Very low birthweight (VLBW) infants, or infants <1,500 g at birth, have decreased morbidity and mortality when born at **Level III** hospitals. In a meta-analysis, neonatal or predischarge death occurred in 38% of VLBW infants receiving care at a non–Level III hospital and 23% of those receiving care at a Level III hospital. A main objective of *Healthy People 2020* addresses this issue, with a goal of increasing the proportion of VLBW infants born at Level III hospitals or subspecialty perinatal centers to 83.7%. When possible it is more preferable to transport the pregnant person to meet the goals of regionalization.

LEVELS OF NEONATAL CARE

A **Level I** facility must be able to provide *basic neonatal care*. Appropriate equipment and staff must be available to perform neonatal resuscitation and care for healthy term and late preterm infants. In addition, Level I facilities must have the capacity to work to stabilize ill or preterm infants before transport to a higher level of care. A Level I nursery is the minimum requirement for a hospital providing inpatient maternity care. Providers at Level I facilities usually include pediatricians, family physicians, and nurse practitioners.

In addition to the care provided at a Level I facility, **Level II** nurseries must also be capable of providing care to moderately ill term infants with problems expected to resolve quickly. Level II centers also care for infants born ≥32 weeks' gestational age and >1,500 g at birth; therefore they must be comfortable with treating conditions common in this population, such as difficulty with oral feeds, apnea of prematurity, respiratory distress requiring continuous positive airway pressure (CPAP), and temperature regulation. These centers must also be capable of stabilizing infants born <32 weeks' gestation and <1,500 g until transfer to a higher-level facility is feasible, including the ability to intubate and provide mechanical ventilation for a brief duration if necessary. In addition to providers in Level I facilities, Level II facilities also typically have pediatric hospitalists, neonatologists, and neonatal nurse practitioners.

Level III NICUs are equipped to care for extremely preterm and critically ill neonates in addition to those infants cared for at Level I and II units. Level III units must have continuously available personnel and equipment to treat conditions commonly seen in this population, such as respiratory distress syndrome, pulmonary hypertension, and need for total parenteral nutrition. Resources should be available to obtain and interpret urgent imaging needed (e.g., CT, echocardiography). Pediatric subspecialists and pediatric surgeons should be available either on-site or through prearranged consultative agreements.

In addition to the care available at Level III neonatal intensive care units (NICUs), **Level IV** NICUs are also capable of providing continuously available pediatric subspecialty consultation and pediatric surgical intervention. Many Level IV sites are located at regional children's hospitals and also serve to provide outreach education. Level IV NICUs also have the capacity to provide extracorporeal membrane oxygenation (ECMO), an intervention that requires surgeons for catheter placement and ECMO specialists who are typically nurses or respiratory therapists with additional training in managing the ECMO circuit.

TRANSPORT OF THE CRITICALLY ILL NEONATE

In the event that a neonate requires a higher level of care, transport must be arranged to a unit with the appropriate level of care available. Additional decisions that need to be made before transport include composition of the transport team, equipment required for transport, and mode of transportation.

The composition of the **transport team** varies depending on personnel available and the needs of the infant being transported. The transport team often comprises at least two individuals, whether two registered transport trained nurses (RNs), an RN and a respiratory therapist, or an RN and a paramedic. In addition, a neonatologist, neonatology fellow, or neonatal nurse practitioner will sometimes accompany the transport team for critically ill neonates. A **medical command physician** is also available and can communicate with the transport team during the transport, as needed. The command physician is also able to communicate with the referring neonatologist to discuss the case and offer advice while the transport team is en route.

Transport staff must be competent in the treatment of common neonatal conditions and complications, as well as neonatal procedures. Many Level IV facilities have specialized teams designed only for neonatal transports. However, a Cochrane review found no evidence to support or to refute improved infant morbidity or mortality when transport occurred with a specialized neonatal team versus those that transported both neonatal as well as pediatric patients. Depending on the volume of neonatal transports and composition of the team, staff may have limited exposure to neonatal transports and procedures. **Simulation-based learning** is recommended by the American Academy of Pediatrics (AAP) Section on Transport Medicine (SOTM) as a method to help achieve and retain competency in rarely experienced procedures, as well as improve team interactions for transport teams.

The **transport vehicle** should be equipped with appropriate medicines, intravenous (IV) fluids, oxygen tanks, catheters, chest tubes, endotracheal tubes (ETTs), laryngoscopes, bag-valve-mask, and infant warming device. It should be well illuminated and have ample room for emergency procedures and monitoring equipment. Additional needs for an individual transport should be anticipated. Specifically, inhaled nitric oxide is not standard equipment for most transport teams and will need to be requested if thought necessary for safe transport. For neonates with hypoxemic ischemic encephalopathy who require hypothermia therapy, a servo-controlled cooling device is recommended as it will achieve the target temperature faster and there is less risk of overshooting the goal temperature. Prostaglandin E1 should be available for suspected ductal dependent congenital heart disease.

Common **modes of transport** include ground transport by ambulance and air transport by helicopter or fixed-wing aircraft. The stability of the infant, travel distance, traffic, and weather must all be taken into account when deciding the most appropriate mode of transportation.

Steps should be taken to stabilize the infant, as able, in a timely fashion before the transport. Securing an airway, providing oxygen, assisting with infant ventilation, providing antimicrobial therapy, maintaining the circulation, providing a warmed environment, checking a glucose level, and placing IV or arterial lines or chest tubes should be initiated, if indicated, before transport. Appropriate placement of lines and ETT should be evaluated before transport.

Some hospitals and their associated level IV NICUs offer transport of a patient on ECMO. Most commonly this is designed to transport a patient who is already cannulated onto ECMO who needs subspecialized care such as evaluation for transplant, or assessment for longer-term mechanical cardiac support. In other situations, a hospital may have the capacity to cannulate a patient onto ECMO, but do not have a program in place to support the patient for the coming days. These patients may therefore include more common patients who require ECMO such as neonates with persistent pulmonary hypertension, severe hypoxemic respiratory failure, sepsis, congenital diaphragmatic hernia, or hypoplastic left heart syndrome. In these circumstances, a transport team needs to include an ECMO specialist or perfusionist, and commonly adds a

critical care physician or surgeon. There are some programs that will bring the necessary personnel and equipment to cannulate a patient onto an ECMO circuit at the referring hospital before transport. There are considerable logistical challenges and added risks for transporting a patient on ECMO. These include inadvertent decannulation, problems with sustaining flow on the circuit, and bleeding.

Risks of transport and **consent** for transportation should be reviewed and obtained from parents before transport. Although transport teams attempt to anticipate and prepare for possible complications that could occur during transport, there is an inherent risk of complications, including death, in the event of a decompensation during transport resulting from the limited resources and personnel available. It is intrinsically more difficult to perform procedures in the physically confined space of an ambulance or helicopter. Additionally, there is the risk associated with the mode of transport itself including car and helicopter crashes. Parents should be made aware of these risks. Efforts should be made to allow parents to see their baby briefly before transport.

Communication with the transport team as well as the receiving facility is paramount throughout the transport process. Available prenatal history, information on the infant's resuscitation and hospital course, laboratory data, and radiographic images should be sent with the transport team to the receiving hospital to aid in future care. Video-assisted telecommunications can assist in giving the **medical command physician** visual as well as audio information about what is happening on-site before the patient is loaded onto the ambulance.

Reverse transport of an infant back to a lower level of care should be considered when infants are stabilized or have received and recovered from their subspecialist or surgical interventions, and no longer require the higher-level care available at the receiving hospital. Transport back to the hospital of birth aids in appropriate utilization of resources, decreases costs of care, and may further promote parent–infant bonding because of proximity to the mother's home.

Chapter 121

Clinical Manifestations of Diseases in the Newborn Period

Kathleen A. Gibbs and Eric C. Eichenwald

A variety of conditions that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders can be caused by prematurity, congenital malformations, disruption of chromosome structure, or acquired diseases and injuries.

ABNORMAL MOVEMENTS

Neonatal seizures usually suggest a central nervous system (CNS) disorder, such as hypoxic-ischemic encephalopathy (HIE), intracranial hemorrhage, stroke, cerebral anomaly, subdural effusion, or meningitis (see Chapter 633.7). In the neonate, seizures can also be secondary to hypocalcemia, hypoglycemia, benign familial seizures, or rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal.

Seizures in premature infants are often subtle and associated with abnormal eye movement (fluttering, tonic horizontal deviation, sustained eye opening with ocular fixation) or facial movement (chewing, tongue thrusting); the motor component is often that of tonic extension of the limbs, neck, and trunk. Autonomic phenomena include hypertension and tachycardia. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have subtler manifestations of seizure activity. **Apnea** may be the first manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and may even predispose an infant to seizures outside the neonatal period. Electroencephalographic (EEG) evidence of seizures can occur without clinical manifestations, particularly in preterm infants. If seizures are suspected, video-EEG monitoring will improve the detection of both subtle and electrographic but clinically silent seizures. Seizures contribute to brain injury and the impact of treatment on neurodevelopmental outcomes is an active area of research, particularly in patients with HIE. Although many medications used to treat seizures have side effects, it is recommended to treat both clinical and subclinical seizures.

Seizures should be distinguished from the **jitteriness**, defined as *recurrent tremors,* that may be present in healthy newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. An examiner can suppress the tremors by holding the infant's extremity; jitteriness often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Tremors are often more rapid with a smaller amplitude than those of tonic-clonic seizures.

After severe birth asphyxia, infants may exhibit **motor automatisms** characterized by recurrent oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized EEG discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, and are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Failure to move an extremity **(pseudoparalysis)** suggests fracture, dislocation, or a paralytic brachial plexus injury, often following a traumatic delivery. It is also seen in neonatal stroke (paralytic) as well as septic arthritis, osteomyelitis, and other infections that cause pain on movement of the affected part.

ABNORMAL TONE

Hypotonia, or low tone in one or more extremities, may be due to specific genetic etiologies or as a result of pathology in the peripheral or central nervous system. Features in the history and physical examination can help narrow the differential diagnosis and guide further diagnostic evaluations (see Chapter 647). A history of decreased fetal movement in utero may be suggestive of a congenital myopathy, or spinal muscular atrophy. In a male infant with cryptorchidism, Prader-Willi syndrome can be considered. **Hypotonia** is a common finding in an infant with trisomy 21. Hypertonia is less common and should be distinguished from fixed joint contractures seen in arthrogryposis. If present in the hours after birth and associated with the need for resuscitation after birth, a case of HIE should be considered.

ALTERED MENTAL STATUS

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, an inborn error of metabolism (IEM), or, almost any severe disease. Shortly after birth, lethargy is most likely caused by maternal medications (opioids, magnesium, general anesthesia) or moderate to severe HIE. Lethargy appearing after the second day should suggest infection or an IEM manifesting with hyperammonemia, acidosis, or hypoglycemia. Lethargy with emesis may suggest increased intracranial pressure or an IEM.

critical care physician or surgeon. There are some programs that will bring the necessary personnel and equipment to cannulate a patient onto an ECMO circuit at the referring hospital before transport. There are considerable logistical challenges and added risks for transporting a patient on ECMO. These include inadvertent decannulation, problems with sustaining flow on the circuit, and bleeding.

Risks of transport and **consent** for transportation should be reviewed and obtained from parents before transport. Although transport teams attempt to anticipate and prepare for possible complications that could occur during transport, there is an inherent risk of complications, including death, in the event of a decompensation during transport resulting from the limited resources and personnel available. It is intrinsically more difficult to perform procedures in the physically confined space of an ambulance or helicopter. Additionally, there is the risk associated with the mode of transport itself including car and helicopter crashes. Parents should be made aware of these risks. Efforts should be made to allow parents to see their baby briefly before transport.

Communication with the transport team as well as the receiving facility is paramount throughout the transport process. Available prenatal history, information on the infant's resuscitation and hospital course, laboratory data, and radiographic images should be sent with the transport team to the receiving hospital to aid in future care. Video-assisted telecommunications can assist in giving the **medical command physician** visual as well as audio information about what is happening on-site before the patient is loaded onto the ambulance.

Reverse transport of an infant back to a lower level of care should be considered when infants are stabilized or have received and recovered from their subspecialist or surgical interventions, and no longer require the higher-level care available at the receiving hospital. Transport back to the hospital of birth aids in appropriate utilization of resources, decreases costs of care, and may further promote parent–infant bonding because of proximity to the mother's home.

Chapter 121

Clinical Manifestations of Diseases in the Newborn Period

Kathleen A. Gibbs and Eric C. Eichenwald

A variety of conditions that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders can be caused by prematurity, congenital malformations, disruption of chromosome structure, or acquired diseases and injuries.

ABNORMAL MOVEMENTS

Neonatal seizures usually suggest a central nervous system (CNS) disorder, such as hypoxic-ischemic encephalopathy (HIE), intracranial hemorrhage, stroke, cerebral anomaly, subdural effusion, or meningitis (see Chapter 633.7). In the neonate, seizures can also be secondary to hypocalcemia, hypoglycemia, benign familial seizures, or rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal.

Seizures in premature infants are often subtle and associated with abnormal eye movement (fluttering, tonic horizontal deviation, sustained eye opening with ocular fixation) or facial movement (chewing, tongue thrusting); the motor component is often that of tonic extension of the limbs, neck, and trunk. Autonomic phenomena include hypertension and tachycardia. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have subtler manifestations of seizure activity. **Apnea** may be the first manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and may even predispose an infant to seizures outside the neonatal period. Electroencephalographic (EEG) evidence of seizures can occur without clinical manifestations, particularly in preterm infants. If seizures are suspected, video-EEG monitoring will improve the detection of both subtle and electrographic but clinically silent seizures. Seizures contribute to brain injury and the impact of treatment on neurodevelopmental outcomes is an active area of research, particularly in patients with HIE. Although many medications used to treat seizures have side effects, it is recommended to treat both clinical and subclinical seizures.

Seizures should be distinguished from the **jitteriness**, defined as *recurrent tremors,* that may be present in healthy newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. An examiner can suppress the tremors by holding the infant's extremity; jitteriness often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Tremors are often more rapid with a smaller amplitude than those of tonic-clonic seizures.

After severe birth asphyxia, infants may exhibit **motor automatisms** characterized by recurrent oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized EEG discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, and are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Failure to move an extremity **(pseudoparalysis)** suggests fracture, dislocation, or a paralytic brachial plexus injury, often following a traumatic delivery. It is also seen in neonatal stroke (paralytic) as well as septic arthritis, osteomyelitis, and other infections that cause pain on movement of the affected part.

ABNORMAL TONE

Hypotonia, or low tone in one or more extremities, may be due to specific genetic etiologies or as a result of pathology in the peripheral or central nervous system. Features in the history and physical examination can help narrow the differential diagnosis and guide further diagnostic evaluations (see Chapter 647). A history of decreased fetal movement in utero may be suggestive of a congenital myopathy, or spinal muscular atrophy. In a male infant with cryptorchidism, Prader-Willi syndrome can be considered. **Hypotonia** is a common finding in an infant with trisomy 21. Hypertonia is less common and should be distinguished from fixed joint contractures seen in arthrogryposis. If present in the hours after birth and associated with the need for resuscitation after birth, a case of HIE should be considered.

ALTERED MENTAL STATUS

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, an inborn error of metabolism (IEM), or, almost any severe disease. Shortly after birth, lethargy is most likely caused by maternal medications (opioids, magnesium, general anesthesia) or moderate to severe HIE. Lethargy appearing after the second day should suggest infection or an IEM manifesting with hyperammonemia, acidosis, or hypoglycemia. Lethargy with emesis may suggest increased intracranial pressure or an IEM.

Irritability may be a sign of discomfort accompanying intraabdominal conditions, meningeal irritation, drug withdrawal, infections, trauma (birth or nonaccidental), or any condition producing pain. It must be distinguished from normal crying behavior associated with hunger or benign environmental stimuli.

The lack of an interest to feed may indicate a sick infant and should prompt a careful search for infection, a CNS (brain or spine) or peripheral nervous system disorder, IEM, or intestinal obstruction.

APNEA

Periods of apnea, particularly in premature infants, can be attributed to many different underlying causes (see Chapter 125). When apnea occurs in a term infant, it should be considered pathologic until proven otherwise, and an immediate diagnostic evaluation for the underlying cause is imperative.

CONGENITAL ANOMALIES

Congenital anomalies are a common cause of neonatal morbidity and mortality worldwide (see Chapters 98–100). Early recognition of anomalies during fetal life is important to plan for delivery room management and subsequent neonatal care. Some malformations, including congenital heart disease, tracheoesophageal fistula, diaphragmatic hernia, choanal atresia, and intestinal obstruction, require immediate medical/surgical therapy for postnatal survival (Table 121.1). Prenatal and postnatal testing strategies, including advanced imaging techniques and genetic testing, have improved the specific diagnosis of congenital anomalies (see Chapter 103.1). Historically, genetic testing was performed by obtaining a karyotype with or without *fluorescence in situ hybridization* (FISH). A karyotype can identify a large number of chromosomal abnormalities; FISH can test for classic microdeletion syndromes such as 22q11. Chromosomal microarray is also indicated for genetic testing of infants with congenital anomalies because it can identify microdeletions or microduplications that are too small to be detected by more traditional techniques. In cases where a common aneuploidy, such as trisomy 13, 18, or 21, is suspected, obtaining a conventional karyotype and/or FISH may be the more appropriate test as those results are available in a few days. Whole exome sequencing (WES) uses next-generation sequencing to identify variants in protein coding genes that may be responsible for a disease phenotype. Rapid WES can have results available in 1-2 weeks. This can be used in a critically ill infant with a suspected genetic disorder that lacks a unifying diagnosis, and it may lead to a specific treatment and prognosis. Limitations of both microarray and WES include the identification of variants that may not be pathogenic in nature. Parents should receive genetic counseling as part of any testing strategy. It is important that healthcare providers are aware of the indication and limitations of the type of genetic test being performed.

CYANOSIS

Central cyanosis generates a broad differential diagnosis encompassing respiratory, cardiac, CNS, infectious, hematologic, and metabolic etiologies (Table 121.2). Typically, 5 g/dL of deoxyhemoglobin must be present in the blood for central cyanosis to be clinically apparent. If respiratory insufficiency is caused by pulmonary conditions, respirations tend to be rapid with increased work of breathing. If caused by CNS depression, respirations tend to be irregular and weak and are often slow. Cyanosis unaccompanied by obvious signs of respiratory difficulty suggests cyanotic congenital heart disease or methemoglobinemia. Cyanosis resulting from congenital heart disease may be difficult to distinguish clinically from cyanosis caused by respiratory disease. Episodes of cyanosis may also be the initial sign of hypoglycemia, bacteremia, meningitis, shock, or pulmonary hypertension. **Peripheral acrocyanosis** is common in neonates and thought to represent peripheral venous congestion associated with immature control of peripheral vascular tone. It does not usually warrant concern unless poor perfusion is suspected.

GASTROINTESTINAL DISTURBANCES

Vomiting during the first day of life can suggest obstruction in the upper digestive tract, metabolic disease, or may be physiologic**. Abdominal distention** with emesis**,** usually a sign of intestinal obstruction or an intraabdominal mass, may also be seen in infants with enteritis, necrotizing enterocolitis (NEC), isolated intestinal perforation, ileus accompanying sepsis, respiratory distress, ascites, or hypokalemia. Imaging studies are indicated when obstruction is suspected; proximal intestinal obstruction often occurs with a normal physical examination, whereas distal obstruction will likely be accompanied by distention. Vomiting may also be a nonspecific symptom of an illness such as sepsis with associated abdominal distention and ileus. It is a common manifestation of overfeeding, as well as gastroesophageal or physiologic reflux. Rarely, vomiting is caused by pyloric stenosis, milk protein allergy, duodenal ulcer, stress ulcer, an IEM (hyperammonemia, metabolic acidosis), or adrenal insufficiency. Vomitus containing blood is usually a sign of a serious illness, but the benign possibility of swallowed maternal blood associated with the delivery process should also be considered. Tests for maternal vs fetal hemoglobin can help

Table 121.1 Common Life-Threatening Congenital Anomalies

ANOMALY	MANIFESTATIONS
Choanal atresia	Respiratory distress in delivery room; nasogastric tube cannot be passed through nares Suspect CHARGE (coloboma of eye, heart anomaly, choanal atresia, retardation, genital and ear anomalies) syndrome
Pierre Robin syndrome, Stickler syndrome	Micrognathia, cleft palate, airway obstruction
Diaphragmatic hernia	Scaphoid abdomen, bowel sounds present in chest, respiratory distress
Tracheoesophageal fistula	Polyhydramnios, aspiration pneumonia, excessive salivation; nasogastric tube cannot be placed in stomach Suspect VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) syndrome
Intestinal obstruction: volvulus, duodenal atresia, ileal atresia	Polyhydramnios, bile-stained emesis, abdominal distention Suspect trisomy 21, cystic fibrosis, or cocaine use
Gastroschisis, omphalocele	Polyhydramnios, intestinal obstruction
Renal agenesis, Potter syndrome	Oligohydramnios, anuria, pulmonary hypoplasia, pneumothorax
Neural tube defects: anencephaly, meningomyelocele	Polyhydramnios, elevated α-fetoprotein, decreased fetal activity
Ductus-dependent congenital heart disease	Cyanosis, hypotension, murmur

Table 121.2 Differential Diagnosis of Cyanosis in the Newborn

CENTRAL OR PERIPHERAL NERVOUS SYSTEM HYPOVENTILATION
Birth asphyxia
Intracranial hypertension, hemorrhage
Oversedation (direct or through maternal route)
Diaphragm palsy
Neuromuscular diseases
Seizures

RESPIRATORY DISEASE
Airway
Choanal atresia/stenosis
Pierre Robin syndrome
Intrinsic airway obstruction (laryngeal/bronchial/tracheal stenosis)
Extrinsic airway obstruction (bronchogenic cyst, duplication cyst, vascular compression)

Lung
Respiratory distress syndrome
Transient tachypnea
Meconium aspiration
Pneumonia (sepsis)
Pneumothorax
Congenital diaphragmatic hernia
Pulmonary hypoplasia

CARDIAC RIGHT-TO-LEFT SHUNT
Abnormal Connections (Pulmonary Blood Flow Normal or Increased)
Transposition of great vessels
Total anomalous pulmonary venous return
Truncus arteriosus
Hypoplastic left heart syndrome
Single ventricle or tricuspid atresia with large ventricular septal defect but without pulmonic stenosis

OBSTRUCTED PULMONARY BLOOD FLOW (PULMONARY BLOOD FLOW DECREASED)
Pulmonic atresia with intact ventricular septum
Tetralogy of Fallot
Critical pulmonic stenosis with patent foramen ovale or atrial septal defect
Tricuspid atresia
Single ventricle with pulmonic stenosis
Ebstein malformation of tricuspid valve
Persistent fetal circulation (persistent pulmonary hypertension of newborn)

METHEMOGLOBINEMIA
Congenital (hemoglobin M, methemoglobin reductase deficiency)
Acquired (nitrates, nitrites)

INADEQUATE DELIVERY
Inadequate ambient O2 or less O2 delivered than expected (rare)
Disconnection of O2 supply to nasal cannula, head hood
Connection of air, rather than O2, to a mechanical ventilator

SPURIOUS/ARTIFACTUAL
Oximeter artifact (poor contact between probe and skin, poor pulse searching)
Arterial blood gas artifact (contamination with venous blood)

OTHER
Hypoglycemia
Adrenogenital syndrome
Polycythemia
Blood loss

From Smith F: Cyanosis. In: Kliegman RM: *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: Saunders; 1996.

discriminate between these possibilities. Bilious emesis in a term infant should be considered a surgical emergency with a presumed diagnosis of intestinal malrotation with or without volvulus until proven otherwise. This finding warrants urgent contrast radiography of the upper gastrointestinal tract (see Chapter 376.3).

Diarrhea may be a symptom of overfeeding (especially high–caloric density formula), acute gastroenteritis, congenital diarrhea syndromes, or malabsorption, or it may be a nonspecific symptom of infection. Diarrhea should be differentiated from the normal loose, seedy, yellow stool seen typically in breastfed infants. Diarrhea may occur in conditions accompanied by compromised circulation of part of the intestinal or genital tract, such as mesenteric thrombosis, NEC, strangulated hernia, intussusception, and torsion of the ovary or testis.

HYPOTENSION

Hypotension in term infants implies hypovolemic shock (hemorrhage, dehydration), a systemic inflammatory response syndrome (bacterial sepsis, intrauterine infection, NEC, cardiac dysfunction, myocarditis, asphyxia-induced myocardial stunning, anomalous coronary artery), congenital heart disease with ductal-dependent systemic blood flow (hypoplastic left heart syndrome, congenital aortic stenosis), pneumothorax, pneumopericardium, pericardial effusion, or metabolic disorders (hypoglycemia, adrenal insufficiency).

Hypotension is a common problem in sick preterm infants and may also be caused by any of the problems noted in a term infant. Some extremely low gestational age infants do not respond to fluids or inotropic agents but may improve with administration of intravenous hydrocortisone (Fig. 121.1). Sudden onset of hypotension in a very low birthweight (VLBW) infant suggests pneumothorax, intraventricular hemorrhage, or subcapsular hepatic hematoma. Strategies used to support blood pressure include volume expansion with crystalloid and/or colloid, vasopressors (dopamine, dobutamine, epinephrine, norepinephrine, vasopressin), or corticosteroids (hydrocortisone) (see Chapter 85).

JAUNDICE

Jaundice during the first 24 hours of life warrants diagnostic evaluation and should be considered pathologic until proven otherwise. Hemolytic disease of the newborn due to rhesus blood group system (Rh) isoimmunization or blood type compatibility are the most common cause (see Chapter 140). Intrauterine infections (e.g., syphilis, cytomegalovirus, and toxoplasmosis), early-onset sepsis, or gestational alloimmune liver disease (formerly described as neonatal hemochromatosis) should be considered in infants with neonatal cholestasis, identified by an increase in *direct* bilirubin value. Immediate evaluation includes obtaining total and direct bilirubin, infant blood type and Coombs status, CBC, and reticulocyte count. There are nomograms specific to the age (in hours) of the infant to guide the initiation of therapeutic interventions depending on the levels of serum bilirubin values (see Chapter 137). Phototherapy is the standard first-line therapy. In the case of Coombs-positive hemolysis, strong consideration should be made to giving intravenous immunoglobulin (IVIG) if there is no response to intensive phototherapy. Double volume exchange transfusion is recommended in situations with rapidly rising indirect bilirubin levels, particularly in infants whose bilirubin levels rise over 20 mg/dL. In these cases, obtaining a serum albumin is also recommended.

Jaundice that is identified after the first 24 hours of age may be physiologic or pathologic. Physiologic conditions include breast-milk and breast-feeding jaundice. Pathologic conditions include bacterial sepsis, congenital hypothyroidism, galactosemia, congenital atresia of the bile ducts, or other conditions (see Chapter 137).

PAIN

Pain in neonates may be unrecognized and/or undertreated. The intensive care of neonates may involve several painful procedures, including blood sampling (heelstick, venous or arterial puncture), endotracheal intubation and suctioning, mechanical ventilation, and insertion of chest tubes and intravascular catheters. Pain in neonates results in

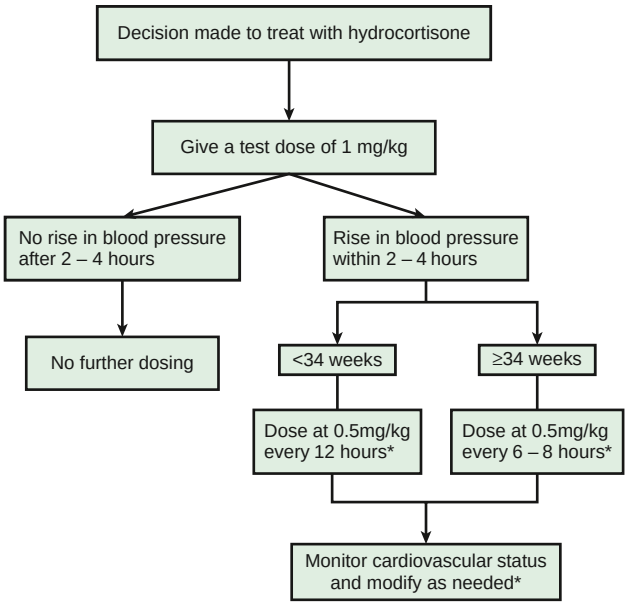

Fig. 121.1 Suggested treatment algorithm for hydrocortisone dosing in the newborn. *(From Watterberg KL. Hydrocortisone dosing for hypotension in newborn infants: less is more. J Pediatr. 2016;174:23–26.)*

obvious distress and acute physiologic stress responses, which may have developmental implications for pain in later life.

Pain and discomfort are potentially avoidable problems during the treatment of sick infants. The most common painful stimuli for healthy newborns include circumcision and phlebotomy while obtaining metabolic screening tests. There are pharmacologic and nonpharmacologic options to both prevent and treat pain. **Oral sucrose solutions** are well tolerated by most infants and have proven efficacy for procedural pain. A dorsal penile nerve block is effective to prevent procedural-related pain during a circumcision. For neonatal intensive care unit (NICU) infants, the most frequently used drugs are intermittent or continuous doses of opioids. Although the specific long-term effects of opioids and sedatives are not well established, the first concern should be the treatment and/or prevention of acute pain (Table 121.3).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

121.1 Hyperthermia

Kathleen A. Gibbs and Eric C. Eichenwald

Serious infection (pneumonia, bacteremia, meningitis, and viral infections, particularly herpes simplex or enteroviruses) may cause **fever** and must be considered, although such infections often occur without provoking a febrile response in newborn infants (see Chapter 220). Providers should consider evaluation for bacterial infection in infants <28 days old with a rectal temperature ≥38°C (100.5°F), including blood culture, urine culture, and lumbar puncture (LP), although stepwise approaches to identify low-risk patients and limiting LP to a subset of higher-risk infants are gaining favor. Fever immediately after birth may be caused by radiant warmers, maternal fever, or maternal epidural analgesia. Fever may also be caused by elevated environmental temperatures because of weather, overheated nurseries, incubators, or radiant warmers, or excessive clothing. It has also been attributed to dehydration, although *dehydration fever* is a diagnosis of exclusion in newborn infants.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 121.3 Pain in the Neonate: General Considerations

- Pain in newborns is often unrecognized and/or undertreated.
- If a procedure is painful in adults, it should be considered painful in newborns.
- Healthcare institutions should develop and implement patient care policies to assess, prevent, and manage pain in neonates.
- Pharmacologic agents with known pharmacokinetic and pharmacodynamic properties and demonstrated efficacy in neonates should be used. Agents known to compromise cardiorespiratory function should be administered only by persons experienced in neonatal airway management and in settings with the capacity for continuous monitoring.
- Educational programs to increase the skills of healthcare professionals in the assessment and management of stress and pain in neonates should be provided.
- Further research is needed to develop and validate neonatal pain assessment tools that are useful in the clinical setting; to determine optimal behavioral and pharmacologic interventions; and to study long-term effects of pain and pain management.

Data from American Academy of Pediatrics Committee on Fetus and Newborn, Committee on Drugs, Section on Anesthesiology, Section on Surgery; Canadian Paediatric Society, Fetus and Newborn Committee. Prevention and Management of Pain and Stress in the Neonate: An Update. *Pediatrics* 2016;137:e20154271.

121.2 Hypothermia and Cold Stress

Kathleen A. Gibbs and Eric C. Eichenwald

Unexplained **hypothermia** may accompany infection or other serious disturbances of the circulation or CNS. A sudden servo-controlled increase in incubator ambient temperature to maintain body temperature is a sign of temperature instability and may be associated with sepsis or any of the conditions already mentioned.

Cold stress can lead to profound decompensation, including apnea, bradycardia, respiratory distress, hypoglycemia, and poor feeding. For this reason, it is paramount for the neonate to maintain normothermia in the delivery room and afterward, especially low birthweight and premature infants. For VLBW infants, a combination of occlusive plastic wrap, radiant warmers, and thermal mattresses to maintain normothermia can be used to reduce cold stress.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

121.3 Edema

Kathleen A. Gibbs and Eric C. Eichenwald

Generalized edema noted in the delivery room can be caused by hydrops fetalis secondary to several underlying causes (see Chapter 143). An infant with suspected hydrops in utero should be delivered at a specialty perinatal center with capacity for neonatal intubation, thoracentesis, paracentesis, and pericardiocentesis in the delivery room. If noted after 24 hours of age, causes are similar to those of older children and may be multifactorial and likely related to the underlying disease state. Edema may be due to interstitial fluid "third-spacing" due to a systemic inflammatory response seen in sepsis or NEC; or, in the immediate postoperative period, hypoalbuminemia may be due to low production in hepatic synthetic dysfunction or increased losses in underlying renal disease such a congenital nephrotic syndrome (see Chapter 567.3).

121.4 Hypocalcemia

Kathleen A. Gibbs and Eric C. Eichenwald

Hypocalcemia in a neonate can manifest as irritability, jitteriness, clonus, or seizures. Electrocardiography can show a prolonged QT interval. The cause may simply represent an exaggerated physiologic decrease in serum calcium levels within the first 24 hours of life or pathologic conditions such as genetic disorders (22q deletions), prematurity, growth restriction, perinatal hypoxia, hypomagnesemia, or maternal diabetes. Hypocalcemia is more common in term infants receiving formula than in those exclusively receiving breast milk. Most infants remain asymptomatic and can be managed conservatively with early nutrition and close monitoring, whereas symptomatic neonates should receive intravenous or oral calcium replacement.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

121.5 Hypermagnesemia

Kathleen A. Gibbs and Eric C. Eichenwald

Hypermagnesemia is most often caused by maternal administration of magnesium in the perinatal period for treatment of conditions such as preeclampsia and preterm labor, and as prophylaxis to mitigate brain injury associated with preterm birth. Infants are usually present with signs at birth and improve over the next 24-48 hours. Symptoms include respiratory depression, hypotonia, lethargy, and feeding intolerance. No treatment is indicated other than supportive measures.

Chapter 122
Nervous System Disorders

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

Central nervous system (CNS) disorders are important causes of neonatal mortality and both short-term and long-term morbidity. The CNS can be injured as a result of asphyxia, hemorrhage, trauma, infection, hypoglycemia, or direct cytotoxicity. The etiology of CNS injury is often multifactorial and includes perinatal complications, postnatal hemodynamic instability, and developmental abnormalities that may be genetic and/or environmental. Predisposing factors for brain injury include chronic and acute maternal illness resulting in uteroplacental dysfunction, intrauterine infection, macrosomia/dystocia, malpresentation, prematurity, and intrauterine growth restriction. Acute and often unavoidable emergencies during the delivery process may result in mechanical and hypoxic-ischemic brain injury.

122.1 The Cranium

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

Erythema, abrasions, ecchymoses, and subcutaneous fat necrosis of facial or scalp soft tissues may be noted after a normal delivery or after forceps or vacuum-assisted deliveries. The location depends on the area of contact with the pelvic bones or application of the forceps. Traumatic hemorrhage may involve any layer of the scalp as well as intracranial contents (Fig. 122.1).

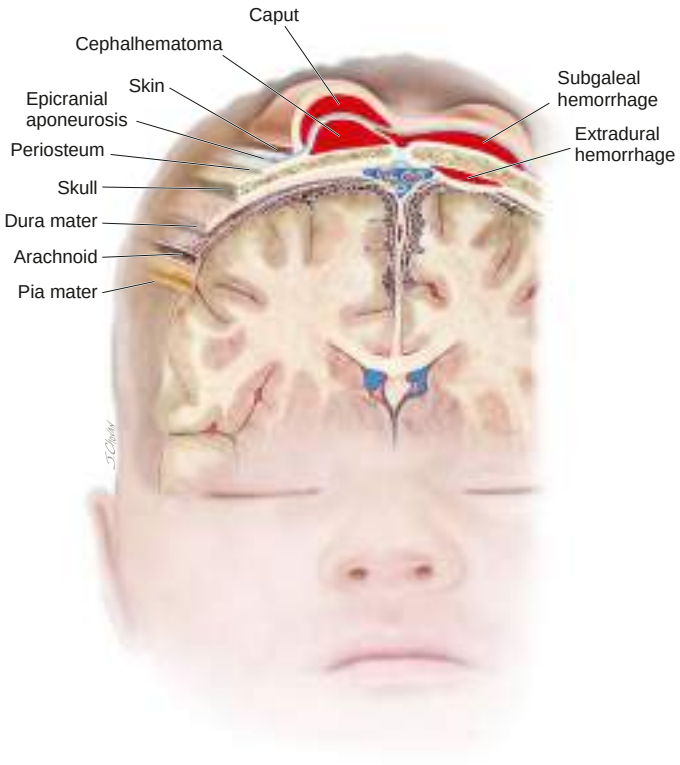

Fig. 122.1 Sites of extracranial (and extradural) hemorrhages in the newborn. Schematic diagram of important tissue planes from skin to dura. *(From Volpe JJ. Injuries of extracranial, cranial, intracranial, spinal cord, and peripheral nervous system structures. In: Volpe JJ, Inder TE, Darras BT, et al., eds. Volpe's Neurology of the Newborn. 6th ed. Philadelphia: Elsevier; 2018: Fig. 36-1.)*

Caput succedaneum is a diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp due to the increased pressure of the vaginal and uterine walls on the fetal head during labor. The pressure causes a serosanguinous/edematous infiltration above the periosteum and below the skin or subcutaneous tissue. The edema is soft and extends across the midline of the skull, crossing suture lines and disappears within the first few days of life. Molding of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded; they disappear during the first few weeks of life. Rarely, a hemorrhagic caput may result in shock and require blood transfusion. Analogous swelling, discoloration, and distortion of the face are seen in face presentations. No specific treatment is needed, but if extensive ecchymoses are present, hyperbilirubinemia may develop.

Cephalohematoma is a unilateral subperiosteal hemorrhage that does not cross the suture lines as it usually occurs within a single cranial plate (Fig. 122.2). Cephalohematomas occur in 1–2% of live births regardless of the mode of delivery. No discoloration of the overlying scalp occurs, and due to slow bleeding, the clinical presentation of swelling is delayed for several hours to days. The lesion becomes a firm, tense mass with a palpable rim localized over one area of the skull. Most cephalohematomas are resorbed within 3 to 4 weeks, depending on their size. They may begin to calcify by the end of the second week of life. A few remain for years as bony protuberances and are detectable on radiographs as widening of the diploic space; cystlike defects that may persist for months or years. An underlying skull fracture, usually linear and not depressed, may be associated with 10–25% of cases. A sensation of central depression suggesting but not indicative of an underlying fracture or bony defect is usually encountered on palpation of the organized rim of a cephalohematoma. Osteomyelitis of the skull is a rare complication of cephalohematoma; *Escherichia coli* and *Staphylococcus aureus* are common agents. Cephalohematomas

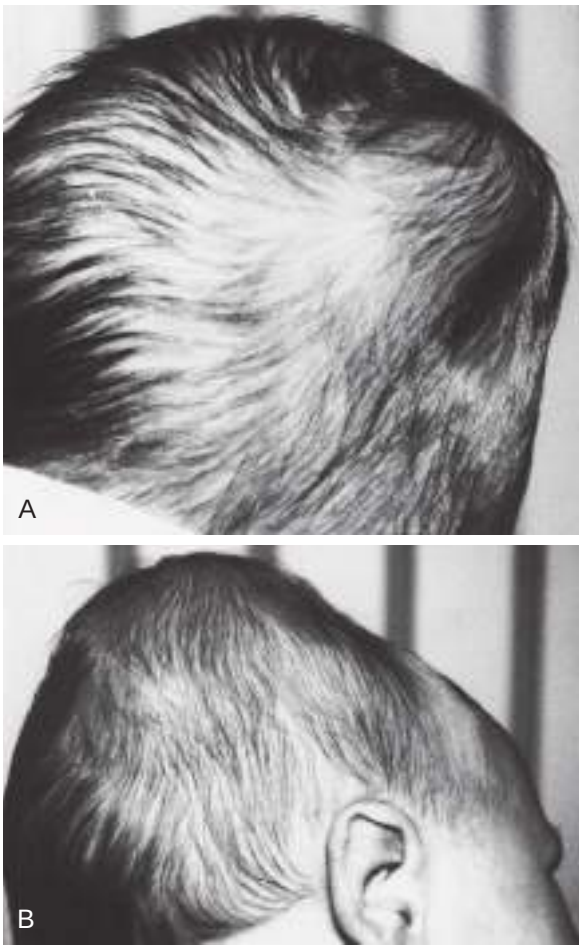

Fig. 122.2 Parietal cephalhematoma. Clinical appearance of 10-day-old infant delivered with the aid of mid-forceps. A, Posterior view. B, Right lateral view. Note prominent swelling that extends medially to the sagittal suture, posteriorly to the lambdoid suture, and laterally to the squamosal suture. *(From Volpe JJ. Injuries of extracranial, cranial, intracranial, spinal cord, and peripheral nervous system structures. In: Volpe JJ, Inder TE, Darras BT, et al. eds. Volpe's Neurology of the Newborn. 6th ed. Philadelphia: Elsevier; 2018: Fig. 36-3.)*

require no treatment, although phototherapy may be necessary to treat hyperbilirubinemia.

A **subgaleal hemorrhage** is a collection of blood in the loose connective tissue of the subgaleal space, located between the epicranial aponeurosis and the periosteum (see Fig. 122.1). There is often an association with vacuum-assisted delivery. A subgaleal hemorrhage manifests as a fluctuant mass that straddles cranial sutures or fontanels that increases in size after birth. The mechanism of injury is most likely secondary to rupture of emissary veins connecting the dural sinuses within the skull and the superficial veins of the scalp. Subgaleal hemorrhages are sometimes associated with skull fractures, suture diastasis, and fragmentation of the superior margin of the parietal bone. Extensive subgaleal bleeding can result in sequestration of more than 40% of the newborn's blood volume, which can potentially result in hemorrhagic shock. The mortality can be up to 14% due to hemorrhagic shock and is occasionally secondary to a hereditary coagulopathy **(hemophilia)**. In some cases, patients can develop a consumptive coagulopathy from massive blood loss. Subgaleal hemorrhages can present clinically with the triad of tachycardia, decreased hematocrit, and increasing occipital frontal circumference. When subgaleal hemorrhage is suspected, hemoglobin measurements should be performed as soon as possible and should be monitored every 4 to 8 hours, as should coagulation studies. Although it is not necessary to make the clinical diagnosis, optimal imaging for subgaleal hemorrhage is by CT or MRI. Radiographs of the skull can be done to identity accompanying fractures. These lesions typically resolve over 2 to 3 weeks.

Fractures of the skull may be caused by pressure in the setting of a forceps delivery, but they can occur rarely in uncomplicated vaginal deliveries. *Linear fractures,* the most common, cause no symptoms and require no treatment. Linear fractures should be followed up to demonstrate healing and to detect the possible complication of a leptomeningeal cyst. *Depressed fractures* often are referred to as "ping-pong" fractures because on x-ray they resemble an indented ping-pong ball. Affected infants may be asymptomatic unless they have associated intracranial injury. Surgical management of such an injury may not be necessary due to the infants' relatively thin and flexible skull bones rendering them amenable to remodeling, and intervention could be reserved for larger areas of depression. When intervention is required, the obstetric vacuum extractor is an ideal tool because it provides patent tubing unlikely to collapse during the application of suction. No traction is needed during the suction procedure, and the elevation of the depression can be ascertained by direct visualization, an audible "click" sound or a "give" sensation accompanied by an instantaneous pressure release. There is no clear recommendation for imaging in this population, but with newer techniques of low-dose CT imaging, current technology allows axial imaging to be constructed in the coronal and sagittal planes and into three-dimensional reformats, thus increasing the likelihood of detecting a fracture.

Subconjunctival and **retinal hemorrhages** are frequent; petechiae of the skin of the head and neck are also common. All are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that these hemorrhages are temporary and the result of normal events of delivery. The lesions resolve rapidly within the first 2 weeks of life.

122.2 Neonatal Traumatic Head Injuries

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

Neonatal traumatic head injuries are estimated to affect ~3% of pregnancies and represent approximately 2% of neonatal deaths. Infrequently, these injuries occur during normal birth but the incidence rises in cases when the fetal head is large in proportion to the size of the mother's pelvic outlet, with prolonged labor, in breech or precipitous deliveries, or as a result of mechanical assistance with delivery. Massive **subdural hemorrhage**, often associated with tears in the tentorium cerebelli or less frequently in the falx cerebri, is rare, but is encountered more often in full-term than in premature infants. Patients with massive hemorrhage caused by tears of the tentorium or falx cerebri rapidly deteriorate and may die soon after birth. Most subdural and epidural hemorrhages resolve without intervention. Consultation with a neurosurgeon is recommended. Asymptomatic subdural hemorrhage may be noted within 48 hours of birth after vaginal or cesarean delivery. These are typically small hemorrhages, especially common in the posterior fossa, discovered incidentally in term infants imaged in the neonatal period, and usually of no clinical significance. The diagnosis of large subdural hemorrhage may be delayed until the chronic subdural fluid volume expands and produces macrocephaly, frontal bossing, a bulging fontanel, anemia, and sometimes seizures. CT scan and MRI are useful imaging techniques to confirm these diagnoses. Symptomatic subdural hemorrhage in term infants can be treated by a neurosurgical evacuation of the subdural fluid collection by a needle placed through the lateral margin of the anterior fontanel, or in severe cases an operative burr hole or craniotomy. In addition to birth trauma, **child abuse** must be suspected in all infants with subdural effusion after the immediate neonatal period. Most asymptomatic subdural hemorrhages following labor should resolve by 4 weeks of age.

Subarachnoid hemorrhage is often clinically silent in the neonate. Anastomoses between the penetrating leptomeningeal arteries or the

bridging veins are the most likely source of the bleeding. Most affected infants have no clinical symptoms, but the subarachnoid hemorrhage may be detected because of an elevated number of red blood cells in a lumbar puncture sample. Some infants experience short, benign seizures, which tend to occur on the second day of life. Rarely, an infant has a catastrophic hemorrhage and dies. There are usually no neurologic abnormalities during the acute episode or on follow-up. Significant neurologic findings should suggest an arteriovenous malformation, which can best be detected on CT or MRI.

122.3 Intracranial-Intraventricular Hemorrhage and Periventricular Leukomalacia

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

Intracranial hemorrhage in preterm infants usually develops spontaneously. Less frequently, it may be caused by trauma or asphyxia, and rarely, it occurs from a primary hemorrhagic disturbance or congenital cerebrovascular anomaly. The very low birthweight infant (VLBW; birthweight <1,500 g) is at high risk for intracranial hemorrhages, with the risk for severe hemorrhage inversely related to gestational age. Intracranial hemorrhage often involves the ventricles **(intraventricular hemorrhage [IVH])** of premature infants delivered spontaneously without apparent trauma. Primary hemorrhagic disturbances and vascular malformations are rare and usually give rise to subarachnoid or intracerebral hemorrhage. In utero hemorrhage associated with maternal idiopathic or, more often, fetal alloimmune thrombocytopenia may appear as severe cerebral hemorrhage or as a porencephalic cyst after resolution of a fetal cortical hemorrhage. Intracranial bleeding may be associated with disseminated intravascular coagulation, isoimmune thrombocytopenia, and neonatal vitamin K deficiency, especially in infants born to mothers receiving phenobarbital or phenytoin.

Periventricular leukomalacia (PVL) is a disorder of the periventricular cerebral white matter that may be cystic or diffuse in nature. PVL may initially be observed during the first week of life in the VLBW infant as increased echogenicity of the periventricular white matter, sometime described as an echogenic "blush" or "flare." These areas of white matter abnormalities may become cystic on ultrasonography within 2 to 5 weeks and/or lead to ventriculomegaly from white matter volume loss, which can be visible on repeat ultrasonography at term equivalent age. Clinical risk factors for PVL include gestational age at birth and prenatal/postnatal factors including inflammation, hypoxia, postnatal steroid exposure, and metabolic disturbances.

EPIDEMIOLOGY

The overall incidence of IVH has decreased over the last few decades as a result of improved perinatal care, increased use of antenatal corticosteroids, surfactant to treat respiratory distress syndrome (RDS), and improved positive pressure mechanical ventilation strategies. The global incidence of IVH among preterm infants ranges from 14.7–44.7% with considerable variation across gestational age groups, neonatal intensive care units (NICUs), and countries. The risk for severe IVH is associated with infants with a gestational age ≤30 weeks' gestation, with the highest risk in infants born at ≤24 weeks' gestation. Infants born at >30 weeks' gestation have a low risk of severe IVH unless they have additional clinical risk factors such as low Apgar scores, metabolic acidosis, hypotension, or lack of antenatal steroids.

PVL can be described in three major pathologic forms: macroscopic cystic white matter injury, microscopic cystic white matter injury, and nonnecrotic diffuse white matter injury. Macroscopic cystic white matter injury represents the most severe form of PVL and fortunately affects <5% of very preterm infants born <32 weeks. With advances in neonatal care, there has been a shift from large cystic injury to small punctate injury. In microscopic cystic white matter injury, the necrotic areas are small and result in focal areas of gliosis, which ultrasonography is not sensitive enough to detect. The most common form of PVL in the preterm population is nonnecrotic diffuse PVL. Diffuse PVL is estimated to affect nearly a third of infants born <32 weeks and is best recognized on MRI.

PATHOGENESIS

The major neuropathologic lesions associated with VLBW infants are IVH and PVL. IVH in premature infants occurs in the gelatinous subependymal **germinal matrix**. This periventricular area is the site of origin for embryonal neurons and fetal glial cells, which migrate outwardly to the cortex. Immature and fragile blood vessels in this highly vascular region of the developing brain combined with disturbances in cerebral blood flow and coagulation predispose premature infants to hemorrhage. The germinal matrix involutes as the infant approaches 34 to 36 weeks' gestation, and the tissue's vascular integrity improves; therefore IVH is much less common in the late preterm and term infant. The cerebellum also contains a germinal matrix and is susceptible to hemorrhagic injury. **Periventricular hemorrhagic infarction (PVHI)**, previously known as **grade IV IVH**, often develops after a large IVH because of venous congestion. PVHI is not an extension of the IVH into the parenchyma. Predisposing factors for IVH include prematurity, RDS, hypoxia-ischemia, exaggerated fluctuations in cerebral blood flow (hypotensive injury, hypervolemia, hypertension), reperfusion injury of damaged vessels, reduced vascular integrity, increased venous pressure (pneumothorax, venous thrombus), or thrombocytopenia.

The pathogenesis of PVL appears to involve both intrauterine and postnatal events. A complex interaction exists between the development of the cerebral vasculature and the regulation of cerebral blood flow (both of which depend on gestational age), disturbances in the oligodendrocyte precursors required for myelination, and maternal/fetal infection and inflammation. Postnatal hypoxia or hypotension, necrotizing enterocolitis (NEC) with its resultant inflammation, and severe neonatal infection may all result in white matter injury. The risk for PVL increases in infants with severe IVH or ventriculomegaly.

CLINICAL MANIFESTATIONS

Most infants with IVH, including some with moderate to severe hemorrhages, have no initial clinical signs **(silent IVH)**. Some premature infants with severe IVH may have an acute deterioration on the second or third day of life **(catastrophic IVH)**. Hypotension, apnea, pallor, stupor or coma, seizures, decreased muscle tone, metabolic acidosis, shock, and decreased hematocrit (or failure of hematocrit to increase after transfusion) may be the first clinical indications. A *saltatory progression* may occur over several hours to days and manifest as intermittent or progressive alterations of levels of consciousness, abnormalities of tone and movement, respiratory signs, and eventually other features of the acute catastrophic IVH. Rarely, IVH may manifest at birth or even prenatally; the majority of cases of IVH in the preterm infant occur within the first 3 days of life. Of those, approximately 50% of hemorrhages occur within the first 5 hours, 70% occur within the first day of life, and by 7 days of life 95% of IVH will have occurred. A small percentage of infants have late hemorrhage, between days 14 and 30. IVH as a primary event is rare after the first month of life.

The severity of hemorrhage is defined by the location and degree of bleeding and ventricular dilation on cranial imaging. In a **grade I** hemorrhage, bleeding is isolated to the subependymal area. In **grade II** hemorrhage, there is bleeding within the ventricle *without* evidence of ventricular dilation. **Grade III** hemorrhage is IVH with ventricular dilation. In **PVHI** hemorrhage (formerly called **grade IV**, see previously), there is intraventricular and parenchymal hemorrhage (Fig. 122.3). Another grading system describes three levels of increasing severity of IVH detected on ultrasound: In **grade I,** bleeding is confined to the germinal matrix–subependymal region or to <10% of the ventricle (approximately 35% of IVH cases); **grade II** is defined as intraventricular bleeding with 10–50% filling of the ventricle (40% of IVH cases); and in **grade III**, >50% of the ventricle is involved, with dilated ventricles (see Fig. 122.3).

One of the major complications resulting from IVH is the development of **posthemorrhagic ventricular dilation (PHVD)**. Following a large IVH, multiple small clots throughout the ventricular system may obstruct

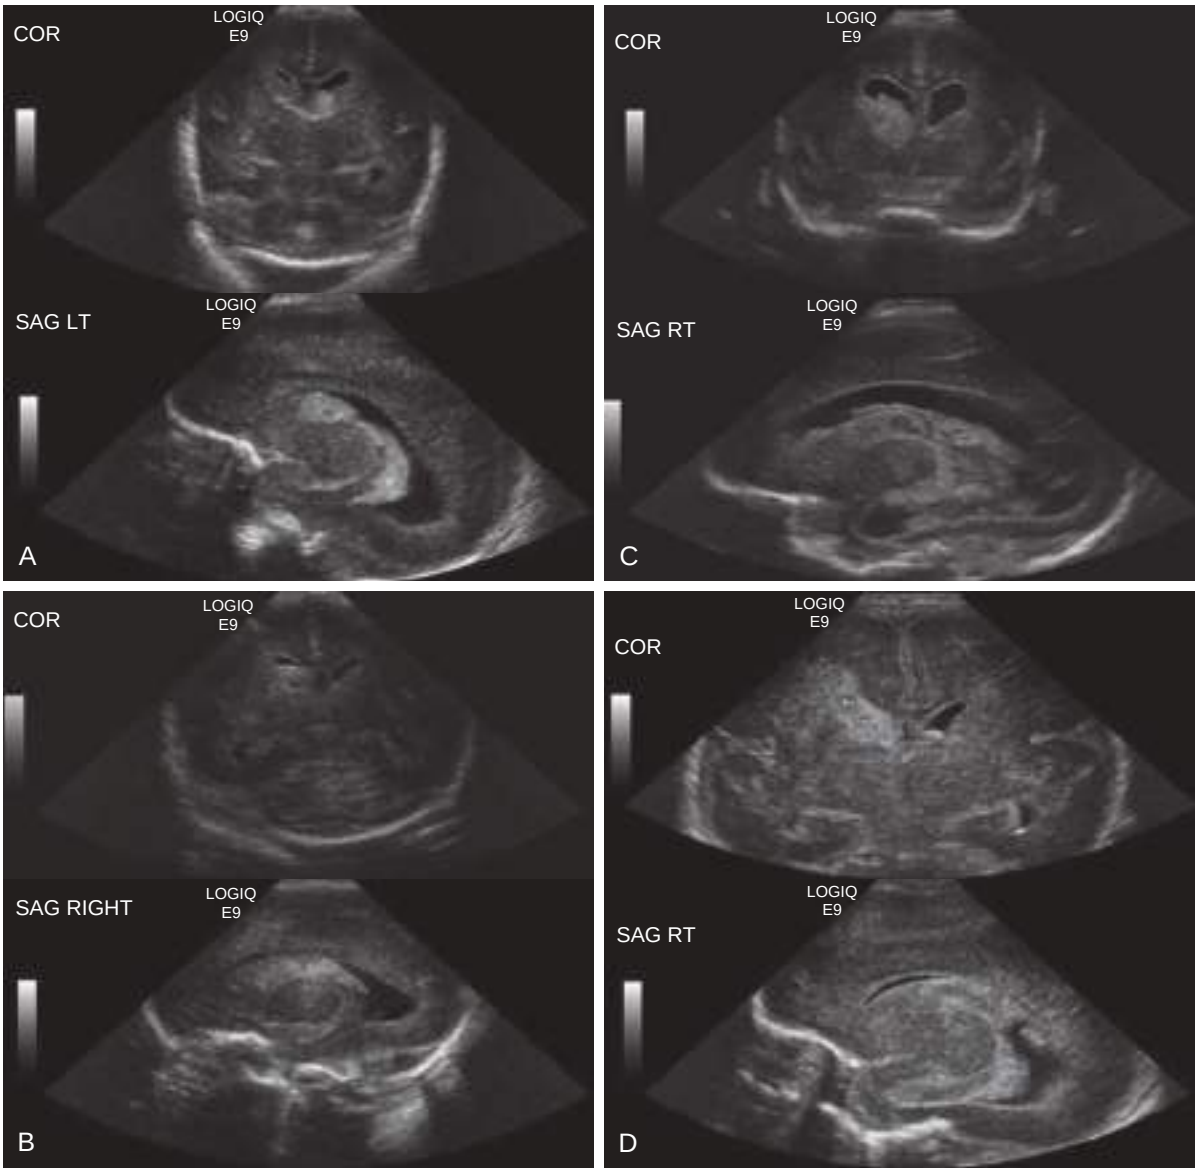

Fig. 122.3 Grading of the severity of germinal matrix–intraventricular hemorrhage (IVH): coronal (COR) and parasagittal (SAG) ultrasound scans. **A,** Germinal matrix hemorrhage, grade I. **B,** IVH (filling <50% of ventricular area), grade II. **C,** IVH with ventricular dilatation, grade III. **D,** Large IVH with associated parenchymal echogenicity (hemorrhagic infarct), grade IV. Note that the terminology has now changed for "grade IV" to periventricular hemorrhagic infarction (PVHI). (*From Inder TE, Perlman JM, Volpe JJ. Preterm intraventricular hemorrhage/posthemorrhagic hydrocephalus. In: Volpe JJ, Inder TE, Darras BT, et al., eds. Volpe's Neurology of the Newborn. 6th ed. Philadelphia: Elsevier; 2018: Fig. 24-2.*)

cerebrospinal fluid (CSF) flow and resorption, all in the face of ongoing production of CSF in the choroid plexus in the lateral ventricles and the roof of the third ventricle. The progressive accumulation of CSF changes the shape of the lateral ventricles from a slit to a balloon. The expanding ventricles distort the developing brain and intracerebral pressure (ICP) eventually starts to rise. As the preterm skull is very compliant, the ventricles can expand without pressure rising initially but eventually can result in increased ICP. PHVD develops in 30–50% of infants with severe IVH and is initially asymptomatic in most patients. *Therefore sequential cranial ultrasonography facilitates early detection*. The term ventriculomegaly is occasionally used for both infants with ventricular enlargement following IVH as well as those without hemorrhage. In infants without IVH, ventricular enlargement is more likely due to *white matter loss* rather than an accumulation of CSF. Therefore it is preferable to use the term PHVD when ventricular enlargement follows IVH.

PVL is usually clinically asymptomatic until the neurologic sequelae of white matter damage become apparent in later infancy as spasticity and/or motor deficits. PVL may be present at birth but usually occurs later, when the echodense phase is seen on ultrasound (3 to 10 days of life), followed by the typical echolucent/cystic phase (14 to 20 days).

DIAGNOSIS

Intracranial hemorrhage is suspected on the basis of history, clinical manifestations, and knowledge of the birthweight-specific risks for IVH. Associated clinical signs of IVH are typically nonspecific or absent. Neuroimaging recommendations that premature infants ≤30 weeks of gestation and selected infants with gestational age >30 weeks who are believed to be at increased risk for brain injury on the basis of identified risk factors should be screened for IVH with cranial ultrasonography. Standard ultrasonography screening includes views from the anterior and mastoid fontanelles. Additional posterior fontanelle and vascular imaging can be performed for additional information. Routine cranial ultrasonographic screening is recommended by 7 to 10 days of age, but earlier imaging may be warranted if clinical signs and symptoms are suggestive of significant injury. Repeat cranial ultrasonography screening is recommended to be performed at 4 to 6 weeks of age and at term equivalent age or before hospital discharge. CT is not considered a part of routine imaging techniques of the preterm brain. MRI for infants born ≤30 weeks gestational age is not indicated as a routine procedure, although could be offered to families of high-risk infants after a conversation about the limits of prognosticating long-term outcomes using MRI.

Sequential ultrasonography appears to have the best yield for identifying lesions associated with cerebral palsy. In one study, 29% of low birthweight (LBW) infants who later experienced cerebral palsy *did not* have radiographic evidence of PVL until after 28 days of age. Ultrasound also detects the precystic and cystic symmetric lesions of PVL and the asymmetric intraparenchymal echogenic lesions of cortical hemorrhagic infarction (Fig. 122.4). Cranial ultrasonography may be useful in monitoring delayed development of cortical atrophy, porencephaly, and the severity, progression, or regression of posthemorrhagic hydrocephalus (PHH).

PHH of prematurity is a common form of pediatric hydrocephalus, accounting for 20% of shunted hydrocephalus in the United States. Under normal conditions, CSF is primarily secreted into the cerebral ventricles by the choroid plexus and moves via bulk flow through the ventricular system and subarachnoid space before being absorbed at the arachnoid villi/granulations, which are fully developed after 35 weeks. An increase in CSF production or reduction in CSF absorption may result in ventricular enlargement if the system cannot compensate for the changes. Secondary white matter injury resulting from ventricular dilation is likely exacerbated by compression and ischemia from increased ICP of symptomatic PHH. Orbitofrontal head circumference, fontanel fullness, and the splaying of sutures all show limited reliability; therefore serial neuroimaging is highly valuable for clinical decision-making for neurosurgical intervention.

PROGNOSIS

The degree of IVH and presence of PVL are strongly linked to survival and neurodevelopmental impairment (Tables 122.1 and 122.2). For infants with birthweight <1,000 g, the incidence of severe neurologic impairment (defined as Bayley Scales of Infant Development IV mental developmental index <70, psychomotor development index <70, cerebral palsy, blindness, or deafness) after IVH is highest with grade IV hemorrhage and lower birthweight. PVL, cystic PVL, and progressive hydrocephalus requiring shunt insertion are each independently associated with a poorer prognosis (Table 122.3). The risk of a poor neurodevelopmental outcome is significantly higher when severe IVH is complicated with PHVD (40–60%) and more so for infants who eventually develop PHH (75–88%). In the pre-surfactant era, up to 82% of infants with PHH who survived developed significant neurologic impairments with cerebral palsy being the most common clinical sequelae (74%). The Drainage, Irrigation, Fibrinolytic Therapy (DRIFT) trial performed neurocognitive assessments at both 2 years and 10 years after birth and demonstrated improved cognitive ability when considering birthweight, IVH grade, and sex. Infants who received DRIFT were almost twice as likely to survive without severe cognitive disability than those who received standard treatment. The

Table 122.3 Ultrasound Diagnosis of Periventricular Leukomalacia

US APPEARANCE	TEMPORAL FEATURES	NEUROPATHOLOGIC CORRELATION
Echogenic foci, bilateral, posterior > anterior	First week	Necrosis with congestion and/or hemorrhage (size >1 cm)
Echolucent foci ("cysts")	1-3 weeks	Cyst formation secondary to tissue dissolution (size >3 mm)
Ventricular enlargement, often with disappearance of "cysts"	≥2-3 months	Deficient myelin formation; gliosis, often with collapse of cyst

From El-Dib M, Limbrick DD, Inder T, et al. Management of post-hemorrhagic ventricular dilation in the infant born preterm. *J Pediatr*. 2020;226:16–26. Fig. 5.

Early versus Late Ventricular Intervention Study (ELVIS) trial demonstrated the effectiveness of intervention at a low threshold of ventricular dilation on the outcomes of death and severe neurodevelopmental disability in preterm infants with PHVD. Post hoc analysis of this study demonstrated that infants who went on to having a shunt had better neurodevelopmental outcome scores if interventions were done at a lower threshold.

TREATMENT

No treatment is available for **IVH** once it has occurred, and the management is largely symptomatic. Seizures should be treated with anticonvulsant drugs. Anemia and coagulopathy require transfusion with packed red blood cells or fresh-frozen plasma. Shock and acidosis are treated with fluid resuscitation.

Insertion of a **ventriculoperitoneal shunt** is the preferred method to treat progressive and symptomatic **PHH**. Some infants require temporary CSF diversion before a permanent shunt can be safety inserted. Diuretics and acetazolamide are not effective. Ventricular access devices (reservoirs) and externalized ventricular drains are potential temporizing interventions, although there is an associated risk of infection and *puncture porencephaly* from injury to the surrounding parenchyma. A **ventriculosubgaleal shunt** inserted from the ventricle into a surgically created subgaleal pocket provides a closed system for constant ventricular decompression without these additional risk factors. Decompression is regulated by the pressure gradient between the ventricle and the subgaleal pocket.

One approach to therapeutic interventions is based on the severity of ultrasonographic dimensions of ventricular size (Table 122.4 and Fig. 122.5)

PREVENTION

Improved perinatal care is imperative to minimize traumatic brain injury and decrease the risk of preterm delivery. The incidence of traumatic intracranial hemorrhage may be reduced by judicious management of cephalopelvic disproportion and operative delivery. Fetal or neonatal hemorrhage caused by maternal idiopathic thrombocytopenic purpura or alloimmune thrombocytopenia may be reduced by maternal treatment with corticosteroids, intravenous immunoglobulin (IVIG), fetal platelet transfusion, or cesarean birth. Meticulous care of the VLBW infant's respiratory status and fluid-electrolyte

management—avoidance of acidosis, hypocarbia, hypoxia, hypotension, wide fluctuations in neonatal blood pressure or P_{CO_2} (and secondarily fluctuation in cerebral perfusion pressure), and pneumothorax—are important factors that may affect the risk for development of IVH and PVL.

The most important protective factor against the development of IVH is antenatal administration of corticosteroids. A single course of antenatal corticosteroids is recommended for pregnant people between 24 0/7 weeks and 36 6/7 weeks of gestation who are at risk for preterm delivery within 7 days. It also may be considered for pregnant people starting at 23 weeks of gestion who are at risk for preterm delivery within 7 days, based on the family's decision regarding resuscitation. A rescue course of corticosteroids could be provided as early as 7 days from the prior dose, if indicated by the clinical scenario. Antenatal administration of magnesium sulfate was not associated with a reduction in the incidence of IVH, although it has been associated with a reduction in the risk of cerebral palsy. Prophylactic indomethacin showed a significant reduction in the incidence of severe IVH; however, this reduction in severe IVH was not associated with a reduction in severe neurosensory impairment.

122.4 Hypoxic-Ischemic Encephalopathy

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

Hypoxemia, a decreased arterial concentration of oxygen, frequently results in **hypoxia**, or decreased oxygenation to cells or organs. **Ischemia** refers to blood flow to cells or organs that is inadequate to maintain physiologic function. **Hypoxic-ischemic encephalopathy (HIE)** is a leading cause of neonatal brain injury, morbidity, and mortality globally. In the developed world, incidence is estimated at 1-8 per 1,000 live births, and in the developing world, estimates are as high as 26 per 1,000.

Approximately 20–30% of infants with HIE (depending on the severity) die in the neonatal period, and 33–50% of survivors are left with permanent neurodevelopmental abnormalities (cerebral palsy, decreased intelligence quotient [IQ], learning/cognitive impairment). The greatest risk of adverse outcome is seen in infants with severe fetal acidosis (pH <6.7) (90% death/impairment) and a base deficit >25 mmol/L (72% mortality). Multiorgan failure and insult can occur (Table 122.5).

ETIOLOGY

Neonatal encephalopathy and seizures, in the absence of major congenital malformations or metabolic or genetic syndromes, appear to be caused by perinatal events. Brain MRI or autopsy findings in full-term neonates with encephalopathy demonstrate that 80% have acute injuries, <1% have prenatal injuries, and 3% have non–hypoxic-ischemic diagnoses. Fetal hypoxia may be caused by various disorders in the mother, including (1) inadequate oxygenation of maternal blood from hypoventilation during anesthesia, cyanotic heart disease, respiratory failure, or carbon monoxide poisoning; (2) low maternal blood pressure from acute blood loss, spinal anesthesia, or compression of the vena cava and aorta by the gravid uterus; (3) inadequate relaxation of the uterus to permit placental filling as a result of uterine tetany caused by the administration of excessive oxytocin; (4) premature separation of the placenta; (5) impedance to the circulation of blood through the umbilical cord as a result of compression or knotting of the cord; and (6) placental insufficiency from maternal infections, exposures, diabetes, toxemia or postmaturity.

Table 122.5 Multiorgan Systemic Effects of Asphyxia

SYSTEM	EFFECTS
Central nervous	Hypoxic-ischemic encephalopathy, infarction, intracranial hemorrhage, seizures, cerebral edema, hypotonia, hypertonia
Cardiovascular	Myocardial ischemia, poor contractility, cardiac stunning, tricuspid insufficiency, hypotension
Pulmonary	Pulmonary hypertension, pulmonary hemorrhage, respiratory distress syndrome
Renal	Acute tubular or cortical necrosis
Adrenal	Adrenal hemorrhage
Gastrointestinal	Perforation, ulceration with hemorrhage, necrosis
Metabolic	Inappropriate secretion of antidiuretic hormone, hyponatremia, hypoglycemia, hypocalcemia, myoglobinuria
Integumentary	Subcutaneous fat necrosis
Hematologic	Disseminated intravascular coagulation

Table 122.6 Topography of Brain Injury in Term Infants with Hypoxic-Ischemic Encephalopathy and Clinical Correlates

AREA OF INJURY	LOCATION OF INJURY	CLINICAL CORRELATES	LONG-TERM SEQUELAE
Selective neuronal necrosis	Entire neuraxis, deep cortical area, brainstem and pontosubicular	• Stupor or coma • Seizures • Hypotonia • Oculomotor abnormalities • Suck/swallow abnormalities	• Cognitive delay • Cerebral palsy • Dystonia • Seizure disorder • Ataxia • Bulbar and pseudobulbar palsy
Parasagittal injury	Cortex and subcortical white matter Parasagittal regions, especially posterior	• Proximal-limb weakness • Upper extremities affected > lower extremities	• Spastic quadriparesis • Cognitive delay • Visual and auditory processing difficulty
Focal ischemic necrosis	Cortex and subcortical white matter Vascular injury (usually middle cerebral artery distribution)	• Unilateral findings • Seizures common and typically focal	• Hemiparesis • Seizures • Cognitive delays
Periventricular injury	Injury to motor tracts, especially lower extremity	• Bilateral and symmetric weakness in lower extremities • More common in preterm infants	• Spastic diplegia

Adapted from Volpe JJ, ed. *Neurology of the Newborn*. 4th ed. Philadelphia: Saunders; 2001.

Placental insufficiency often remains undetected on clinical assessment. Intrauterine growth restriction may develop in chronically hypoxic fetuses without the traditional signs of fetal distress. Doppler umbilical waveform velocimetry (demonstrating increased fetal vascular resistance) and cordocentesis (demonstrating fetal hypoxia and lactic acidosis) identify a chronically hypoxic infant (see Chapter 117). Uterine contractions may further reduce umbilical oxygenation, depressing the fetal cardiovascular system and CNS and resulting in low Apgar scores and respiratory depression at birth.

After birth, hypoxia may be caused by (1) failure of oxygenation as a result of severe forms of cyanotic congenital heart disease or severe pulmonary disease; (2) severe anemia (severe hemorrhage, hemolytic disease); (3) shock severe enough to interfere with the transport of oxygen to vital organs from overwhelming sepsis, massive blood loss, and intracranial or adrenal hemorrhage; or (4) failure to breathe after birth because of in utero CNS injury or drug-induced suppression.

PATHOPHYSIOLOGY AND PATHOLOGY

The topography of cerebral injury typically correlates with areas of decreased cerebral blood flow and areas of relatively higher metabolic demand, although regional vulnerabilities are impacted by gestational age and severity of insult (Table 122.6). After an episode of hypoxia and ischemia, anaerobic metabolism occurs and generates increased amounts of lactate and inorganic phosphates. Excitatory and toxic amino acids, particularly glutamatergic mechanism has a role in neurotoxicity. Whether this mechanism involves tissue accumulation of an abnormal amount of glutamate or altered sensitivity to the interaction between glutamate and its endogenous family of receptors (i.e., *N*-methyl-D-aspartate [NMDA], amino-3-hydroxy-5-methyl-4-isoxazole propionate [AMPA], and kainite) is unknown. However, receptor activation results in a cascade of events that leads to cell death by swelling (oncosis) or apoptosis. Along with these changes in the CNS, there are also potentially exacerbating bioenergetic changes as a result of the circulatory response with increased shunting through the ductus venosus, ductus arteriosus, and foramen ovale, at first trying to maintain perfusion of the brain, heart, and adrenal glands in preference to the lungs, liver, kidneys, and intestine.

The pathology of hypoxia-ischemia in tissues outside the CNS depends on the affected organ and the severity of the injury. Early congestion, fluid leak from increased capillary permeability, and endothelial cell swelling may lead to signs of coagulation necrosis and cell death. Congestion and petechiae are seen in the pericardium, pleura, thymus, heart, adrenals, and meninges. Prolonged intrauterine hypoxia may result in inadequate perfusion of the periventricular white matter, resulting in PVL. Pulmonary arteriole smooth muscle hyperplasia may develop, which predisposes the infant to pulmonary hypertension (see Chapter 130). If fetal distress produces gasping, amniotic fluid contents (i.e., meconium, desquamation products, lanugo) may be aspirated into the trachea or lungs with subsequent complications, including pulmonary hypertension and pneumothoraces.

Table 122.7 Poor Predictive Variables for Death/Disability After Hypoxic-Ischemic Encephalopathy

- Low (0-3) 10 min Apgar score
- Need for CPR in the delivery room
- Delayed onset (≥20 min) of spontaneous breathing
- Severe neurologic signs (coma, hypotonia, hypertonia)
- Seizures onset ≤12 hr or difficult to treat
- Severe, prolonged (~7 days) EEG findings including burst suppression pattern
- Prominent MRI basal ganglia/thalamic lesions
- Oliguria/anuria >24 hr
- Abnormal neurologic exam ≥14 days

CPR, Cardiopulmonary resuscitation; EEG, electroencephalogram.

CLINICAL MANIFESTATIONS

At delivery, the presence of meconium-stained amniotic fluid indicates that fetal distress may have occurred. At birth, affected infants may have neurologic impairment and may fail to breathe spontaneously. Pallor, cyanosis, apnea, a slow heart rate, and unresponsiveness to stimulation are also nonspecific initial signs of potential HIE. During the ensuing hours, infants may be hypotonic, may change from a hypotonic to a hypertonic state, or their tone may appear normal (Tables 122.7 and 122.8). Cerebral edema may develop during the next 24 hours and result in profound brainstem depression. During this time, seizure activity may occur; seizures may be severe and refractory to standard doses of anticonvulsants. Although most often a result of the HIE, seizures in asphyxiated newborns may also be caused by vascular events (hemorrhage, arterial ischemic stroke, or sinus venous thrombosis), metabolic derangements (hypocalcemia, hypoglycemia), CNS infection, and cerebral dysgenesis or genetic disorders (nonketotic hyperglycinemia, vitamin-dependent epilepsies, channelopathies). Congenital conditions that result in neuromuscular weakness and poor respiratory effort may also result secondarily in neonatal hypoxic brain injury and seizure. Such conditions might include congenital myopathies, congenital myotonic dystrophy, or spinal muscular atrophy.

In addition to CNS dysfunction, systemic organ dysfunction is noted in up to 80% of affected neonates. Myocardial dysfunction and

Table 122.8 Hypoxic-Ischemic Encephalopathy in Term Infants

SIGNS	STAGE 1 (MILD)	STAGE 2 (MODERATE)	STAGE 3 (SEVERE)
Level of consciousness	Hyperalert, responds to minimal stimuli	Lethargic	Stuporous, coma
Spontaneous activity	Normal or decreased	Decreased	None
Posture	Mild flexion of distal joints (fingers, wrist)	Distal flexion or complete extension	Decerebrated
Tone	Normal	Hypotonia (focal or general) or hypertonia	Flaccid or rigid
PRIMITIVE REFLEXES	1	2	3
Suck	Weak or incomplete	Weak or bite	Absent
Moro reflex	Intact, low threshold	Incomplete	Absent
AUTONOMIC NERVOUS SYSTEM	1	2	3
Pupils	Mydriasis	Miosis	Variable or nonreactive
Heart rate	Tachycardia	Bradycardia	Variable heart rate
Respirations	Hyperventilation	Periodic breathing	Apnea or requiring ventilation
Seizures	None	Common	Decerebration
Electroencephalographic findings	Normal	Low voltage changing to seizure activity	Burst suppression to isoelectric
Duration	<24 hr if progresses; otherwise, may remain normal	24 hr to 14 days	Days to weeks
Outcome	Good	Variable	Death, severe deficits

Adapted from Chalak L, Latremouille S, Mir I, Sánchez PJ, Sant'Anna G. A review of the conundrum of mild hypoxic-ischemic encephalopathy: current challenges and moving forward. *Early Hum Dev.* 2018;120:88–94.

cardiogenic shock, persistent pulmonary hypertension, RDS, gastrointestinal perforation, and acute kidney and liver injury are associated with perinatal asphyxia secondary to inadequate perfusion (see Table 122.5).

The severity of neonatal encephalopathy depends on the duration and timing of injury. The need to define severity is rooted in the need to determine eligibility for *therapeutic hypothermia*, a treatment that decreases death and disability in moderate to severe HIE. A clinical grading score first proposed by Sarnat and colleagues continues to be a useful tool. Symptoms develop over hours and days, making it important to perform serial neurologic examinations (see Tables 122.7 and 122.8). Infants with moderate to severe HIE are characterized by disturbed neurologic function, altered level of consciousness, depressed tone, abnormal reflexes, and difficulty maintaining spontaneous respirations, and seizures. An empirically validated definition of mild HIE within 6 hours uses two steps: the first step is screening for fetal acidosis and acute perinatal events, and the second step has an examiner use a modified Sarnat scoring, which is expanded to include mild in addition to moderate and severe abnormalities.

DIAGNOSIS

MRI is the most sensitive imaging modality for detecting hypoxic brain injury in the neonate. Although such injury can be detected at various times and with varying pulse sequences, diffusion-weighted sequences obtained in the first 3-5 days following a presumed sentinel event are optimal for identifying acute injury (Figs. 122.6-122.9 and Table 122.9). Severe HIE is characterized on MRI by a central pattern injury that includes the thalamus, posterior limb of the internal capsule, and hippocampus with the most severe HIE resulting in involvement of the entire cortex. Magnetic resonance spectroscopy performed within first 24 hours after birth in a full-term infant is very sensitive to the severity of HIE-related brain injury. Elevated lactate/creatine ratio on day 1 of life is a predictor of adverse neurologic outcome, whereas absence of lactate predicts a normal outcome. Where MRI is unavailable or prevented by clinical instability, brain CT scans may be helpful in ruling out focal hemorrhagic lesions or large arterial ischemic strokes. Loss of gray-white differentiation and injury to the basal ganglia in more severe HIE can be detected on CT by experienced readers, but CT often misses more subtle forms of neonatal hypoxic brain injury and results in significant radiation exposure. Ultrasound has limited utility in evaluation of hypoxic injury in the term infant, but it too can be useful for excluding hemorrhagic lesions or hydrocephalus. Because of factors of size and clinical stability, ultrasound is the initial preferred (and sometimes only feasible) modality in evaluation of the preterm infant.

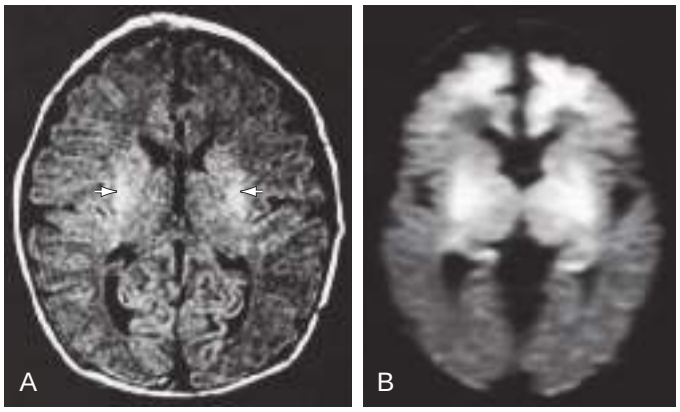

Fig. 122.6 MR images of selective neuronal injury. The infant experienced intrapartum asphyxia and had seizures on the first postnatal day. MRI was performed on the fifth postnatal day. **A,** Axial, fluid-attenuated, inversion recovery image shows increased signal in the putamen bilaterally *(arrows)* but no definite abnormality in the cerebral cortex. **B,** By contrast, a diffusion-weighted image shows striking increased signal intensity (i.e., decreased diffusion) in the frontal cortex (in addition to a more pronounced basal ganglia abnormality). (*From Volpe JJ, ed. Neurology of the Newborn. 5th ed. Philadelphia: Saunders; 2008. p. 420.*)

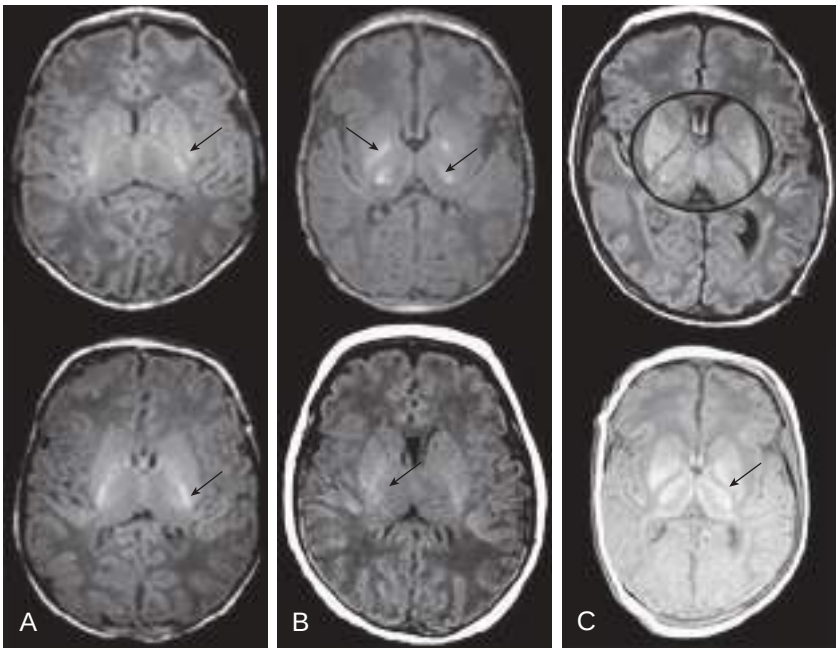

Fig. 122.7 MR images of basal ganglia/thalamic (BG/T) injury and signal intensity. *Top row,* Axial T1 weighted MR images showing mild BG/T lesions *(arrow)* **(A)**, moderate BG/T injury *(arrows)* **(B)**, and severe BG/T abnormalities *(circled)* **(C).** *Bottom row,* Axial T1 weighted MR images showing normal signal intensity (SI) in the posterior limb of the internal capsule (PLIC) *(arrow)* **(A),** equivocal, asymmetric, and slightly reduced SI in the PLIC *(arrow)* **(B),** and abnormal, absent SI in the PLIC *(arrow)* **(C).** (*From Martinez-Biarge M, Diez-Sebastian J, Rutherford MA, Cowan FM. Outcomes after central grey matter injury in term perinatal hypoxic-ischaemic encephalopathy. Early Hum Dev. 2010;86:675–682.*)

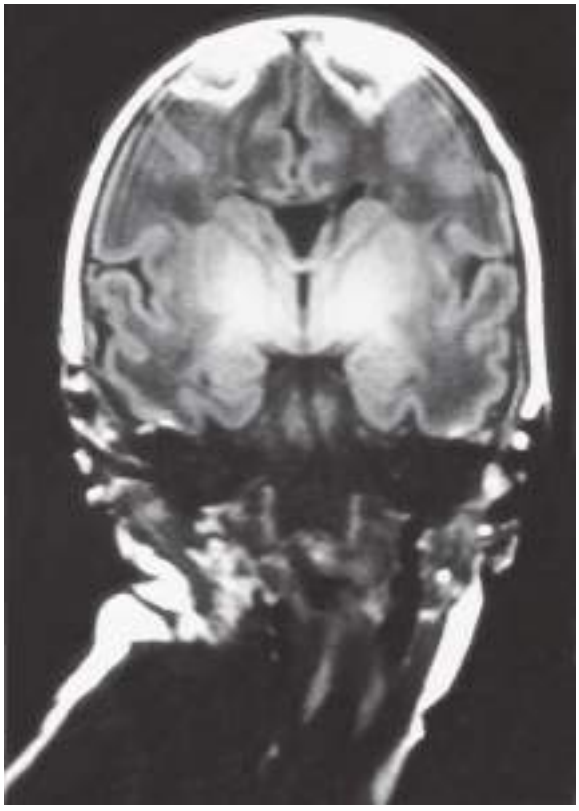

Fig. 122.8 MR image of a parasagittal cerebral injury. Coronal T1 weighted image, obtained on the fifth postnatal day in an asphyxiated term infant, shows striking triangular lesions in the parasagittal areas bilaterally; increased signal intensity is also apparent in the basal ganglia and thalamus bilaterally. (*From Volpe JJ, ed. Neurology of the Newborn. 5th ed. Philadelphia: Saunders; 2008. p. 421.*)

Neurophysiology Studies

Monitoring the brain of the sick newborn infant in the NICU using either multichannel electroencephalography (EEG) or limited channel amplitude integrated EEG (aEEG) may help to determine which infants are at highest risk for developmental sequelae of neonatal brain injury (Tables 122.10 and 122.11). Multichannel EEG with video is the gold standard for monitoring newborn brain function; at least 24-hour monitoring is recommended for infants at risk for seizures. The neonatal EEG contains complex spatiotemporal information and can be difficult to interpret, requiring many years in neurophysiology training. As a result, in many NICUs, EEG signal processing of a limited number of channels, with a more accessible method of data presentation, has been adopted (aEEG). Even in the absence of obvious seizures, a 24-hour multichannel EEG recording is recommended and, in infants undergoing hypothermia therapy, 72 hours is optimal to cover duration of intervention. It is known that EEG in HIE evolves following the primary HIE injury and that EEG monitoring is essential to assess this evolution and recovery. Description of EEG background grades and seizures in HIE include normal trace, which is a normal amplitude with sleep–wake cycling; mildly abnormal trace, which is a period of low amplitude and lack of sleep–wake cycling; moderately abnormal trace, which is periods of discontinuity <10 seconds; and severely abnormal trace with burst suppression pattern and discontinuity of activity for 10-60 seconds (Fig. 122.10). An aEEG is a good option if multichannel EEG is not available. The signal from biparietal electrodes is smoothed and the amplitude integrated and shows the baseline background electrical activity. A voltage classification scheme for aEEG use in HIE has been developed as follows: normal voltage (5-10 μV) and abnormal voltage (lower margin <5 μV and upper margin >10 μV).

TREATMENT

Therapeutic hypothermia, whether head cooling or systemic cooling (by servo-control to a core rectal or esophageal temperature of 33.5°C [92.3°F] within the first 6 hours after birth and maintained for 72 hours) has been shown to reduce mortality and major neurodevelopmental impairment at 18 months of age. Infants treated with systemic hypothermia have a lower incidence of cortical neuronal injury on MRI, suggesting systemic hypothermia may result in more uniform cooling of the brain and deeper CNS structures than selective head cooling. The therapeutic effect of hypothermia likely results from decreased secondary neuronal injury achieved by reducing rates of apoptosis and production of mediators related to neurotoxicity. There is also benefit in seizure reduction. The therapeutic benefit of hypothermia noted at 18-22 months of age is maintained later in childhood. Once established, hypothermia may not alter the prognostic findings on MRI.

Numerous studies seeking ways to extend the benefits of therapeutic hypothermia have been attempted. The foundational clinical trials of therapeutic hypothermia had strict treatment protocols and excluded infants born before 35 or 36 weeks completed gestational weeks, those weighing <1,800 g, and infants with major congenital abnormality. Practice variation exists for offering therapeutic hypothermia to infants

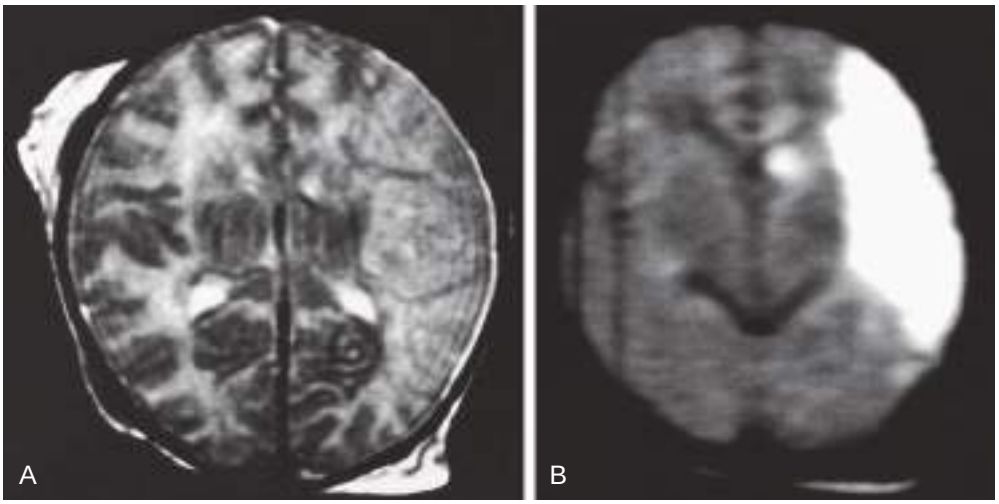

Fig. 122.9 MR images of focal ischemic cerebral injury. MRI was performed on the third postnatal day. **A,** Axial T2 weighted image shows a lesion in the distribution of the main branch of the left middle cerebral artery. **B,** Diffusion-weighted image demonstrates the lesion more strikingly. (*From Volpe JJ, ed. Neurology of the Newborn. 5th ed. Philadelphia: Saunders; 2008. p. 422.*)

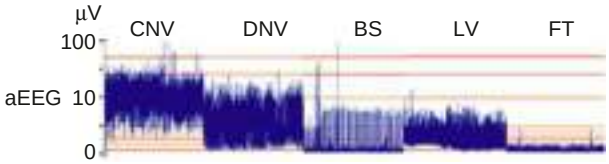

Fig. 122.10 Amplitude EEG patterns. Patterns are highlighted with pattern classification (continuous normal voltage [CNV], discontinuous normal voltage [DNV], burst suppression [BS], low voltage [LV], flat tracings [FT]). Table 122.9 Major Aspects of MRI in Diagnosis of Hypoxic-Ischemic Encephalopathy in the Term Infant

MAJOR CONVENTIONAL MR FINDINGS IN FIRST WEEK

- Cerebral cortical gray-white differentiation lost (on T1W or T2W)
- Cerebral cortical high signal (T1W and FLAIR), especially in parasagittal peri-rolandic cortex
- Basal ganglia/thalamus, high signal (T1W and FLAIR), usually associated with the cerebral cortical changes but possibly alone with increased signal in brainstem tegmentum in cases of acute severe insult
- Parasagittal cerebral cortex, subcortical white matter, high signal (T1W and FLAIR)
- Periventricular white matter, decreased signal (T1W) or increased signal (T2W)
- Posterior limb of internal capsule, decreased signal (T1W or FLAIR)
- Cerebrum in a vascular distribution, decreased signal (T1W), but much better visualized as decreased diffusion (increased signal) on diffusion-weighted MRI
- **Diffusion-weighted MRI** more sensitive than conventional sequences in MRI, especially in first days after birth, when former shows decreased diffusion (increased signal) in injured areas

FLAIR, Fluid-attenuated inversion recovery; T1W and T2W, T1 weighted and T2 weighted images.
From Volpe JJ, ed. *Neurology of the Newborn.* 5th ed. Philadelphia: Elsevier; 2008: Table 9-16.

Table 122.10 Value of Electroencephalography in Assessment of Asphyxiated Term Infants

- Detection of severe abnormalities (i.e., CLV, FT, BSP) in first hours of life has a positive predictive value of an unfavorable outcome of 80–90%.
- Severe abnormalities may improve within 24 hr (~50% of BSP and 10% of CLV/FT).
- Rapid recovery of severe abnormalities is associated with a favorable outcome in 60% of cases.
- The *combination* of early neonatal neurologic examination and early aEEG enhances the positive predictive value and specificity.

aEEG, Amplitude integrated encephalography; BSP, burst suppression pattern; CLV, continuous low voltage; FT, flat trace.
From Inder TE, Volpe JJ. Hypoxic-ischemic injury in the term infant: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In: Volpe JJ, Inder TE, Darras BT, et al., eds. *Volpe's Neurology of the Newborn.* 6th ed. Philadelphia: Elsevier; 2018: Table 20-28.

who do not meet the original study criteria, although debate for these practices also exist. A multicenter randomized clinical trial investigating the benefit of use of therapeutic hypothermia beyond 6 hours after birth reported a modest and "nonconclusive" effect. Importantly, this study extended the duration of hypothermia from 72 to 96 hours based on preclinical data suggesting that a longer period of treatment was needed at later initiation times. Assessment of deeper or longer cooling failed to show benefit in short-term outcomes, and its use is not supported by evidence nor clinically justifiable. Multicenter clinical trials are underway to assess the use of therapeutic hypothermia in preterm infants born between 33 and 35 weeks' gestation. The term "major congenital anomalies" in the original trials lead to the exclusion of numerous conditions with a favorable prognosis for survival and neurodevelopment, including trisomy 21. Unless the identified anomaly specifically imparts a medical contraindication to therapeutic hypothermia, the infant is moribund, or treatment does not align with the broader goals of care for the infant, categorical exclusion of the infant from therapeutic hypothermia solely based on the presence of one or more major congenital anomalies is likely not ethically justifiable. There have been few studies to investigate the use of therapeutic hypothermia in neonates who are beyond the perinatal period. Presently, clinical research on "targeted temperature management" in infants has been done in the pediatric intensive care setting and has little applicability to NICUs.

Complications of induced hypothermia include thrombocytopenia (usually without bleeding), reduced heart rate, and subcutaneous fat necrosis (sometimes with associated hypercalcemia) as well as the potential for overcooling and the **cold injury syndrome**. The latter is usually avoided with a servo-controlled cooling system. Therapeutic hypothermia may theoretically alter drug metabolism, prolong the QT interval, and affect the interpretation of blood gases. In clinical practice, these concerns have not been observed.

For treating seizures associated with HIE, phenobarbital continues to be used in many instances. It is typically given by intravenous loading dose (20 mg/kg). Additional doses of 5-10 mg/kg (up to 40-50 mg/kg total) may be needed. Phenobarbital levels should be monitored 24 hours after the loading dose has been given and maintenance therapy (5 mg/kg/24 hr) begun. Therapeutic phenobarbital levels are 20-40 μg/mL.

For refractory seizures, there is a high degree of variability regarding choice of a second agent. Historically, phenytoin (20 mg/kg loading dose) or lorazepam (0.1 mg/kg) have been preferred, but currently the use of levetiracetam is preferred (at times even as a first-line agent) as a second-line agent. Pharmacokinetic data suggest that due to the higher volume of distribution created by higher relative body water content in neonates, loading doses should be higher than in older children or adults. Suggested appropriate loading doses may be closer to 60 mg/kg. In addition to levetiracetam and phenytoin, other second- or third-line agents commonly used include midazolam, topiramate, and lidocaine. Pyridoxine should also be attempted, particularly in ongoing refractory seizures with highly abnormal EEG background. Status epilepticus, multifocal seizures, and need for multiple anticonvulsant medications during therapeutic hypothermia are associated with a poor prognosis.

Additional therapy for infants with HIE includes supportive care directed at management of organ system dysfunction. Hyperthermia has been associated with impaired neurodevelopment and should be prevented, particularly in the interval between initial resuscitation and initiation of hypothermia. Careful attention to ventilatory status and adequate oxygenation, blood pressure, hemodynamic status, acid-base balance, and possible infection is important. Secondary hypoxia or hypotension from complications of HIE must be prevented. Aggressive treatment of seizures is critical and may necessitate continuous EEG monitoring. In addition, hyperoxia, hypocarbia, and hypoglycemia are associated with poor outcomes, so careful attention to resuscitation, ventilation, and blood glucose homeostasis is essential.

PROGNOSIS

The outcome of HIE ranges from complete recovery to death. The prognosis varies depending on the severity of the insult and the treatment. Infants with initial cord or initial (~1 hour of age) blood pH <6.7 have a 90% risk for death or severe neurodevelopmental impairment at 18 months of age. In addition, infants with Apgar scores of 0-3 at 5 minutes, high base deficit (>20-25 mmol/L), decerebrate posture, severe basal ganglia/thalamic (BG/T) lesions (Fig. 122.11; see also Fig. 122.7), persistence of severe HIE by clinical examination at 72 hours, and lack of spontaneous activity are also at increased risk for death or impairment. These predictor variables can be combined to determine a score that helps with prognosis (see Table 122.7). Infants with the highest risk are likely to die or have severe disability despite aggressive treatment, including hypothermia. Those with intermediate scores are likely to benefit from treatment. In general, severe encephalopathy, characterized by flaccid coma, apnea, absence of oculocephalic reflexes, and refractory seizures, is associated with a poor prognosis (see Table 122.8). Apgar scores alone in patients with HIE can also be associated with subsequent risk of neurodevelopmental impairment. At 10 minutes, each point decrease in Apgar score increases odds of death or disability by 45%. Death or disability occurs in 76–82% of infants with HIE with Apgar scores of 0-2 at 10 minutes. Absence of spontaneous respirations at 20 minutes of age and persistence of abnormal neurologic signs at 2 weeks of age also predict death or severe cognitive and motor deficits.

The combined use of early multichannel EEG or aEEG and MRI offers additional insight in predicting outcome in term infants with HIE (see Table 122.11). EEG or aEEG background characteristics such as pattern, voltage, reactivity, state change, and evolution after acute injury are important predictors of outcome. MRI markers include location of injury, identification of injury by certain pulse sequences, measurement of diffusivity and/or fractional anisotropy, and presence of abnormal metabolite ratios on MR spectroscopy, and all have shown

Table 122.11 Electroencephalographic Patterns of Prognostic Significance in Asphyxiated Term Infants*

ASSOCIATED WITH FAVORABLE OUTCOME
Mild depression (or less) on day 1
Normal background by day 7
ASSOCIATED WITH UNFAVORABLE OUTCOME
Predominant interburst interval >20 sec on any day
Burst suppression pattern on any day
Isoelectric tracing on any day
Mild (or greater) depression after day 12

*Associations with favorable or unfavorable outcome are generally ≥90%, but the clinical context must be considered.

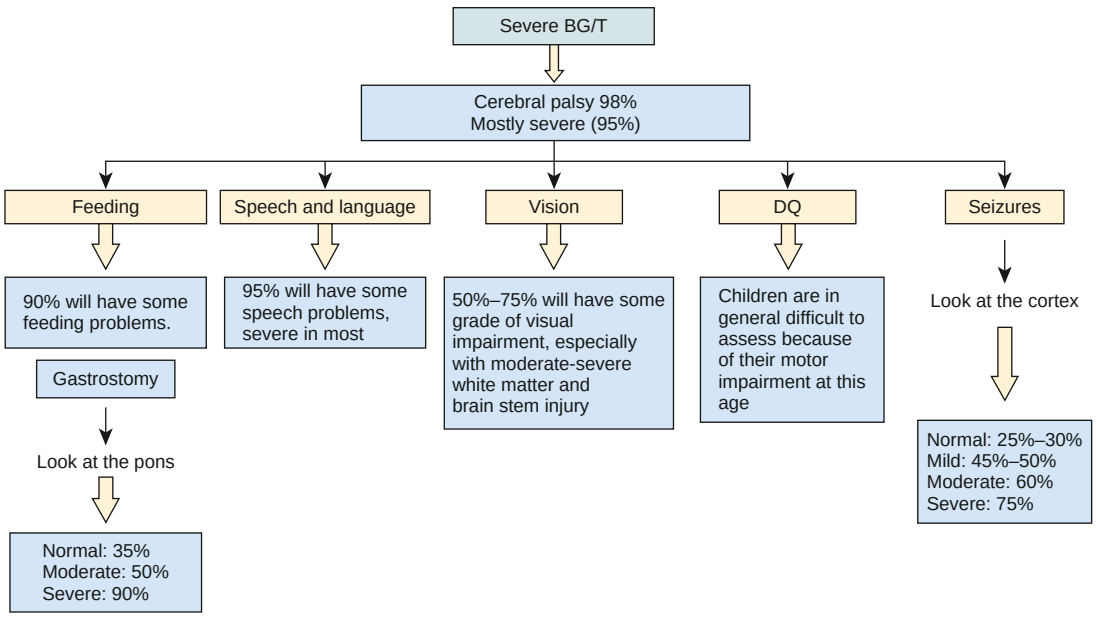

Fig. 122.11 Flow chart showing patterns of outcome with severe basal ganglia/thalamic (BG/T) injury. DQ, Developmental quotient. (*From Martinez-Biarge M, Diez-Sebastian J, Rutherford MA, Cowan FM. Outcomes after central grey matter injury in term perinatal hypoxic-ischaemic encephalopathy. Early Hum Dev. 2010;86:675–682.*)

correlation with outcome. Severe BG/T lesions with abnormal signal in the posterior limb of the internal capsule are highly predictive of the poorest cognitive and motor prognosis (see Fig. 122.11). Normal MRI and EEG findings are associated with a good recovery.

Microcephaly and poor head growth during the first year of life also correlate with injury to the BG/T and white matter and adverse developmental outcome at 12 months. All survivors of moderate to severe encephalopathy require comprehensive high-risk medical and developmental follow-up. Early identification of neurodevelopmental problems allows prompt referral for developmental, rehabilitative, and neurologic early intervention services so that the best possible outcomes can be achieved.

Brain death (death by neurologic criteria) after neonatal HIE is diagnosed from the clinical findings of coma unresponsive to pain, auditory, or visual stimulation; apnea with P_{CO_2} rising from 40 to >60 mm Hg without ventilatory support; and absence of brainstem reflexes (pupillary, oculocephalic, oculovestibular, corneal, gag, sucking) (see Chapter 83). These findings must occur in the absence of hypothermia, hypotension, and elevations of depressant drugs (phenobarbital), which may take days to be metabolized and cleared completely from the blood. In the term infant, the national guideline for determination should be followed. There is no agreement on such criteria in the preterm infants. Consideration of withdrawal of life support must include discussions with the family and the healthcare team, and, if there is disagreement, an ethics committee. The best interest of the infant involves judgments about the benefits and harm of continuing therapy or avoiding ongoing futile therapy.

122.5 Spine and Spinal Cord

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

See also Chapter 751.

Injury to the spine/spinal cord during birth is rare but can be devastating. Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral, or forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, especially when combined with flexion and torsion of the vertical axis, may produce fracture and separation of the vertebrae. Such injuries are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations. The injury occurs most often at the level of the 4th cervical vertebra with cephalic presentations and the lower cervical–upper thoracic vertebrae with breech presentations. Transection of the cord may occur *with or without* vertebral fractures; hemorrhage and edema may produce neurologic signs that are indistinguishable from those of transection, except that they may not be permanent. Areflexia, loss of sensation, and complete paralysis of voluntary motion occur below the level of injury, although the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion.

If the injury is severe, the infant, who from birth may be in poor condition because of respiratory depression, shock, or hypothermia, may deteriorate rapidly to death within several hours before any neurologic signs are obvious. Alternatively, the course may be protracted, with symptoms and signs appearing at birth or later in the first week; Horner syndrome, immobility, flaccidity, and associated brachial plexus injuries may not be recognized for several days. Constipation may also be present. Some infants survive for prolonged periods, their initial flaccidity, immobility, and areflexia being replaced after several weeks or months by rigid flexion of the extremities, increased muscle tone, and spasms. Apnea on day 1 and poor motor recovery by 3 months are poor prognostic signs.

The **differential diagnosis** of neonatal spine/spinal cord injury includes amyotonia congenita and myelodysplasia associated with spina bifida occulta, spinal muscular atrophy (type 0), spinal vascular malformations (e.g., arteriovenous malformation causing hemorrhage or stroke), and congenital structural anomalies (syringomyelia, hemangioblastoma). Ultrasound or MRI confirms the diagnosis. Treatment of the survivors is supportive, including home ventilation; patients often remain permanently disabled. When a fracture or dislocation is causing spinal compression, the prognosis is related to the time elapsed before the compression is relieved.

122.6 Peripheral Nerve Injuries

Susan S. Cohen, Alicia J. Sprecher, and Krishna K. Acharya

See also Chapter 753.

BRACHIAL PALSY

Brachial plexus injury is a common problem, with an incidence of 0.6-4.6 per 1,000 live births. Injury to the brachial plexus may cause paralysis of the upper part of the arm with or without paralysis of the forearm or hand or, more often, paralysis of the entire arm. These injuries occur in macrosomic infants and when lateral traction is exerted on the head and neck during delivery of the shoulder in a vertex presentation, when the arms are extended over the head in a breech presentation, or when excessive traction is placed on the shoulders. The primary risk factor for brachial plexus injuries are shoulder dystocia and macrosomia (birthweight >4,000 g).

Erb-Duchenne paralysis results from injury to the nerve roots of the 5th and 6th cervical nerves, with the 7th affected in 50% of instances. The infant loses the power to abduct the arm from the shoulder, rotate the arm externally, and supinate the forearm. The characteristic position consists of adduction and internal rotation of the arm with pronation of the forearm, often described as the "waiter's tip hand." Power to extend the forearm is retained, but the biceps reflex is absent; the Moro reflex is absent on the affected side (Fig. 122.12). The outer aspect of the arm may have some sensory impairment. Power in the forearm and hand grasps is preserved unless the lower part of the plexus is also injured; the presence of hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve (in about 5% of patients), alteration in diaphragmatic excursion may be observed with ultrasound, fluoroscopy, or as asymmetric elevation of the diaphragm on chest radiograph.

Klumpke paralysis is a rare form of brachial palsy in which injury to the 7th and 8th cervical nerves and the 1st thoracic nerve produces a paralyzed hand and ipsilateral ptosis and miosis **(Horner syndrome)** if the sympathetic fibers of the first thoracic root are also injured. The incidence is as low as 0.6%, and some suggest the reason for this is modern obstetric practice and a sharp decline in the vaginal breech deliveries where there is a risk of hyperabduction of the arms. Mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury; from fracture, dislocation, or epiphyseal separation of the humerus; and from fracture of the clavicle. MRI demonstrates nerve root rupture or avulsion.

Most patients have full recovery. If the paralysis was a result of edema and hemorrhage around the nerve fibers, function should return within a few months; if it resulted from laceration, permanent damage may result. Involvement of the deltoid is usually the most serious problem and may result in **shoulder drop** secondary to muscle atrophy. In general, paralysis of the upper part of the arm has a better prognosis than paralysis of the lower part.

Treatment for **peripheral nerve injuries** consists of initial conservative management with monthly follow-up and a decision for surgical intervention by 3 months if function has not improved. Partial immobilization and appropriate positioning are used to prevent the development of contractures. In upper arm paralysis, the arm should be abducted 90 degrees with external rotation at the shoulder, full supination of the forearm, and slight extension at the wrist with the palm turned toward the face. This position may be achieved with a brace or splint during the first 1-2 weeks. Immobilization should be intermittent throughout the day while the infant is asleep and between

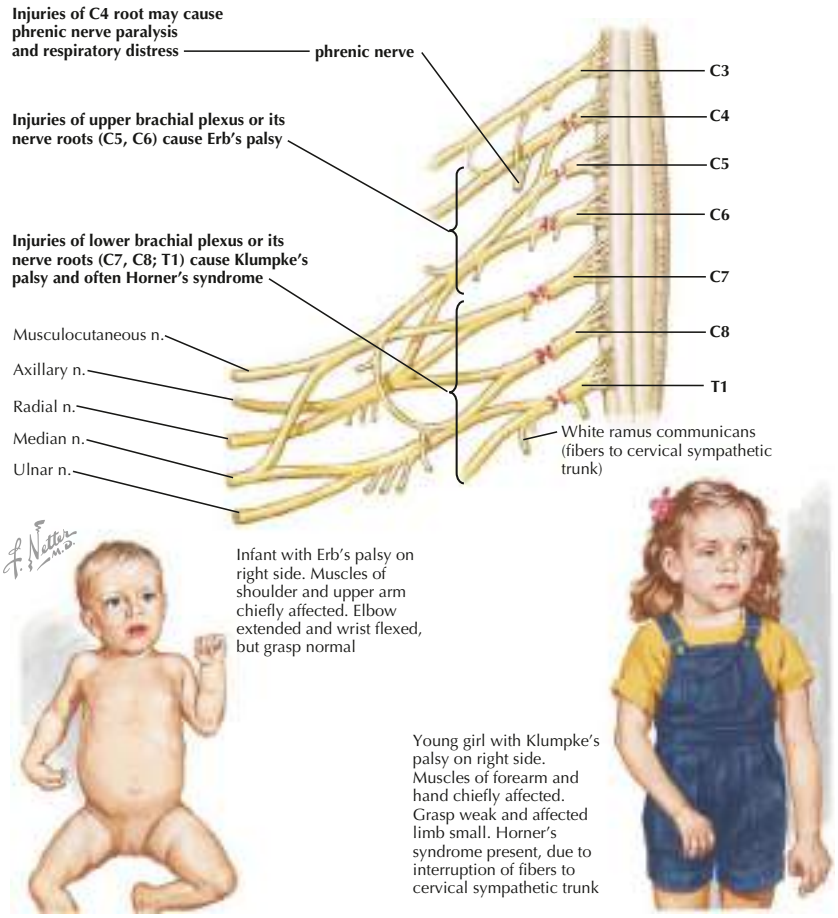

Fig. 122.12 Schematic representation of the brachial plexus with its terminal branches. The major sites of brachial plexus injury are shown. (*Courtesy Netter Images, Image ID 19943. www.netterimages.com.*)

feedings. In lower arm or hand paralysis, the wrist should be splinted in a neutral position and padding placed in the fist. When the entire arm is paralyzed, the same treatment principles should be followed. Gentle massage and range-of-motion exercises may be started by 7-10 days of age. Infants should be closely monitored with active and passive corrective exercises. If the paralysis persists without improvement for 3 months, neuroplasty, neurolysis, end-to-end anastomosis, and nerve grafting offer hope for partial recovery.

The type of treatment and the prognosis depend on the mechanism of injury and the number of nerve roots involved. The mildest injury to a peripheral nerve **(neurapraxia)** is caused by edema and heals spontaneously within a few weeks. **Axonotmesis** is more severe and is a consequence of nerve fiber disruption with an intact myelin sheath; function usually returns in a few months. Total disruption of nerves **(neurotmesis)** or root avulsion is the most severe, especially if it involves C5-T1; microsurgical repair may be indicated. Fortunately, most (75%) injuries are at the root level C5-C6, involve neurapraxia and axonotmesis, and should heal spontaneously. Botulism toxin may be used to treat biceps-triceps co-contractions.

PHRENIC NERVE PARALYSIS

Phrenic nerve injury (3rd, 4th, 5th cervical nerves) with diaphragmatic paralysis must be considered when cyanosis and irregular and labored respirations develop. Such injuries, usually unilateral, are associated with ipsilateral upper brachial plexus palsies in 75% of cases. Because breathing is thoracic in type, the abdomen does not bulge with inspiration. Breath sounds are diminished on the affected side. The thrust of the diaphragm, which may often be felt just under the costal margin on the normal side, is absent on the affected side. The diagnosis is established by ultrasound or fluoroscopic examination, which reveals elevation of the diaphragm on the paralyzed side and seesaw movements of the two sides of the diaphragm during respiration. It may also be apparent on chest or abdominal radiograph.

Infants with phrenic nerve injury should be placed on the involved side and given oxygen if necessary. Some may benefit from pressure introduced by continuous positive airway pressure (CPAP) to expand the paralyzed hemidiaphragm. In extreme cases, mechanical ventilation may be needed. Initially, intravenous feedings may be needed; later, progressive gavage or oral feeding may be started, depending on the infant's condition. Pulmonary infections are a serious complication. If the infant fails to demonstrate spontaneous recovery in 1-2 months, surgical plication of the diaphragm may be indicated.

FACIAL NERVE PALSY

Facial palsy is usually a peripheral paralysis that results from pressure over the facial nerve in utero, during labor, or from forceps use during delivery. Rarely, it may result from nuclear agenesis of the facial nerve.

Peripheral facial paralysis is flaccid and, when complete, involves the entire side of the face, including the forehead. The main reported risk factors associated with traumatic facial paralysis are primigravida, birthweight >3,500 g, forceps usage, cesarean birth, and prematurity. When the infant cries, movement occurs only on the nonparalyzed side of the face, and the mouth is drawn to that side. On the affected side the forehead is smooth, the eye cannot be closed, the nasolabial fold is absent, and the corner of the mouth droops. **Central facial paralysis** spares the forehead (e.g., forehead wrinkles will still be apparent on the affected side) because the nucleus that innervates the upper face has overlapping dual innervation by corticobulbar fibers originating in bilateral cerebral hemispheres. The infant with central facial paralysis usually has other manifestations of intracranial injury, most often 6th nerve palsy from the proximity of the 6th and 7th cranial nerve nuclei in the brainstem. Prognosis depends on whether the nerve was injured by pressure or the nerve fibers were torn; improvement occurs within a few weeks in the former case. The majority of infants with traumatic facial nerve palsy will recover within the first 2 months of life. Care of the exposed eye is essential. Neuroplasty may be indicated when the paralysis is persistent. Facial palsy may be confused with absence of the depressor muscles of the mouth, which is a benign problem or with variants of Möbius syndrome.

Chapter 123

Neonatal Resuscitation and Delivery Room Emergencies

Heidi M. Herrick and Elizabeth E. Foglia

Most infants complete the transition to extrauterine life without difficulty; however, a small proportion require resuscitation after birth (Fig. 123.1). For a newborn infant, the need for resuscitation is often caused by a respiratory problem leading to inadequate ventilation. This is in contrast to an adult cardiac arrest, which is usually caused by inadequate circulation. The goals of neonatal resuscitation are to establish adequate spontaneous respirations, obtain adequate cardiac output, and prevent the morbidity and mortality associated with hypoxic-ischemic tissue (brain, heart, kidney) injury (see Chapter 122). High-risk situations should be *anticipated* from pregnancy history and labor. Improved perinatal care and prenatal diagnosis of fetal anomalies allow for appropriate maternal transports for high-risk deliveries. Infants who are born limp, cyanotic, apneic, or pulseless require immediate resuscitation before assignment of the 1 minute Apgar score. Rapid and appropriate resuscitative efforts improve the likelihood of preventing brain damage and achieving a successful outcome.

NEONATAL RESUSCITATION

See also Chapter 79.

Recommendations for the **Neonatal Resuscitation Program (NRP)** propose an *integrated* assessment/response approach for the initial evaluation of an infant, consisting of simultaneous assessment of infant general appearance and risk factors. The fundamental principles include evaluation of the airway and establishing effective respirations and adequate circulation. The guidelines also highlight the importance of the neonatal heart rate as a primary indicator of the need for and response to resuscitation.

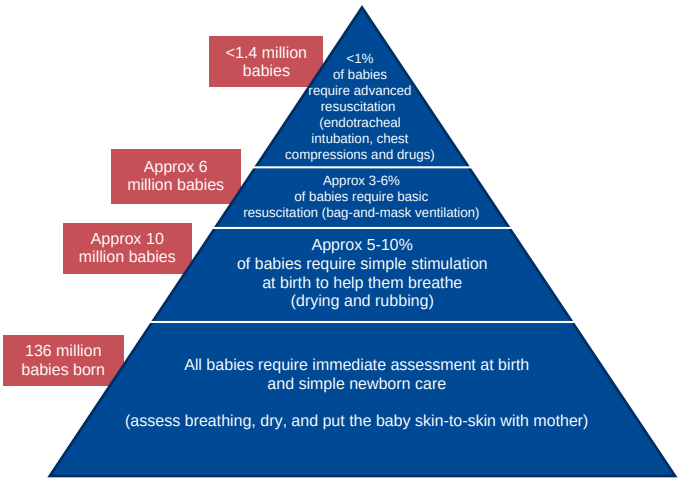

Fig. 123.1 Estimates of infants requiring resuscitation at birth. *(From Wall SN, Lee ACC, Niermeyer S, et al. Neonatal resuscitation in low-resource settings: what, who, and how to overcome challenges to scale up? Int J Gynaecol Obstet. 2009;107:S47–S64. Fig. 1.)*

Before the birth of a baby, sufficient preparation for the birth should occur. At least one individual capable of initiating neonatal resuscitation should be present at the delivery. If advanced resuscitation is anticipated, more providers should be available. Necessary equipment should be available, which routinely includes a warmer bed, blankets, infant hat, stethoscope, bulb suction, suction catheter with wall suction, bag-mask device, oxygen source with blender, pulse oximeter, laryngoscope with blade, endotracheal tubes (ETTs), laryngeal mask airway, pulse oximeter, and electrocardiogram (ECG) leads. Based on the specific details of the pregnancy, further equipment may be needed and should be readily available. The equipment should be checked to make sure it is functioning appropriately. Team members should introduce themselves, define a team leader, assign roles for the resuscitation, and discuss what actions they will take during the resuscitation. For complex resuscitations, there may be one individual whose sole job is to document the resuscitation by keeping track of time and recording interventions performed. This can help ensure the correct steps are performed in a timely manner and inform the team debriefing after resuscitation.

The umbilical cord management plan should be established before delivery. **Delayed cord clamping** after birth can be performed in both preterm and term infants. Benefits to term infants include higher hemoglobin levels at birth with improved iron stores in infancy. Benefits for preterm infants include improved hemodynamic stability, decreased need for inotropic support, and decreased red blood cell transfusions. The 2020 Neonatal Resuscitation Guidelines call for at least 30-60 seconds of delayed cord clamping after birth for vigorous term and preterm infants unless contraindications are present. It is unclear whether delayed cord clamping should be continued when an infant requires resuscitation; this is an area of active research. Umbilical cord milking should not be performed for extremely preterm infants <28 weeks' gestation because this has been associated with an increased risk of intraventricular hemorrhage.

Failure to initiate or sustain respiratory effort at birth is fairly common, with 5–10% of newborns requiring some intervention. Infants with **primary apnea** respond to stimulation by establishing normal breathing. Infants with **secondary apnea** require ventilatory assistance to establish spontaneous respiratory effort. Secondary apnea usually originates as a result of prolonged interruption of adequate oxygen delivery in the perinatal period.

Immediately after birth, all term infants should be dried, warmed, and stimulated. If the infant does not need resuscitation, these steps can occur on the mother's abdomen while delayed cord clamping is taking place. Simultaneously, the infant's tone, respiratory effort, and heart rate should be assessed (Fig. 123.2). If the infant remains apneic or bradycardic (heart rate is <100 beats/min) after stimulation, positive pressure ventilation (PPV) should be given via face mask. PPV should be initiated at peak inspiratory pressures of approximately 20 cm H_2O, positive end-expiratory pressures of 5 cm H_2O at a rate of 40-60 breaths/min.

At the same time PPV is initiated, a pulse oximeter should be placed on the right hand (preductal). Resuscitation with room air in **term infants** is effective and may reduce the risk of hyperoxia, which is associated with decreased cerebral blood flow and generation of oxygen free radicals. Room air, which is 21% fraction of inspired oxygen (F_{IO_2}), is the preferred *initial gas* for neonatal resuscitation in infants ≥35 weeks. O_2 concentration should then be titrated as needed to meet targeted peripheral oxygen saturations (>80% by 5 minutes), as defined by normal reference range by minute of life (see Fig. 123.2; see the following section on "Resuscitation of the Preterm Infant").

The most important sign of effective ventilation is a rise in heart rate. Additional signs include adequate chest rise, symmetric breath sounds, increasing O_2 saturation, spontaneous respirations, and improved tone. *If after 30 seconds of providing PPV there is no response in heart rate, corrective steps should be performed to improve ventilation.* The six

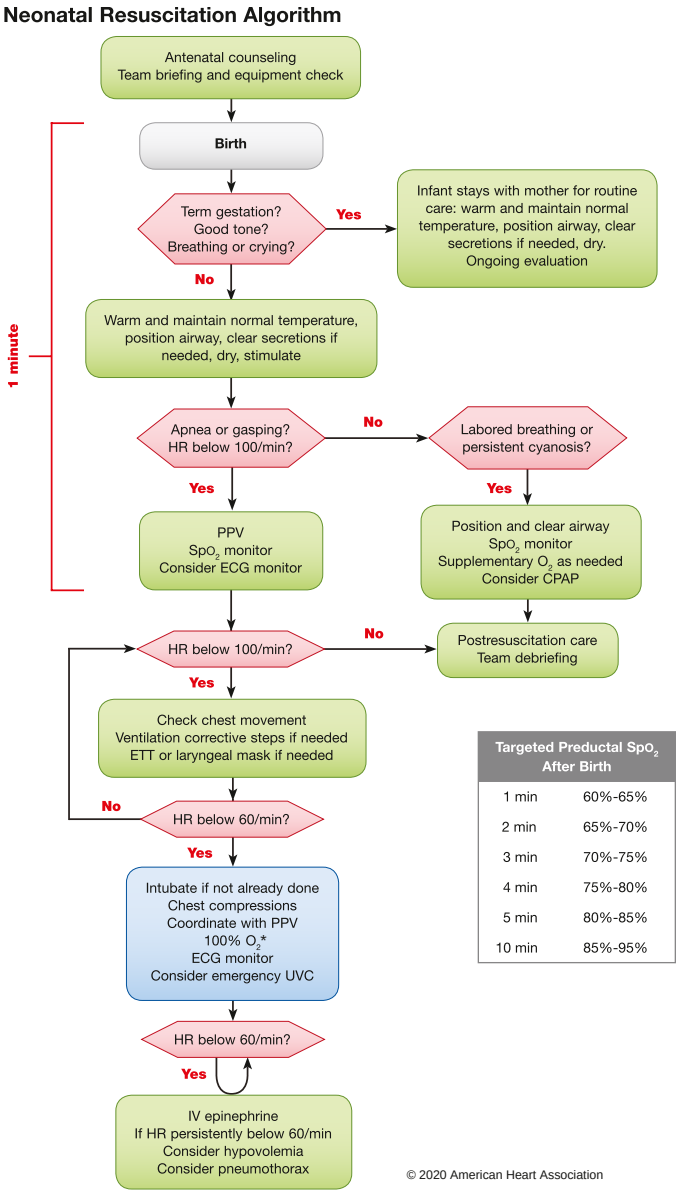

Fig. 123.2 Newborn resuscitation algorithm. CPAP, Continuous positive airway pressure; ECG, electrocardiogram; ETT, endotracheal tube; HR, heart rate; IV, intravenous; PPV, positive pressure ventilation; UVC, umbilical venous catheter. *(From Aziz K, Lee HC, Escobedo MB, et al. Part 5: Neonatal Resuscitation: 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 2020;142[16_suppl_2]:S524–S550. Fig. 1.)*

ventilation corrective steps can be remembered with the mnemonic **MRSOPA**: *m*ask readjustment, *r*eposition the head, *s*uction mouth and nose, *o*pen the mouth, *p*ressure increase, and *a*lternative airway.

Causes of poor response to ventilation are mask leak, airway obstruction, insufficient pressure, pleural effusions, pneumothorax, excessive air in the stomach leading to abdominal competition, hypovolemia, diaphragmatic hernia, or prolonged intrauterine asphyxia. For infants who do not respond to noninvasive PPV after corrective steps have been taken, endotracheal intubation should be performed. For infants with an otherwise normal airway weighing <1,000 g, ETT size is usually 2.5 mm; for infants 1,000-2,000 g, 3 mm; and for infants >2,000 g, 3.5 mm. A general rule for depth of insertion from upper lip in centimeters is 6 + infant's weight in kilograms. The best method to confirm accurate ETT position is exhaled CO_2 detection. A laryngeal mask airway is an alternative method to establish an airway, especially if face mask PPV is ineffective or providers skilled in intubation are unavailable.

For most infants, the underlying cause for a persistently low heart rate (<60 beats/min) is not a primary cardiac cause, but instead the result of **ineffective ventilation**. Therefore if the heart rate remains <60 beats/min after 60 seconds of PPV with corrective MRSOPA steps, the infant should be intubated (if not already done) to achieve effective ventilation. *Once the infant is intubated, if the heart rate remains <60 beats/min, chest compressions should be initiated with continued ventilation, and* F_{IO_2} *should be increased to 100%.* Chest compressions should be initiated over the lower third of the sternum at a rate of 90 per minute. A provider, separate from the person providing ventilation, is needed to administer chest compressions. The *thumb technique* should be used for chest compressions; the tips of both thumbs are used to depress the sternum, with the fingers on each side encircling the chest; this is the preferred method to administer chest compressions, because it has been shown to achieve a higher blood pressure, increase coronary perfusion, and result in less fatigue. In infants, regardless of whether an alternative airway has been secured, chest compressions are always coordinated with PPV. The ratio of compressions to ventilation is 3:1 (90 compressions:30 breaths). Chest compressions should continue uninterrupted for 60 seconds before reassessing heart rate to determine next steps.

Medications are rarely required, but **epinephrine** should be administered when the heart rate is <60 beats/min after 60 seconds of combined ventilation and chest compressions or during asystole. An intravenous route is recommended for epinephrine administration. The umbilical vein can generally be readily cannulated and is the preferred method for administration of medications and volume expanders during neonatal resuscitation (Fig. 123.3). An intraosseous route is another option if umbilical venous access is not obtained. Epinephrine (initial dose recommendation of 0.02 mg/kg *intravenously/intraosseously* followed by a 3-mL flush) is given for asystole or for continued heart rate <60 beats/min after 60 seconds of combined resuscitation. The dose may be repeated every 3-5 minutes. Epinephrine may also be given through the ETT (0.1 mg/kg). If adequate resuscitation continues for 20 minutes without a detectable heart rate, it is reasonable to discuss redirection of care with the team and family and to stop resuscitative efforts.

RESUSCITATION OF THE PRETERM INFANT

Resuscitation of the preterm infant should follow the same steps as a term infant, with some special considerations. Whereas resuscitation of term infants should start with room air, resuscitation of preterm infants <35 weeks' gestation should be initiated with F_{IO_2} between 21% and 30%. Pulse oximetry of the preductal (right) hand should be used to titrate O_2 concentrations for targeted saturations per the NRP algorithm (see Fig. 123.2). Most very low birthweight infants will need more than 30% once titration begins.

Special attention should be paid to *keeping the preterm infant warm in the delivery room.* Quality improvement projects have initiated bundles to improve admission temperatures of preterm infants to the neonatal intensive care unit (NICU) and have included such interventions as higher ambient temperatures in the delivery room, immediate placement of preterm infants into a plastic bag or under plastic wrap rather than drying, and exothermic mattress for resuscitation and transport of the preterm infant.

SPECIAL CIRCUMSTANCES IN THE DELIVERY ROOM

Meconium

Meconium staining of the amniotic fluid may be an indication of fetal stress. All infants born through meconium-stained amniotic fluid (regardless if the infant is vigorous or nonvigorous) should receive the same initial steps of neonatal resuscitation as infants without

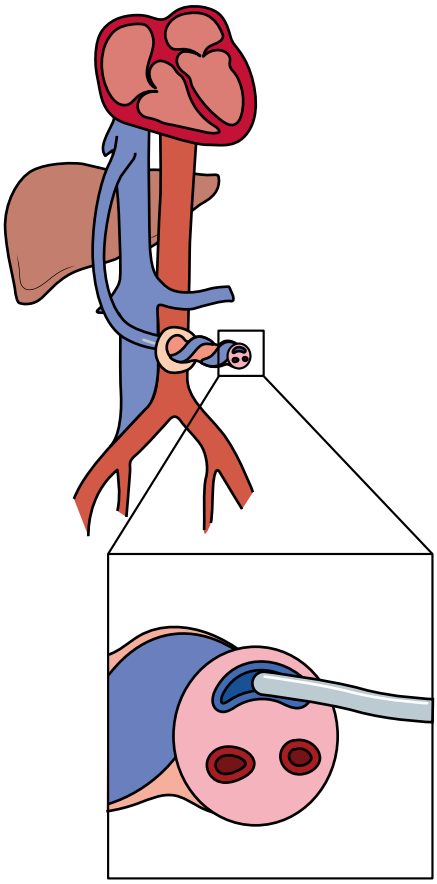

Fig. 123.3 Emergently placed umbilical venous catheter suitable for neonatal resuscitation.

meconium-stained fluid and should be assessed as any other infant. Tracheal intubation for meconium aspiration may delay the initiation of effective PPV and ultimately delay effective gas exchange and is not indicated.

Placental Abruption

Placental abruption (abruptio placentae) or uterine rupture at birth can lead to acute fetal blood loss and a hypovolemic, anemic infant at delivery. Infants can present pale and apneic with poor tone, decreased perfusion, and bradycardia. In addition to performing routine neonatal resuscitation, when an infant is suspected to be symptomatic from acute blood loss, an emergency low-lying umbilical venous catheter (UVC) or interosseous needle should be placed and emergent type O Rh-negative blood should be obtained. In acute blood loss, the blood should be administered as quickly as possible in 10 mL/kg aliquots in the delivery room. Adequate communication between obstetrics and pediatrics regarding suspected acute blood loss is crucial to early recognition and treatment of the infant.

Neonatal Encephalopathy

Infants with neonatal encephalopathy are born with abnormal neurologic function, including level of consciousness, muscle tone, apnea, and reflexes. Although there are many possible etiologies, when symptoms are accompanied by a defined perinatal event such as cord prolapse or placental abruption, hypoxic-ischemic brain injury is the presumed cause. These infants are often born with impaired respiratory drive. Immediately after initial resuscitation and stabilization, a thorough neurologic examination should be performed to assess if the infant meets formal criteria for moderate to severe encephalopathy and qualifies for therapeutic hypothermia (see Chapter 122.4).

Airway Anomalies

Hypoplasia of the mandible with posterior displacement of the tongue may result in upper airway obstruction (Pierre Robin, Stickler, DiGeorge, and other syndromes; see Chapters 118 and 357). Symptoms may sometimes be temporarily relieved by pulling the tongue or mandible forward or placing the infant in the prone position. Other rare anatomic causes of upper airway obstruction at birth include laryngeal atresia or stenosis, teratomas, hygromas, and oral tumors. Critical fetal and then neonatal airway obstruction represents an emergency in the delivery room. High-risk perinatal care has led to the more frequent prenatal diagnosis of these disorders. When diagnosed prenatally, planning can identify the location of delivery and interventions available at delivery. The **ex utero intrapartum treatment (EXIT)** procedure allows time to secure the airway in an infant known prenatally to have critical airway obstruction, before the infant is separated from the placenta (Fig. 123.4; see Chapter 118). Uteroplacental gas exchange is maintained throughout the procedure.

Pulmonary Disorders

Both congenital and acquired abnormalities can contribute to respiratory failure in the neonate. A **scaphoid abdomen** suggests a diaphragmatic hernia, as does asymmetry in contour or movement of the chest. An infant with a known diaphragmatic hernia should be immediately intubated in the delivery room and an orogastric tube placed to avoid gaseous distention of the bowel from crying or PPV. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment (see Chapter 124.1).

In infants with a prenatal diagnosis of hydrops, pleural effusions may be present at delivery, preventing adequate lung expansion and gas exchange. Similarly, infants requiring PPV in the delivery room are at risk for **pneumothorax**. Infants with pulmonary hypoplasia or meconium-stained fluid are at increased risk of this complication. Clinically, infants with a pleural effusion or pneumothorax present with respiratory distress and hypoxia, with *diminished* breath sounds on the affected side. Transillumination may be helpful to confirm the diagnosis. Emergency evacuation of a pneumothorax or pleural effusion without radiographic confirmation is indicated in an infant who is unresponsive to resuscitation efforts and has asymmetric breath sounds, bradycardia, and cyanosis. An angiocatheter attached to a stopcock and syringe should be used for evacuation. For a pleural effusion, with the infant in the supine position, the angiocatheter should be inserted in the fourth or fifth intercostal space in the anterior axillary line and directed posteriorly to evacuate the fluid. For a pneumothorax, an angiocatheter can be inserted in the fourth intercostal space in the anterior axillary line or the second intercostal space in the midclavicular line and air evacuated (see Chapter 124).

Abdominal Wall and Neural Tube Defects

Appropriate management of patients with abdominal wall defects (omphalocele, gastroschisis) in the delivery room prevents excessive fluid loss and minimizes the risk for injury to the exposed viscera. **Gastroschisis** is the more common defect, and typically the intestines are not covered by a membrane. The infant's lower body, including exposed intestines, should be gently placed in a sterile clear plastic bag after delivery. A membrane often covers an **omphalocele**, and care should be taken to prevent its rupture. The omphalocele should either be wrapped in a sterile dressing or the infant's lower body, including the omphalocele, which should be placed within a sterile bag. With both defects, a nasogastric tube should be placed, and the infant transferred to a tertiary referral center for surgical consultation and evaluation for associated anomalies (see Chapter 144).

Fig. 123.4 Ex utero intrapartum therapy (EXIT) procedure. Baby with teratoma and critical high airway obstruction syndrome (CHAOS). Trachea is displaced to the lateral neck. *(Courtesy Dr. Mark Wulkan, Pediatric Surgery, Emory University.)*

Similarly, infants born with neural tube defects such as a **myelomeningocele** need special care at delivery to protect the exposed neural tube tissue from trauma and infection; infants should be placed on their side or abdomen for resuscitation. The site of the neural tube defect should be covered with a moist sterile dressing to prevent drying and infection. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment.

INJURY DURING DELIVERY

Central Nervous System

Both extracranial and intracranial birth injuries can be seen in infants after birth. **Extracranial** lesions include cephalohematoma, caput succedaneum, and subgaleal hemorrhage. **Intracranial** birth injuries include subdural hemorrhage, subarachnoid hemorrhage, and epidural hematoma. The most common intracranial injury experienced at birth is **subdural hemorrhage**, with increasing incidence seen with instrument-assisted vaginal deliveries (see Chapters 122.1 and 122.2).

Fractures

The clavicle is the most frequently fractured bone during labor and delivery. It is particularly vulnerable to injury with difficult delivery of the shoulder in the setting of **shoulder dystocia**, as well as with extended arms in breech deliveries. In the treatment of shoulder dystocia, the obstetrician may intentionally fracture the clavicle so that delivery can proceed. Symptoms of a clavicular fracture include an infant not moving the arm freely on the affected side, palpable crepitus or bony irregularity, and asymmetric or absent Moro reflex on the affected side. The prognosis for this fracture is excellent. Often, no specific treatment is needed, although in some cases the arm and shoulder on the affected side are immobilized for comfort.

Fractures of the long bones are fairly rare. Injuries often present with absent spontaneous movement of the extremity. Associated nerve involvement may also occur. Treatment involves immobilization of the affected extremity with a splint and orthopedic follow-up.

Brachial Plexus Injuries

Brachial plexus injuries result from stretching and tearing of the brachial plexus (spinal roots C5-T1) at delivery. Although shoulder dystocia is associated with an increased risk of brachial plexus injury, it can also occur during a routine delivery (see Chapter 122.6).

ONGOING CARE AFTER RESUSCITATION

The "golden hour" after a baby's birth should emphasize effective neonatal resuscitation, postresuscitation care, prevention of hypothermia (including maternal skin-to-skin contact), immediate breastfeeding if able, prevention of hypoglycemia, and therapeutic hypothermia for cases of moderate to severe neonatal encephalopathy (birth asphyxia). After supportive measures have stabilized the infant's condition, a specific diagnosis should be established and appropriate continuing treatment instituted.

For infants who receive more intensive resuscitation, a plan for ongoing monitoring and treatment should be established. These infants may experience ongoing acidosis, electrolyte abnormalities, hypo- or hyperglycemia, impaired thermoregulation, and respiratory insufficiency. If infection is suspected, appropriate antibiotics should be started as soon as possible. Severe neonatal encephalopathy may also depress myocardial function and cause cardiogenic shock despite the recovery of heart and respiratory rates. Fluids and dopamine or epinephrine as a continuous infusion should be started after initial resuscitation efforts, to improve cardiac output in an infant with poor peripheral perfusion, weak pulses, hypotension, tachycardia, or poor urine output. Regardless of the severity of neonatal encephalopathy or the response to resuscitation, asphyxiated infants should be monitored closely for signs of multiorgan hypoxic-ischemic tissue injury (see Chapter 122.4).

Chapter 124

Transition to Newborn Pulmonary Respiration

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Successful establishment of adequate lung function at birth depends on airway patency, functional lung development, and maturity of respiratory control. Fetal lung fluid must be removed and replaced with gas. Functional residual capacity (FRC) must be established and maintained to develop a ventilation-perfusion relationship that will provide optimal exchange of oxygen and carbon dioxide between alveoli and blood. Pulmonary blood flow increases dramatically, and the newborn must establish and maintain breathing patterns that are distinct from fetal breathing movements.

CLEARANCE OF FETAL LUNG FLUID

In utero, lung fluid is actively secreted by epithelial cells into air spaces. This fluid is essential for normal lung development and severe pulmonary hypoplasia results in infants who are unable to maintain appropriate fetal lung fluid. During birth, fluid must be cleared from the airways to allow for gas exchange. During birth, the lung epithelial cells must transition from fluid secreting to fluid absorbing.

Increased intrathoracic pressure from uterine squeeze and flexion of the infant during delivery likely contribute to movement of fluid out of the infant's nose and mouth at delivery. Additionally, inspiration decreases intrapleural pressure forming a pressure gradient that leads to the movement of fluid toward the smaller airways and ultimately out of the air spaces. As fluid moves out of the airways there is an increased interstitial hydrostatic pressure that contributes to fluid reentering the airway during each expiration until it is eventually cleared from the interstitial tissues over the course of hours.

ESTABLISHMENT OF A FUNCTIONAL RESIDUAL CAPACITY

FRC represents a balance point between collapsing and distending forces on the lung at end-expiration. Lung recoil comes from a combination of the intrinsic elasticity of the lung tissue and the surface tension within the lung. **Surfactant** plays an important role in reducing surface tension in the newborn. Premature infants and those infants with insufficient surfactant have an increased tendency toward lung collapse as observed in **respiratory distress syndrome** (see Chapter 126). Although the chest wall provides resistance to collapse in older children and adults, the highly compliant chest wall of the newborn and particularly the preterm newborn provides little resistance to lung recoil. Instead, resistance to lung collapse comes from a combination of lung tissue hydrostatic, osmotic, and oncotic pressures in addition to expiratory braking maneuvers. The neonate's expiratory braking maneuvers include adduction of the glottis and engagement of the diaphragm during expiration. Additional activities such as grunting and crying further support establishment of FRC.

INCREASED PULMONARY BLOOD FLOW

In utero, the placenta is the source of gas exchange, and blood is diverted away from the developing lungs by way of the foramen ovale and ductus arteriosus. Only 10% of the cardiac output passes through the fetal lung circulation. Following birth, blood flow to the pulmonary circulation increases due to decreasing **pulmonary vascular resistance** and closure of in utero shunts. The decline in pulmonary vascular resistance is driven by clearance of fetal lung fluid, oxygen-stimulated smooth muscle relaxation, and release of nitric oxide. Pulmonary vascular resistance decreases 50% over the first 24 hours and continues to decline over the first weeks of life. The foramen ovale is functionally closed after birth due to increased systemic vascular resistance and increased pressures in the left ventricle and left atrium. The ductus arteriosus is slower to close and ductal constriction is driven by a loss of prostaglandins from the placenta, increased oxygen exposure, and decreased local nitric oxide. Increasing pulmonary blood flow and decreasing mixing of oxygenated and deoxygenated blood after birth contributes to changing saturations in the newborn, which rise from 60% immediately after birth to over 90% by approximately 10 minutes of life (Fig. 124.1)

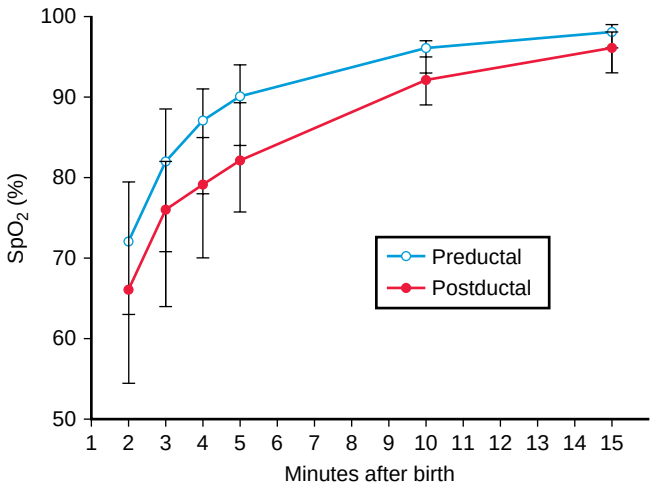

Fig. 124.1 Pre- and postductal Spo_2 levels during the first 15 minutes after birth (median; IQR). Postductal Spo_2 levels were significantly lower than preductal Spo_2 levels at 3, 4, 5, 10, and 15 minutes. *(Modified from Mariani G, Dik PB, Ezquer A, et al. Pre-ductal and post-ductal O_2 saturation in healthy term neonates after birth. J Pediatr. 2007;150:418–421.)*

BREATHING PATTERNS IN NEWBORNS

Fetal breathing movements can be observed before birth. They are generally discontinuous and generate only small tidal volumes. Following delivery, the infant must establish a regular breathing pattern with increased tidal volumes. Triggers driving this change include increased $Paco_2$, activation of chemoreceptors, and a loss of placental prostaglandins, which suppress respiratory drive. Within the fetus, low oxygen tension has an inhibitory effect on breathing. Following birth, hypoxia will eventually become a driver of respiratory effort, but in the immediate postpartum period and in the premature infant, hypoxia may depress respiratory drive.

DISORDERED TRANSITION TO PULMONARY RESPIRATION

The successful transition from placental derived oxygen delivery to pulmonary respiration requires timely completion of fetal lung fluid clearance, creation of FRC, increased pulmonary blood flow, and establishment of normal breathing patterns. Failures in any of these tasks are associated with respiratory disorders in the neonate. Failure in the timely clearance of fetal lung fluid is associated with **transient tachypnea of the newborn** (see Chapter 128). An inability to establish FRC is a feature of respiratory distress syndrome (see Chapter 126). A failure in decreasing pulmonary vascular resistance causes persistent pulmonary hypertension of the newborn (see Chapter 130) and in infants without appropriate respiratory patterns, **apnea** (see Chapter 125) is a presenting concern.

Chapter 125

Apnea

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Apnea is a prolonged cessation of respiration and must be distinguished from *periodic breathing* because apnea is often associated with serious illness. Although there is no universal agreement, apnea is usually defined as cessation of breathing for a period of ≥20 seconds, or a period <20 seconds that is associated with a change in tone, pallor, cyanosis, or bradycardia (<80-100 beats/min). Based on the absence of respiratory effort and/or airflow, apnea can be obstructive, central, or mixed. **Obstructive apnea** is characterized by absence of airflow but persistent chest wall motion. Pharyngeal collapse may follow the negative airway pressures generated during inspiration, or it may result from incoordination of the tongue and other upper airway muscles involved in maintaining airway patency. **Central apnea** is caused by decreased central nervous system (CNS) stimuli to respiratory muscles and results in both airflow and chest wall motion being absent. Gestational age (GA) is the most important determinant of respiratory control, with the frequency of central apnea being inversely related to GA. The immaturity of the brainstem respiratory centers is manifest by an attenuated response to CO_2 and a paradoxical response to hypoxia that results in central apnea rather than hyperventilation. Mixed apnea is most often observed in apnea of prematurity with obstructive apnea preceding central apnea. Short episodes of apnea are usually central, whereas prolonged ones are often mixed.

OBSTRUCTIVE APNEA

Obstructive apnea derives from interrupted upper airway flow. Causes of obstructive apnea can largely be divided into anatomic abnormalities and neuromuscular abnormalities.

Craniofacial disorders are a common cause of obstructive apnea of the newborn. Micrognathia, retrognathia, or Pierre Robin sequence all cause upper airway obstruction due to backward dislodgement of the tongue into the airway. This obstruction may be improved by prone positioning of the neonate. Although cleft lip and palate are not always associated with obstructive apnea, infants with these conditions are at risk for apnea related to abnormal narrowing of the upper airway structures. Additional anatomic abnormalities that can contribute to obstructive apnea include narrowing or occlusion of the nasal passages (i.e., choanal atresia) or narrowing of the airways (i.e., laryngomalacia). Many causes of anatomic obstruction are syndromic and include skeletal dysplasia, VACTERL association, Joubert syndrome, CHARGE syndrome, DiGeorge syndrome, and Stickler syndrome.

Neuromuscular weakness can contribute to **obstructive apnea** via airway collapse in the setting of low tone. Additionally, respiratory muscle weakness may impede the infant from overcoming normal airway resistance.

CENTRAL APNEA

Central apnea has a wide range of etiologies and should always lead to a diagnostic evaluation as it can often be an early warning sign of clinical decompensation. Table 125.1 provides a framework for the disease processes that can contribute to apnea. Infection or metabolic derangements should always be considered as an etiology for infants with new or worsening apnea. Abnormal CNS control of breathing can be related to prematurity, but other CNS abnormalities including injury or malformation can contribute to central apnea. **Congenital central hypoventilation syndrome** is a rare permanent genetic cause of central apnea that begins in the neonatal period (see Chapter 468.2).

APNEA OF PREMATURITY

Apnea in preterm infants is defined as cessation of breathing for ≥20 seconds or for any duration if accompanied by cyanosis and bradycardia (<80-100 beats/min). The incidence of associated bradycardia increases with the length of the preceding apnea and correlates with the severity of hypoxia. Short apnea episodes (10 seconds) are rarely associated with bradycardia, whereas longer episodes (>20 seconds) have a higher incidence of bradycardia. Bradycardia follows the apnea by 1-2 seconds in >95% of cases and is most often sinus. Vagal responses and rarely heart block are causes of bradycardia *without* apnea. Short, self-resolving oxygen desaturation episodes noted with continuous monitoring are normal in neonates, and treatment is not necessary.

Apnea of prematurity results from immature respiratory control, most frequently occurs in infants <34 weeks of GA, and occurs in the absence of identifiable predisposing diseases. The incidence of apnea of prematurity varies inversely with GA. Apnea of prematurity is almost universal in infants born at <28 weeks of GA, and the incidence rapidly decreases from 85% of infants <30 weeks of GA to 20% of infants <34 weeks of GA. The onset of apnea of prematurity can be during the initial days to weeks of age but is often delayed if there is respiratory distress syndrome (RDS) or other causes of respiratory distress. In premature infants without respiratory disease, apneic episodes can occur throughout the first 7 postnatal days with equal frequency. In infants with apnea of prematurity, the events decline significantly by 34 weeks corrected GA. Resolution may be delayed in infants with **bronchopulmonary dysplasia** (see Chapter 127) because of poorer reserves and an increased incidence of subglottic stenosis, laryngomalacia, or tracheomalacia, which can contribute to **obstructive apneas**.

Table 125.1 Potential Causes of Neonatal Apnea and Bradycardia

Central nervous system	Intraventricular hemorrhage, drugs, seizures, hypoxic injury, herniation, neuromuscular disorders, Leigh syndrome, brainstem infarction or anomalies (e.g., olivopontocerebellar atrophy), transient following general anesthesia, congenital central hypoventilation syndrome
Respiratory	Pneumonia, obstructive airway lesions, upper airway collapse, atelectasis, extreme prematurity, laryngeal reflex, phrenic nerve paralysis, pneumothorax, paradoxical response to hypoxia
Infectious	Sepsis, meningitis (bacterial, fungal, viral), respiratory syncytial virus, pertussis
Gastrointestinal	Oral feeding, bowel movement, necrotizing enterocolitis, intestinal perforation
Metabolic	↓ Glucose, ↓ calcium, ↓/↑ sodium, ↑ ammonia, ↑ organic acids, ↑ ambient temperature, hypothermia
Cardiovascular	Hypotension, hypertension, heart failure, anemia, hypovolemia, vagal tone
Other	Immaturity of respiratory center (prematurity); sleep state; sudden unexpected postnatal collapse

Preterm infants born at <35 weeks of GA are at risk for apnea of prematurity and therefore should receive cardiorespiratory monitoring. Apnea that occurs in the absence of other clinical signs of illness in the first 2 weeks in a preterm infant is likely apnea of prematurity; therefore additional evaluation for other etiologies is often unwarranted. However, *the onset of apnea in a previously well preterm neonate after the second week of life is a critical event that may be associated with serious underlying pathology*. Prompt investigation for sepsis/meningitis, medication side effects, metabolic derangements, structural CNS anomalies, intracranial hemorrhage, or seizures is warranted.

TREATMENT

Observation is the most common treatment strategy for infants with **obstructive apnea,** and temporizing measures including prone positioning can help to minimize symptoms until sufficient patient growth alleviates the obstruction. The use of supplemental oxygen, **nasal continuous positive airway pressure (nCPAP),** or bilevel positive airway pressure may facilitate stenting of airways and limit obstructive events. Surgical interventions depend on the underlying cause and include supraglottoplasty, palatoplasty, tongue-lip adhesion, tongue base reduction, nasal stent, mandibular distraction, and in severe cases, tracheostomy to bypass areas of obstruction.

For apnea of prematurity, gentle tactile stimulation, or provision of flow and/or supplemental oxygen by nasal cannula, is often adequate therapy for mild and intermittent episodes. **nCPAP** (3-5 cm H_2O) and **high-flow nasal cannula** (**HFNC**; 1-4 L/min) are appropriate therapies for **mixed** or **obstructive apnea**. The efficacy of both nCPAP and HFNC is related to their ability to splint the upper airway to prevent airway obstruction. Additionally, the maintenance of a higher functional residual capacity can decrease the duration of **central apnea**. Both are used widely, but nCPAP may be preferred in extremely preterm infants because of its proven efficacy and safety.

Recurrent or persistent apnea of prematurity is effectively treated with methylxanthines. **Methylxanthines** increase central respiratory drive by lowering the threshold of response to hypercapnia as well as enhancing contractility of the diaphragm. **Caffeine** and **theophylline** are similarly effective methylxanthines, but caffeine is preferred because of its longer half-life and lower potential for side effects (less tachycardia and feeding intolerance). In preterm infants, caffeine reduces the incidence and severity of apnea of prematurity, facilitates successful extubation from mechanical ventilation, reduces the rate of bronchopulmonary dysplasia (see Chapter 127), and improves neurodevelopmental outcomes. Caffeine therapy can be safely administered orally (PO) or intravenously (IV). Generally, infants are given an initial loading dose of 20 mg/kg of caffeine citrate followed 24 hours later by once-daily maintenance doses of 5-10 mg/kg. Because the therapeutic window is wide and serious side effects associated with caffeine are rare, monitoring of serum drug concentrations is usually unnecessary. Monitoring is primarily through observation of vital signs (tachycardia) and clinical response. Higher doses of caffeine may be more effective without serious adverse events, but additional studies are needed to ensure safety. Studies suggest that early initiation of caffeine, in the first 3 days of life, in extremely preterm infants improves outcomes. However, it is reasonable to delay caffeine therapy until apnea occurs in older infants. Caffeine therapy is usually continued until an infant is free of clinically significant apnea or bradycardia for 5-7 days without positive pressure respiratory support, or at 34 weeks' postmenstrual age (PMA).

In an infant with significant anemia, transfusion of packed red blood cells (RBCs) increases blood O_2-carrying capacity, improves tissue oxygenation, and may be associated with a short-term reduction in apnea. However, a long-term benefit with regard to apnea appears unlikely.

Gastroesophageal reflux (GER) is common in neonates, but despite being associated with apnea anecdotally, data do not support a causal relationship between GER and apneic events. In preterm infants, medications that inhibit gastric acid production have potentially harmful side effects (increased incidence of sepsis, necrotizing enterocolitis, death) and may increase the incidence of apnea and bradycardia. Therefore the routine use of medications that inhibit gastric acid synthesis or promote gastrointestinal motility to reduce the frequency of apnea in preterm infants should be discouraged. Antireflux treatment does correlate with decreased rates of obstructive apnea; however, this does not seem to be a causal relationship. Feeding strategies including more frequent or slower/longer feedings may be considered. Thickening feedings with xanthan gum is linked to late-onset necrotizing enterocolitis and should not be attempted. Other thickeners (i.e., rice) are not nutritionally appropriate for the preterm infant. The use of elemental or extensively hydrolyzed formulas can decrease transit time and may decrease symptoms of GER and can be considered in age-appropriate populations.

PROGNOSIS

In 92% of infants by 37 weeks' PMA and in 98% of infants by 40 weeks' PMA, apnea of prematurity resolves spontaneously. However, infants born well before 28 weeks' GA may experience apnea and bradycardic events until 44 weeks' PMA. Beyond 44 weeks' PMA, extreme events (apnea >30 seconds and/or bradycardia <60 beats/min for >10 seconds) are very rare. The period that an infant should be observed to ensure resolution of apnea and bradycardia is not defined and among institutions is highly variable. However, many experts would recommend that an infant demonstrate an event-free period of 5-7 days before discharge. Although the nature and severity of events should dictate the length of observation, sufficiently large retrospective cohort studies suggest that a 1–3-day (infants born at ≥30 weeks' GA), 9–10-day (27-28 weeks' GA), or 13–14-day (<26 weeks' GA) event-free period predicts resolution of apnea in up to 95% of infants successfully. Brief, isolated bradycardic episodes associated with oral feeding are common in preterm infants and are generally not considered significant during the event-free period.

Despite its high frequency in preterm infants, the harm associated with apnea of prematurity is unknown. However, apnea of prematurity does not appear to alter an infant's prognosis unless it is severe, recurrent, and refractory to therapy. Prompt, effective therapy and careful monitoring are vital to avoid prolonged, severe hypoxia, which may increase the risk of death and neurodevelopmental impairment.

Sudden Infant Death Syndrome and Home Monitoring

Although preterm infants are at higher risk for sudden infant death syndrome (SIDS), apnea of prematurity *does not* further increase that risk. The epidemiologic evidence that placing babies supine during sleep reduces the rate of SIDS deaths by >50% suggests that positioning, and not prematurity, primarily influences the incidence of SIDS. Supine positioning on a firm sleep surface separate from the parents' bed, promotion of breastfeeding, and pacifier use during sleep reduce the incidence of SIDS. Avoidance of cigarette smoke exposure and no parental use of alcohol or illicit drugs during pregnancy and after birth are also important in the prevention of SIDS.

In-home monitoring is an area that has received significant interest in prevention of SIDS. In a large cohort study, episodes of apnea and bradycardia were not uncommon (severe events detected in 10% of infants monitored and 2.3% of healthy term infants). Preterm infants remained at risk for apnea until approximately 43 weeks' PMA; however, most SIDS deaths occurred after apnea has resolved occurring at an average of 45.8 weeks' PMA for premature infants and 52.3 weeks' PMA for term infants. There was no evidence that home monitoring impacted the incidence of SIDS. The role for home monitors is likely limited to premature infants with prolonged or extreme episodes of apnea (and should be discontinued after 44 weeks' PMA in this population), infants with specific risk factors for obstructive apnea, or requiring supplemental oxygen or mechanical ventilation.

Chapter 126

Respiratory Distress Syndrome (Hyaline Membrane Disease)

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

INCIDENCE

Respiratory distress syndrome (RDS) occurs primarily in premature infants; its incidence is inversely related to gestational age (GA) and birthweight. It occurs in 60–80% of infants <28 weeks' GA, in 15–30% of those between 32 and 36 weeks' GA, and rarely in those >37 weeks' GA. The risk for development of RDS increases with maternal diabetes, multiple births, cesarean delivery, precipitous delivery, asphyxia, cold stress, and a maternal history of previously affected infants. The risk of RDS is reduced in pregnancies with chronic or pregnancy-associated hypertension, maternal opiate use, prolonged rupture of membranes, and antenatal corticosteroid prophylaxis.

ETIOLOGY AND PATHOPHYSIOLOGY

Surfactant deficiency (decreased production and secretion) is the primary cause of RDS. In the absence of pulmonary surfactant, significantly increased alveolar **surface tension** leads to atelectasis, and the ability to attain an adequate **functional residual capacity (FRC)** is impaired. Additionally, insufficient surfactant contributes to heterogenous lung expansion with atelectatic areas remaining unventilated and progressive overdistension of ventilated regions according to Laplace's law (Fig. 126.1).

Although surfactant is present in high concentrations in fetal lung by 20 weeks of gestation, it does not reach the surface of the lungs until later. It appears in amniotic fluid between 28 and 32 weeks. Mature levels of pulmonary surfactant are present usually after 35 weeks of gestation. The major constituents of surfactant are dipalmitoyl phosphatidylcholine (lecithin), phosphatidylglycerol, apoproteins (surfactant proteins SP-A, SP-B, SP-C, and SP-D), and cholesterol (Fig. 126.2). With advancing GA, increasing amounts of phospholipids are synthesized and stored in type II alveolar cells (Fig. 126.3). These surface-active agents are released into the alveoli, where they reduce surface tension and help maintain alveolar stability at end-expiration. Synthesis of surfactant depends in part on normal pH, temperature, and perfusion. Asphyxia, hypoxemia, and pulmonary ischemia, particularly in association with hypovolemia, hypotension, and cold stress, may suppress surfactant synthesis. The epithelial lining of the lungs may also be injured by high O_2 concentrations and mechanical ventilation, thereby further reducing secretion of surfactant.

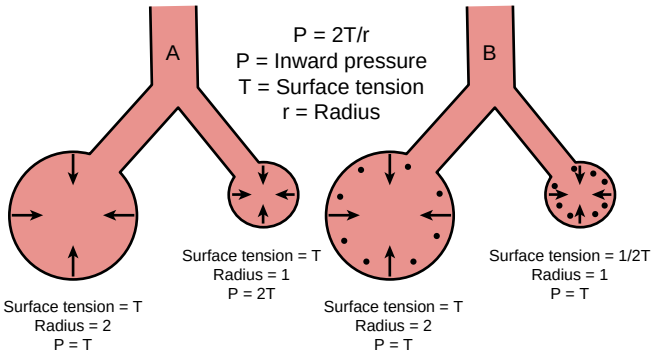

Fig. 126.1 Laplace's law as it applies to alveolar distension. Laplace's law states that the collapsing pressure in the alveolus is directly related to **surface tension** and inversely related to alveolar radius. In **A** the collapsing pressure is higher in the smaller alveoli thus the smaller alveolus further collapses, and larger alveolus distends leading to asymmetry in ventilation. In **B** with **surfactant** present, the particles become more densely spaced as the alveolus collapses, which decreases **surface tension**, and the resulting collapsing pressure is equalized between the two alveoli.

Atelectasis results in perfused but not ventilated alveoli, causing hypoxia. Decreased lung compliance, small tidal volumes, increased physiologic dead space, and insufficient alveolar ventilation eventually result in hypercapnia. The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction with increased right-to-left shunting through the foramen ovale and ductus arteriosus and within the lung itself. Progressive injury to epithelial and endothelial cells results from atelectasis (atelectrauma), volutrauma, ischemic injury, and oxygen toxicity. This injury leads to effusion of proteinaceous material and cellular debris into the alveolar spaces (forming the classic hyaline membranes) further impairing oxygenation. RDS represents a vicious cycle of diminished surfactant production, worsening atelectasis, lung injury, and severe hypoxia (Fig. 126.4).

CLINICAL MANIFESTATIONS

Signs of RDS usually appear within minutes of birth, although they may not be recognized for several hours in larger premature infants, until rapid, shallow respirations and cyanosis become more obvious. A later onset of tachypnea should suggest other conditions. Some patients require resuscitation at birth because of intrapartum asphyxia or initial severe respiratory distress (especially with birthweight <1,000 g). Characteristically, tachypnea, prominent (often audible) expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis are noted. Breath sounds may be normal or diminished with a harsh tubular quality, and on deep inspiration, fine crackles may be heard. *The natural course of untreated RDS is characterized by progressive worsening of cyanosis and dyspnea. If the condition is inadequately treated,* blood pressure may fall; *cyanosis and pallor increase, and grunting decreases or disappears, as the condition worsens. Apnea and irregular respirations are ominous signs requiring immediate intervention.* Untreated patients develop a mixed respiratory-metabolic acidosis with hypoxia and the potential to progress to respiratory failure with multisystem organ dysfunction due to inadequate oxygen delivery. In most cases, the signs reach a peak within 3 days, after which improvement is gradual. Improvement is often heralded by spontaneous diuresis and improved blood gas values at lower inspired O_2 levels and/or lower ventilator support. Death can result from severe impairment of gas exchange, pulmonary air leaks (pulmonary interstitial emphysema, pneumothorax; see Chapter 132), pulmonary hemorrhage (see Chapter 133), or intraventricular hemorrhage (IVH).

DIAGNOSIS

The clinical course, chest x-ray findings, and blood gas values help establish the clinical diagnosis. On chest radiograph, the lungs may have a characteristic but not pathognomonic appearance that includes low lung volumes, a diffuse, fine reticular granularity of the parenchyma (ground-glass appearance), and air bronchograms (Fig. 126.5). The initial x-ray appearance is occasionally normal, with the typical pattern developing during the first day. Considerable variation in radiographic findings may be seen, especially in infants who have already received treatment with surfactant replacement and/or positive pressure respiratory support; this variation often results in poor correlation between radiographic findings and the clinical course. Blood gas findings are characterized initially by hypoxemia and later by progressive hypoxemia, hypercapnia, and variable metabolic acidosis.

In the differential diagnosis, early-onset sepsis may be indistinguishable from RDS. In neonates with pneumonia, the chest radiograph may be identical to that for RDS. Clinical factors such as maternal group B streptococcal colonization with inadequate intrapartum antibiotic prophylaxis, maternal fever (>38.5°C) or chorioamnionitis, or prolonged

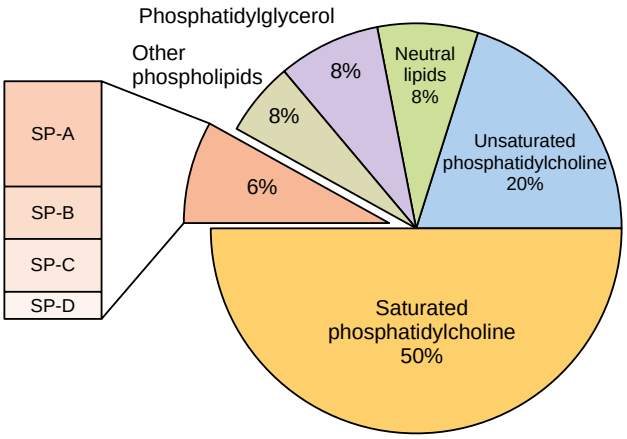

Fig. 126.2 Composition of surfactant. SP-A, Surfactant-associated protein A; SP-B, surfactant-associated protein B; SP-C, surfactant-associated protein C; SP-D, surfactant-associated protein D. *(From Jobe AH, Ikegami M. Biology of surfactant. Clin Perinatol. 2001;28:655–669.)*

rupture of membranes (>18 hours) are associated with an increased risk of early-onset sepsis. Although complete blood counts are neither sensitive nor specific in the diagnosis of early-onset sepsis, the presence of marked neutropenia has been associated with increased risk. **Transient tachypnea of the newborn** (TTN; see Chapter 128) is a common consideration that may be distinguished from RDS by its shorter and milder clinical course and is characterized by low or no need for O_2 supplementation. Cyanotic congenital heart disease (in particular, total anomalous pulmonary venous return) can also mimic RDS both clinically and radiographically. Echocardiography with color-flow imaging can be performed in infants who show no response to surfactant replacement, to rule out cyanotic congenital heart disease as well as ascertain patency of the ductus arteriosus and assess pulmonary vascular resistance (PVR). Persistent pulmonary hypertension, aspiration (meconium, amniotic fluid) syndromes, spontaneous pneumothorax, pleural effusions, and congenital anomalies (pulmonary congenital airway malformations, pulmonary lymphangiectasia, diaphragmatic hernia, lobar emphysema) must be considered in patients with an atypical clinical course but can generally be differentiated from RDS through radiographic and other evaluations (Fig. 126.6).

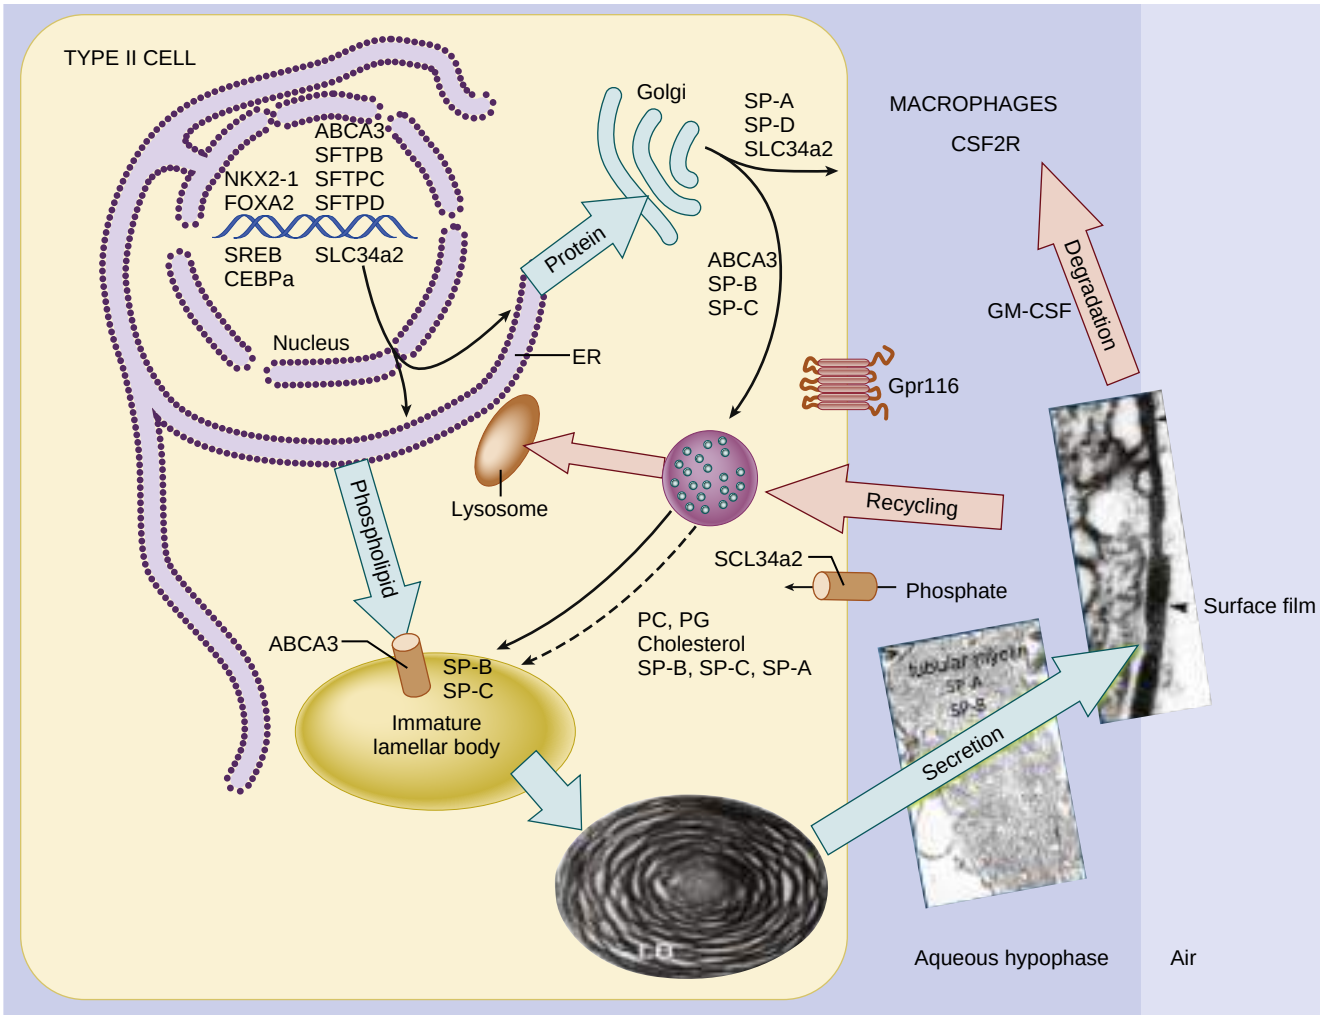

Fig. 126.3 Biosynthesis of surfactant involves distinct pathways for surfactant proteins and lipids. SP-B and SP-C are trafficked from the endoplasmic reticulum (ER) to lamellar bodies via the Golgi complex and multivesicular body (MVB); in contrast, surfactant phospholipids are likely directly transported from the ER to specific lipid importers (ABCA3) in the lamellar body–limiting membrane. Surfactant proteins and lipids are assembled into bilayer membranes that are secreted into the alveolar airspace, where they form a surface film at the air–liquid interface. Cyclical expansion and compression of the bioactive film results in the incorporation and loss of lipids and proteins from the multilayered surface film. Surfactant components removed from the film are degraded in alveolar macrophages or are taken up by type II epithelial cells for recycling or degradation in the lysosome. The MVB plays a key part in the integration of pathways for surfactant synthesis, recycling, and degradation. NKX2-1, FOXA2, SREBP, and CEBPα are transcription factors regulating surfactant protein and lipid synthesis. SLC34a2 is a phosphate transporter. Gpr116 is a membrane receptor regulating surfactant secretion. Fetal and Neonatal Physiology, 6th ed. Philadelphia: Elsevier; 2022: Fig. 75.3.)*

Although rare, genetic disorders may contribute to respiratory distress. Abnormalities in **surfactant protein B and C** genes as well as a gene responsible for transporting surfactant across membranes, ABC transporter 3 *(ABCA3)*, are associated with severe and often lethal familial respiratory disease. **Congenital alveolar proteinosis** (congenital surfactant protein B deficiency) is a rare familial disease that manifests as severe and lethal RDS in predominantly term and near-term infants (see Chapter 434). In atypical cases of RDS, a lung profile (lecithin:sphingomyelin ratio and phosphatidylglycerol determination) performed on a tracheal aspirate can be helpful in establishing a diagnosis of surfactant deficiency. Other familial causes of neonatal respiratory distress (not RDS) include mucopolysaccharidosis, acinar dysplasia, pulmonary lymphangiectasia, and alveolocapillary dysplasia. Evaluation for these disorders should be pursued with the assistance of pediatric pulmonologists and geneticists. Evaluation may include lung imaging, fluid sampling, tissue biopsy, and genetic testing.

New York: Wiley; 1980.)*

PREVENTION

Avoidance of unnecessary or poorly timed early (<39 weeks' GA) cesarean delivery or induction of labor and appropriate management of high-risk pregnancy and labor (including administration of antenatal corticosteroids) are important preventive strategies. Strategies to prevent preterm birth include antenatal use of progesterone; measurement of cervical length and cerclage placement as indicated; and use of antibiotics, tocolytics, and magnesium for threatened preterm labor. In cases where premature delivery cannot be avoided, the transfer of the mother to an institution with appropriate neonatal care capabilities can improve early management of RDS. Antenatal and intrapartum fetal

Differential diagnosis of acute respiratory distress in the neonate. In Frantz ID, ed. Tufts University of School of Medicine and Floating Hospital for Children Reports on Neonatal Respiratory Diseases. Vol. 2. Issue 3. Newtown, PA: Associates in Medical Marketing Co.; 1992.)*

monitoring may decrease the risk of fetal asphyxia; asphyxia is associated with an increased incidence and severity of RDS.

Administration of **antenatal corticosteroids** to women before 37 weeks of gestation significantly reduces the incidence and mortality of RDS as well as overall neonatal mortality. Antenatal corticosteroids also reduce (1) overall mortality, (2) admission to the neonatal intensive care unit (NICU) and need for/duration of ventilatory support, and (3) incidence of severe IVH, necrotizing enterocolitis (NEC), and neurodevelopmental impairment. Betamethasone and dexamethasone have both been used antenatally. The American College of Obstetricians and Gynecologists (ACOG) recommends antenatal corticosteroids for all women presenting between 24- and 34-weeks' gestation in preterm labor. Antenatal corticosteroid use before 24 weeks' gestation for preterm labor or rupture of membranes should be driven by the family's preferences for intervention. ACOG recommends a single course of antenatal corticosteroid for mothers presenting between 34- and 36-weeks' gestation in preterm labor if no previous steroids have been given during the pregnancy. One repeat course of antenatal corticosteroids may be considered for mothers at risk of preterm delivery more than 14 days from the prior course of steroids and with a GA less than 34 weeks. Additional repeat courses of antenatal corticosteroids are not recommended due to impact on birthweight, cerebral myelination, and lung growth. Antenatal corticosteroids do not increase the risk of maternal death, chorioamnionitis, or puerperal sepsis.

TREATMENT

The basic defect requiring treatment in RDS is inadequate pulmonary O_2-CO_2 exchange. Basic supportive care (thermoregulatory, circulatory, fluid, electrolyte, and respiratory) is essential while FRC is established and maintained. Because most cases of RDS are self-limited, the goal of treatment is to minimize abnormal physiologic variations and superimposed iatrogenic problems. Treatment of infants with RDS is best carried out in the NICU.

Continuous monitoring of vital signs, review of chest radiography, and monitoring of blood gas values guides therapy in RDS. Oxygenation (So_2) should be assessed by continuous pulse oximetry. Capillary blood samples are of limited value for determining Po_2 but may be useful for Pco_2 and pH monitoring. Arterial blood gas samples provide the most accurate assessment of oxygenation. Monitoring of blood gas parameters and mean arterial blood pressure through an umbilical or peripheral arterial catheter is useful in managing the shocklike state that may occur during the initial hours in premature infants who have been asphyxiated or have severe RDS. Because of the difficulty in distinguishing group B streptococcal or other bacterial infections from RDS, empirical antibiotic therapy should be indicated until the results of blood cultures are available. Penicillin or ampicillin with an aminoglycoside is suggested, although the choice of antibiotics should be based on the recent pattern of bacterial sensitivity in the hospital where the infant is being treated (see Chapter 129).

Nasal Continuous Positive Airway Pressure

Warm, humidified oxygen should be provided at a concentration sufficient to keep Pao_2 between 50 and 70 mm Hg (91–95% Sao_2) to maintain normal tissue oxygenation while minimizing the risk of O_2 toxicity. If there is significant respiratory distress (severe retractions and expiratory grunting) or if Sao_2 cannot be kept >90% at an Fio_2 of ≥40, applying nasal continuous positive airway pressure (nCPAP) at 5-8 cm H_2O is indicated and usually produces a rapid improvement in oxygenation. Nasal CPAP reduces collapse of surfactant-deficient alveoli and improves both FRC and ventilation-perfusion matching. Early use of nCPAP for stabilization of at-risk preterm infants beginning early (in the delivery room) reduces the need for mechanical ventilation. Alternatives to nCPAP include noninvasive positive pressure ventilation (NIPPV) and high-flow nasal cannula (HFNC). NIPPV is generally unsynchronized, but intermittent higher pressures do appear to improve oxygenation and ventilation over several hours. Additionally, NIPPV may limit apnea as a cause of respiratory failure. **HFNC** used heated and humidified oxygen flow generally upward of 2 L/min to provide distending pressures to the airways. The distending pressure is variable, which may contribute to HFNC failure. The amount of nCPAP required usually decreases after approximately 72 hours of age, and most infants can be weaned from nCPAP shortly thereafter.

Surfactant Replacement Therapy

Surfactant deficiency is the primary pathophysiology of RDS. Immediate effects of surfactant replacement therapy include improved alveolar-arterial oxygen gradients, reduced ventilatory support, increased pulmonary compliance, and improved chest radiograph appearance. In the past, *intratracheal* surfactant replacement for symptomatic premature infants immediately after birth (prophylactic) or during the first few hours of life *(early rescue)* showed reduced air leak and mortality from RDS. However, substantial evidence supports the feasibility and efficacy of **nCPAP** as the *primary* means of respiratory support for preterm infants with RDS with addition of surfactant based on clinical indication. Nasal CPAP started at birth is as effective as prophylactic or early surfactant and is associated with a reduction in bronchopulmonary dysplasia (BPD). *Nasal CPAP is therefore the approach of choice for the delivery room management of a preterm neonate at risk for RDS.*

In neonates with RDS who fail nCPAP and require intubation and mechanical ventilation, treatment with endotracheal surfactant should be initiated immediately to avoid lung injury. *Assisted ventilation and surfactant are indicated for infants with RDS who cannot keep oxygen saturation >90% while breathing 40% oxygen and receiving nCPAP.* Delays in delivering surfactant once clinical criteria are met is associated with poorer outcomes including increased mortality, increased incidence of **pulmonary air leak,** and increased risk for **BPD**. Repeated dosing is given every 6-12 hours for a total of two to four doses, depending on the preparation. Exogenous surfactant should be given by a physician who is qualified in neonatal resuscitation and respiratory management. Additional required on-site staff support includes nurses and respiratory therapists experienced in the ventilatory management of preterm infants. Bolus delivery of surfactant is generally associated with better distribution throughout the lungs and faster improvement. Lung recruitment strategies include modest increase in tidal volume or positive end-expiratory pressure (PEEP) before surfactant administration, which may improve distribution. Appropriate monitoring equipment (radiology, blood gas laboratory, pulse oximetry) must also be available. Complications of surfactant replacement therapy include transient hypoxia, hypercapnia, bradycardia and hypotension, blockage of endotracheal tube (ETT), and pulmonary hemorrhage.

A number of surfactant preparations are available, including synthetic surfactants and natural surfactants derived from animal sources. There do not appear to be significant, consistent benefits to one preparation over another. Infants requiring ventilator support after 1 week of age may experience transient episodes of surfactant dysfunction temporally associated with episodes of infection and respiratory deterioration. Surfactant treatment may be beneficial in these infants.

Recognizing the benefits of surfactant replacement therapy, in addition to the potential protective effects of prophylactic nCPAP, some experts recommend intubation for prophylactic or early rescue surfactant replacement therapy, followed by extubation back to nCPAP immediately once the infant is stable (usually within minutes). This method is commonly referred to *as intubate, surfactant, and extubate (INSURE).* A variation of the INSURE method has evolved known as *MIST (minimally invasive surfactant therapy)* or *LISA (less invasive surfactant administration),* in which a small feeding tube, rather than an ETT, is used to deliver intratracheal surfactant to a spontaneously breathing infant on nCPAP. LISA and/or MIST are increasingly being utilized as the preferred method for delivering surfactant in infants who are not anticipated to require prolonged invasive ventilation. The combination of LISA, antenatal corticosteroids, nCPAP, and limitation of positive pressure ventilation in the delivery room was associated with decreased rates of BPD when compared to INSURE. Other methods of surfactant delivery are under investigation including the use of laryngeal mask airway and the use of nebulized surfactant to avoid airway manipulation altogether. In two studies of aerosolized surfactant, the need for intubation was reduced by ~50%.

Mechanical Ventilation

Infants with respiratory failure or persistent apnea require assisted mechanical ventilation. Strict definitions for respiratory failure in extremely preterm infants with RDS are not agreed on universally, but reasonable measures of respiratory failure are (1) arterial blood pH <7.20, (2) $Paco_2$ ≥60 mm Hg, (3) Sao_2 <90% at O_2 concentration of 40% *and* nCPAP of 5-8 cm H_2O, and (4) persistent or severe apnea. The goal of mechanical ventilation is to improve oxygenation and ventilation without causing pulmonary injury or oxygen toxicity. Acceptable ranges of arterial blood gas (ABG) values vary significantly among institutions but generally range from Pao_2 50-70 mm Hg (Spo_2 >90%), $Paco_2$ 45-65 mm Hg (and higher after the first few days when risk of IVH is less), and pH 7.20-7.35. During mechanical ventilation, **oxygenation** is improved by increasing either Fio_2 or the mean airway pressure. The mean airway pressure can be increased by raising the peak inspiratory pressure (PIP), inspiratory time, ventilator rate, or PEEP. Adjustment in PEEP is usually most effective; however, excessive PEEP may impede venous return, thereby reducing cardiac output and O_2 delivery (see Chapter 89.1). PEEP levels of 4-6 cm H_2O are usually safe and effective and assist in establishing FRC. **CO_2 elimination** is determined by the minute ventilation, which is a product of the tidal volume (dependent on the inspiratory time and PIP) and ventilator rate. Ventilator settings typically include a tidal volume of 4-6 mL/kg and a starting rate of approximately 40 breaths/min. With use of high ventilatory rates, relatively short inspiratory time and sufficient expiratory time should be allowed to avoid air trapping and inadvertent PEEP.

Synchronized intermittent mechanical ventilation (SIMV) delivered by time-cycled pressure-limited, continuous flow ventilators is a common method of conventional ventilation for newborns. With **pressure-limited** SIMV, a set PIP is delivered in synchrony with the patient's own breaths for a specified rate per minute. For breaths above the set rate, pressure support breaths (8-10 cm H_2O above PEEP) are provided to help overcome the resistance associated with spontaneous breathing through the ETT. In pressure-limited ventilation, the delivered tidal volume is directly proportional to the respiratory compliance. Rapid changes in compliance occur with surfactant replacement therapy, requiring careful attention to tidal volumes and appropriate adjustments in PIP. In **volume-targeted** ventilation a specific tidal volume is set, and the PIP required to deliver it varies inversely with the respiratory compliance. Studies indicate that lung damage is related to recurrent lung collapse and overdistension rather than high pressures, thus volume-targeted ventilation may represent the most lung protective strategy of conventional ventilation. Evidence suggests that volume-targeted ventilation results in fewer pulmonary air leaks and may improve survival without BPD.

Neurally adjusted ventilatory assist (NAVA) is a ventilator strategy that integrates electrical signals from the diaphragm to synchronize ventilator breaths with the patient. Increased diaphragmatic electrical signal indicates the impending onset of a breath. The strength of electrical signal indicates the size of breath intended by the patient. Using this strategy, the timing and tidal volume can be customized to the patient on a breath-by-breath basis, and this is believed to decrease overall pressures required and limit lung damage. NAVA technology can also be used to synchronize noninvasive ventilation. To date there is insufficient evidence to compare the outcomes of infants with RDS initially managed on NAVA ventilation to those managed with pressure-limited or volume-limited SIMV.

High-frequency ventilation (HFV) achieves desired alveolar ventilation by using smaller tidal volumes and higher rates (300-1,200 breaths/min or 5-20 Hz). This ventilation strategy maintains sustained alveolar expansion and therefore limits injury associated with recurrent atelectasis. HFV may improve elimination of CO_2 and improve oxygenation in patients who show no response to conventional ventilators, as well as those who have severe RDS, interstitial emphysema, recurrent pneumothoraces, or meconium aspiration pneumonia. High-frequency oscillatory ventilation (HFOV) and high-frequency jet ventilation (HFJV) are the most frequently used methods. There is not strong evidence to favor HFOV over HFJV or vice versa. Many investigators have examined the use of HFV as a primary mode of ventilation in infants with RDS. There is some evidence that HFV may result in decreased rates of BPD and pulmonary air leak when compared to pressure-limited SIMV; however, superiority over volume-targeted SIMV has not been consistently demonstrated.

Permissive Hypercapnia and Avoidance of Hyperoxia

Permissive hypercapnia is a strategy for management of patients receiving ventilatory support in whom priority is given to limiting ventilator-associated lung injury by tolerating relatively high levels of $Paco_2$ (>60-70 mm Hg). Permissive hypercapnia can be implemented during nCPAP and mechanical ventilation but has not been shown to significantly impact outcomes. Hypocarbia is associated with poorer outcomes; therefore careful monitoring of Pco_2 should be undertaken and moderate hypercapnia (>40-50 mmHg) can be tolerated. Hyperoxia may also contribute to lung injury in preterm infants. However, a lower target range of oxygenation (85–89%) compared with a higher range (91–95%) increases mortality and does not alter rates of BPD, BPD/death, blindness, or neurodevelopmental impairment. Therefore the currently recommended range of oxygen saturation targets is 91–95%.

Discontinuation of Mechanical Ventilation

Strategies for weaning infants from ventilators vary widely and are influenced by lung mechanics as well as the availability of ventilatory modes. Extubation to nCPAP prevents postextubation atelectasis and reduces the need for reintubation. NIPPV may further decrease the need for reintubation in premature infants, particularly when combined with NAVA technology to allow synchronization. HFNC (1-8 L/min) oxygen is often used to support term and near-term infants following extubation and appears to be comparable to nCPAP in preventing postextubation failure. It is not clear whether nCPAP, NIPPV, or HFNC is more efficacious for promoting normal lung development and preventing BPD, but there is more evidence associated with nCPAP in extremely preterm infants. Preloading with methylxanthines enhances the success of extubation.

Other Pharmacologic Therapies

There are no pharmacologic therapies superior or equal to the efficacy of maintaining FRC (through noninvasive respiratory support and mechanical ventilation when necessary) and providing surfactant replacement therapy in the treatment of RDS. Systemic corticosteroids (predominantly dexamethasone), although effective in improving respiratory mechanics and reducing the incidence of BPD and death, are associated with increased risk of cerebral palsy and neurodevelopmental impairment when used indiscriminately (see Chapter 127).

Inhaled nitric oxide (iNO) has been evaluated in preterm infants following the observation of its effectiveness in term and near-term infants with hypoxemic respiratory failure. Although iNO improves oxygenation in term and near-term infants with hypoxic respiratory failure or persistent pulmonary hypertension of the neonate, trials in preterm infants have not shown significant benefit.

PROGNOSIS

Early provision of intensive observation and care of high-risk newborn infants can significantly reduce the morbidity and mortality associated with RDS and other acute neonatal illnesses. Antenatal corticosteroids, postnatal surfactant use, and improved modes of ventilation have resulted in low mortality from RDS (approximately 10%). Mortality increases with decreasing GA. Optimal results depend on the availability of experienced and skilled personnel, care in specially designed and organized regional hospital units, proper equipment, and lack of complications such as severe asphyxia, intracranial hemorrhage, or irremediable congenital malformation. Premature infants with RDS may go on to develop chronic lung disease and ultimately BPD (see Chapter 127).

Pulmonary air leaks (pneumothorax, pneumomediastinum, pulmonary interstitial emphysema) are observed in 3–9% of extremely preterm infants with RDS (see Chapter 132). PPV with excessive

inspiratory pressures (and therefore excessive tidal volumes), either during resuscitation at delivery or in the initial hours of mechanical ventilation, is a common risk factor, but air leaks can also occur in infants breathing spontaneously. Although the risk of air leak was increased in infants receiving a higher level of nCPAP (up to 8 cm H_2O) in the CPAP or Intubation at Birth (COIN) trial, subsequent trials have not demonstrated a similar effect.

Additional complications of RDS may result from intubation procedures during the treatment of this disorder. Airway injury may occur at the time of intubation and adequate training is essential. Complications of intubation including ventilator-associated pneumonias and transient obstruction of the artificial airway are possible. With prolonged or recurrent intubation local pressure injury can lead to the development of subglottic stenosis.

126.1 Patent Ductus Arteriosus

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

INCIDENCE AND PATHOPHYSIOLOGY

The ductus arteriosus is a fetal vascular shunt connecting the aorta to the pulmonary artery that allows oxygenated blood to bypass the uninflated fetal lungs and enter the systemic circulation. Following term birth, the ductus arteriosus constricts and is usually closed in the first few days of life. Although ductal closure occurs by 72 hours after birth in almost all term infants, the ductus remains patent in 65% of preterm infants born at <30 weeks' GA and in 85% of infants born at 24 weeks' GA. Risk factors for delayed closure of the PDA include hypoxia, acidosis, increased pulmonary pressure secondary to pulmonary vasoconstriction, systemic hypotension, immaturity, and local release of prostaglandins (which dilate the ductus). Shunting through the patent ductus arteriosus (PDA) may initially be bidirectional or right to left. As RDS resolves, PVR decreases, and predominantly left-to-right shunting may occur, leading to left ventricular (LV) volume overload and pulmonary edema.

CLINICAL MANIFESTATIONS

Manifestations of PDA may include (1) a hyperdynamic precordium, bounding peripheral pulses, wide pulse pressure, and a machine-like continuous or systolic murmur; (2) radiographic evidence of cardiomegaly and increased pulmonary vascular markings; (3) hepatomegaly; (4) increasing oxygen dependence; (5) carbon dioxide retention; and (6) less often renal failure. Infants with a hemodynamically significant PDA often require escalation of ventilator and oxygen support. The diagnosis is confirmed by echocardiographic visualization of a PDA with Doppler flow imaging that demonstrates left-to-right shunting. A hemodynamically significant PDA by echocardiogram has a PDA ≥1.5 mm, unrestricted pulsatile transductal flow, left atrial to aortic root ratio ≥1.5, and absent (end) diastolic flow in the descending aorta (Table 126.1).

TREATMENT

Interventions to encourage ductal closure include fluid restriction, cyclooxygenase (COX) inhibitors (indomethacin or ibuprofen), acetaminophen, and surgical ligation. Short-term benefits of any therapy must be balanced against adverse effects, such as transient renal dysfunction and fluid imbalances associated with indomethacin.

By the time of discharge in the majority of extremely preterm infants (>90%), the PDA will close spontaneously. Spontaneous ductal closure may be facilitated by general supportive measures, including early (<7 days of age) avoidance of excessive fluid administration and judicious use of diuretics to manage pulmonary edema. However, within the first week of life, in 30% of infants with birthweight <1,500 g and 70% of infants <1,000 g, the PDA persists. Although many preterm infants with persistent PDA will remain clinically stable while awaiting spontaneous closure, approximately 60% of infants <1,000 g will develop significant clinical instability (hypotension, renal failure, worsening respiratory failure secondary to pulmonary edema). Pharmacologic and surgical ductal closure may be indicated in the premature infant with a moderate to large, hemodynamically significant PDA when there is a delay in clinical improvement or deterioration.

Table 126.1 Summary of Essential Parameters Used for Echocardiographic Assessment and Hemodynamic Evaluation of PDA

PDA EVALUATION CRITERIA	ESSENTIAL ECHOCARDIOGRAPHIC PARAMETERS FOR ASSESSMENT OF PDA AND HEMODYNAMIC EVALUATION
Ductal characteristics	PDA size (small 2 mm) and flow direction (left to right, right to left, or bidirectional) and Doppler assessment with maximum velocity (Vmax) in systole and end-diastole
Assessment of pulmonary over circulation	Dilated left side of the heart on visual inspection "eyeballing" and LA/Ao ratio (mild 1.6) OR LVEDD (correlate with *z* scores) OR LPA diastolic velocity, mean velocity >0.42 m/sec, end-diastolic velocity >0.2 m/sec OR reversal of mitral E/A ratio *Document presence or absence and magnitude of intraatrial shunt
Assessment of systemic hypoperfusion	Retrograde or absent blood flow during diastole in descending aorta OR celiac trunk or SMA OR anterior or middle cerebral artery

A comprehensive echocardiographic assessment should be performed to rule out any underlying congenital heart defect or pulmonary hypertension and delineate orientation of arch (left or right sidedness) before any intervention to close the PDA.
E/A ratio, ratio of the early (E) to late (A) ventricular filling velocities; LA/Ao, left atrial to aortic ratio; LPA, left pulmonary artery; LVEDD, left ventricular end-diastolic diameter; PDA, patent ductus arteriosus; SMA, superior mesenteric artery.
From Singh Y, Fraisse A, Erdeve O, Atasay B. Echocardiographic diagnosis and hemodynamic evaluation of patent ductus arteriosus in extremely low gestational age newborn (ELGAN) infants. *Front Pediatr.* 2020;8:Article 573627. Table 1.

Pharmacologic Closure

Pharmacologic closure of the PDA has been described using COX inhibitors that inhibit prostaglandin production, with equivalent efficacy and safety profiles described for ibuprofen and indomethacin. The efficacy of pharmacologic *therapy* is inversely proportional to the gestational and postnatal age, and closure is more likely when medication is administered before 21 days of age. However, successful closure has been reported up to 8 weeks of age. Whether indomethacin or ibuprofen is used, 20–40% of infants demonstrate treatment failure, and of those infants, 10–20% require eventual surgical ligation. Rates of recurrence following successful pharmacologic closure in general are low (<15%). Neither therapy significantly impacts the rate of NEC, BPD, or mortality. **General contraindications** to both indomethacin and ibuprofen include thrombocytopenia (<50,000 platelets/mm^3), active hemorrhage (including severe IVH), NEC or isolated intestinal perforation, elevated plasma creatinine (>1.8 mg/dL), or oliguria (urine output <1 mL/kg/hr). Importantly, the concomitant use of hydrocortisone and indomethacin in extremely preterm infants must be avoided because the combination is associated with a dramatic increase in spontaneous intestinal perforation. Although indomethacin reduces

mesenteric blood flow, mounting experience suggests that low-volume trophic enteral feeding during administration is safe.

Prophylactic **indomethacin** given over the first 72 hours of age to preterm infants with birthweight <1,000 g reduces the incidence of severe IVH (grade III/IV), pulmonary hemorrhage, symptomatic PDA, and need for surgical PDA ligation. Although often implicated in spontaneous intestinal perforation and NEC, randomized controlled trials (RCTs) have failed to demonstrate that indomethacin increases their risk significantly. Short-term side effects include reductions in cerebral, mesenteric, and renal blood flow. Oliguria unresponsive to diuretic therapy is observed frequently. Dosing regimens for indomethacin vary considerably, but it usually is administered as a slow IV infusion (0.1-0.2 mg/kg/dose over 30 minutes) every 12-24 hours for three doses. A repeat course can be attempted if the duct fails to close or reopens, but additional (>2) courses do not appear to be efficacious. Longer courses (5-7 days) of indomethacin are not recommended because of to an increased risk of NEC in one trial.

Ibuprofen is as effective as indomethacin in closing a PDA, but ibuprofen is associated with reduced rates of oliguria and a small but significant reduction in the length of mechanical ventilation. Although higher doses may improve closure rates in the most immature infants, the typical IV or enteral dosing regimen for ibuprofen is 10 mg/kg for one dose, followed by two doses of 5 mg/kg every 24 hours. A meta-analysis showed that a higher dose of oral ibuprofen using 20 mg/kg per dose for one dose, followed by 10 mg/kg per dose for two doses 24 hours apart is superior in closing the PDA compared to indomethacin or the traditional ibuprofen dosing. As with indomethacin, a repeat course may be considered, but additional courses of ibuprofen are not efficacious and not recommended. Risk of NEC is *not increased* with indomethacin, but in comparison, ibuprofen *reduces* the relative risk of NEC. Unlike indomethacin, ibuprofen has not been shown to reduce the risk of severe IVH. Compared to the IV route, enteral ibuprofen may be more efficacious. Whether ibuprofen used in combination with hydrocortisone results in increased risk of spontaneous intestinal perforation is unknown.

Oral acetaminophen has been shown to be an effective medication in closing the PDA, with fewer side effects than existing agents. It is given enterally at 15 mg/kg per dose q6h for 3 days. In practice, most clinicians will use a course of one of the previously mentioned medications as first-line therapy (typically ibuprofen) and follow with a second course of acetaminophen in a few days if the PDA remains patent and symptomatic.

Surgical Ligation

The infant whose *symptomatic* PDA fails to close with pharmacologic interventions or who has contraindications to COX inhibitors is a candidate for surgical closure via an open thoracotomy. Although the long-term benefits are unclear, surgical ligation in infants born at <28 weeks' GA and <1,250 g is associated with improved survival. Surgical mortality is very low even in extremely low birthweight (ELBW) infants. However, **postligation cardiac syndrome**, a significant drop in blood pressure 6-12 hours after ductal ligation, is experienced by up to 50% of low birthweight (LBW) infants. The hypotension has been attributed to increased systemic vascular resistance along with decreased pulmonary venous return, resulting in impaired preload and LV function. Fluid resuscitation, inotropic support (with dobutamine or milrinone), and hydrocortisone are usually effective. Other complications of surgery include hemorrhage, pneumothorax, chylothorax, Horner syndrome, and injury to the recurrent laryngeal nerve resulting in vocal cord dysfunction. Inadvertent ligation of the left pulmonary artery or the transverse aortic arch has rarely been reported. Increased rates of neurodevelopmental impairment have been reported following surgical ligation, although a causal relationship remains uncertain. Due to the complications associated with surgical ligation, many centers have moved away from this modality and use a less invasive, percutaneous approach to PDA closure.

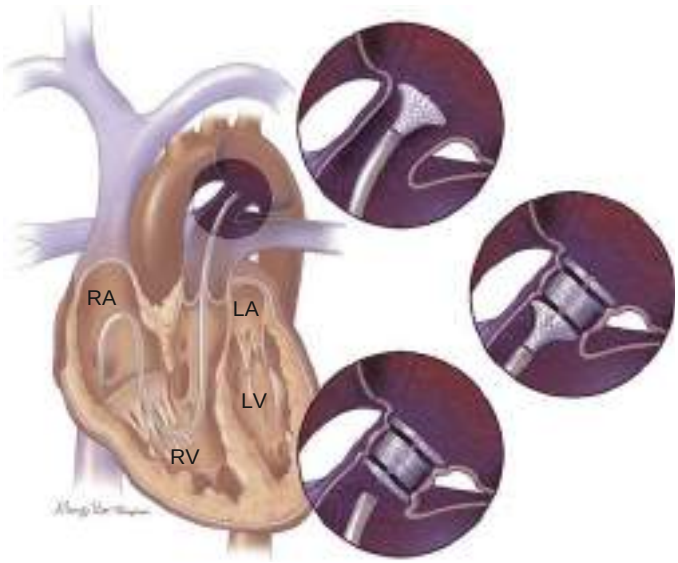

Fig. 126.7 Percutaneous device closure of a PDA using the Amplatzer Piccolo Occluder. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. *(From Backes CH, Giesinger RE, Rivera BK, et al. Percutaneous closure of the patent ductus arteriosus in very low weight infants: considerations following US Food and Drug Administration approval of a novel device. J Pediatr. 2019;213:218–221.)*

Percutaneous Closure of the Patent Ductus Arteriosus

Percutaneous closure of the PDA is a safe and effective procedure for definitive PDA closure. In 2019, the U.S. Food and Drug Administration approved the Amplatzer PiccoloOccluder (Abbott Diagnostics, North Chicago, IL) for percutaneous PDA closure in preterm infants weighing 700 g or more (Fig. 126.7). A trial in 100 infants weighing <2 kg showed that this technique of PDA closure is 99% effective with a 2% risk of adverse events. Although a comparative trial has not been done against the traditional surgical approach, most US centers use percutaneous closure as the first-line approach for PDA closure when conservative treatment fails. This procedure is done under cardiac anesthesia in the catheterization laboratory. The femoral vein is accessed using modified Seldinger technique, and then, under fluoroscopic guidance, a catheter is advanced through the femoral vein all through the right ventricular and across the PDA and the Piccolo device is placed. This technique permits injection of contrast before and after device placement to ensure appropriate device selection, measure size of the PDA, and ensure that there is no occlusion of the descending aorta or left pulmonary artery after device placement. If there is evidence of narrowing, the device can be recaptured and repositioned until a satisfactory result is obtained. Rarely, appropriate device placement is not achieved, and the patient may have to undergo surgical ligation. The short-term complications are bleeding at the insertion site, embolization of the device into the descending aorta or left pulmonary artery, post-PDA ligation syndrome, and residual shunting across PDA. The long-term complications are unknown, but these patients likely need surveillance echocardiography until 2-3 years of age.

Chapter 127

Bronchopulmonary Dysplasia

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

INCIDENCE

Bronchopulmonary dysplasia (BPD; also known as *chronic lung disease of prematurity*) is a clinical pulmonary syndrome that develops in the majority of extremely preterm infants and is defined by a prolonged need for respiratory support and supplemental oxygen. Almost 60% of infants born at ≤28 weeks' gestation will develop BPD, and the incidence of BPD increases inversely with gestational age. For infants born at 22-24 weeks, essentially 100% will develop BPD, the majority of whom will have moderate to severe disease. As neonatal care has improved and use of antenatal corticosteroids has become the standard of care, survival of infants born at the extreme of viability has improved, and BPD is encountered with increased prevalence. In the United States, an additional 10,000-15,000 new cases occur annually. Despite decades of experience, the incidence of BPD remains largely unchanged.

ETIOLOGY AND PATHOPHYSIOLOGY

BPD develops following preterm birth and the necessary life-supporting interventions (particularly mechanical ventilation and supplemental oxygen) that cause neonatal lung injury. As very low birthweight (VLBW) infant's survival has improved by advances in neonatal care, the clinical syndrome associated with BPD has evolved. The clinical, radiographic, and lung histology of classic BPD described in 1967 by Northway, before widespread use of antenatal corticosteroids and postnatal surfactant, was that of a disease of preterm infants who were more mature. Infants who developed BPD initially demonstrated classic respiratory distress syndrome (RDS), but the injurious mechanical ventilation and excessive supplemental oxygen required to support them resulted in a progressive, severe fibroproliferative lung disease. Improvements in respiratory care, as well as the introduction of surfactant and antenatal steroids, have allowed for less aggressive respiratory support strategies, and the need for excessive ventilator support and high percentages of inspired supplemental oxygen has decreased.

Despite a reduction in the fibroproliferative disease described previously, infants born in the modern era of neonatal care continued to require supplemental oxygen for prolonged periods. The *new* BPD is a disease primarily of infants with birthweight <1,000 g who were born at <28 weeks' gestation, some of whom have initially little or no lung disease at birth but over the first weeks of age experience progressive respiratory failure. Infants with the new BPD are born at a more immature stage of distal lung development, and lung histology demonstrates variable saccular wall fibrosis, minimal airway disease, abnormal pulmonary microvasculature development, and alveolar simplification. Although the etiology remains incompletely understood, the histopathology of BPD indicates interference with normal alveolar septation and microvascular maturation.

The pathogenesis of BPD is likely multifactorial, but pulmonary inflammation and lung injury in an immature lung are consistently observed. Alveolar collapse **(atelectrauma)** as a consequence of surfactant deficiency, together with ventilator-induced phasic overdistention of the lung **(volutrauma)**, promotes lung inflammation and injury. Supplemental oxygen produces free radicals that cannot be metabolized by the immature antioxidant systems of VLBW neonates and further contributes to the injury. Pulmonary inflammation evidenced by infiltration of neutrophils and macrophages in alveolar fluid, as well as a host of proinflammatory cytokines, contributes to the progression of lung injury. Pre- and postnatal infection, excessive pulmonary blood flow via the patent ductus arteriosus (PDA), excessive administration of intravenous fluid, and pre- and postnatal growth failure are also significantly associated with the development of BPD. In addition, pulmonary artery hypertension may complicate BPD. Although the mechanisms are unclear, all likely promote lung injury by necessitating increased or prolonged respiratory support or interfering with lung repair. Regardless, the result is an interference with normal development of the alveolar-capillary unit and interference with normal gas exchange.

CLINICAL MANIFESTATIONS

Over the first several weeks of age, infants developing BPD demonstrate persistent, often progressive respiratory distress and the need for respiratory support and supplemental oxygen. In extremely low birthweight (ELBW) infants at risk for BPD, the need for supplemental oxygen over the first 2 weeks of age follows one of three distinct patterns. Infants that follow the natural course of RDS, and by 3-4 days of age require minimal (F_{IO_2} <0.25) supplemental oxygen, have a low (<20%) risk of developing BPD. Infants who initially have a low O_2 requirement (F_{IO_2} <0.25) during the first week, but then experience early pulmonary deterioration and increased O_2 requirement (F_{IO_2} >0.25) during the second week, have a modest risk (approximately 50%) of developing BPD. Infants that have an early, persistently high (F_{IO_2} >0.25) need for supplemental oxygen have a significantly high (70%) risk of developing BPD.

Respiratory distress, commonly characterized by tachypnea and retractions, persists or worsens and is associated with hypercapnia, hypoxia, and oxygen dependence. The chest radiograph evolves from that of RDS to relative hyperinflation and fine, diffuse interstitial opacities. Wandering atelectasis is common. In the most severe cases, usually associated with prolonged mechanical ventilation and chronically high supplemental oxygen needs, frank cystic changes and/or pneumatoceles are observed (Fig. 127.1). Infants with severe BPD receiving invasive ventilation often demonstrate airway obstruction. Excessive airway mucus and edema, airway instability caused by acquired tracheobronchomalacia, and bronchospasm are proposed etiologies. Acute airway obstruction is manifest clinically by abrupt hypoxemia and bradycardia and is often referred to as *BPD spells*. Acute, intermittent right-to-left intracardiac or intrapulmonary shunting caused by abrupt elevations in pulmonary artery pressure (PAP) may also contribute and resemble BPD spells. Spells are notoriously difficult to control, but occasionally will respond to bronchodilators, increasing positive end-expiratory pressure (PEEP), and sedation acutely.

A common complication of BPD is **pulmonary hypertension**. Prospective surveillance indicates that in approximately 15% of all infants born at <1,000 g and <28 weeks' gestational age, echocardiographic signs of pulmonary hypertension will develop. Prenatal growth restriction, prolonged duration of mechanical ventilation and supplemental oxygen, and increasing severity of BPD are all associated with an increased risk. Pulmonary hypertension has been reported in as many as 40% of infants with the most severe BPD and can progress to right-sided heart failure. Pulmonary hypertension complicating BPD has been associated with increased mortality.

DIAGNOSIS

BPD is diagnosed when a preterm infant requires supplemental oxygen for the first 28 postnatal days; it is further classified at 36 weeks' postmenstrual age (PMA) according to the degree of O_2 supplementation (Table 127.1). Neonates receiving positive pressure support or ≥30% supplemental O_2 at 36 weeks' PMA or at discharge (whichever occurs first) are diagnosed as having **severe** BPD; those requiring <30% supplemental O_2 have **moderate** BPD; and those who previously required O_2 supplementation for at least 28 days but are currently breathing room air have **mild** BPD. Infants who require oxygen for <28 days of life have "no BPD." Infants receiving supplemental O_2 should undergo a stepwise reduction in supplemental O_2 to room air at 36 weeks while under continuous observation and with Spo_2 monitoring to determine whether they can be weaned off oxygen

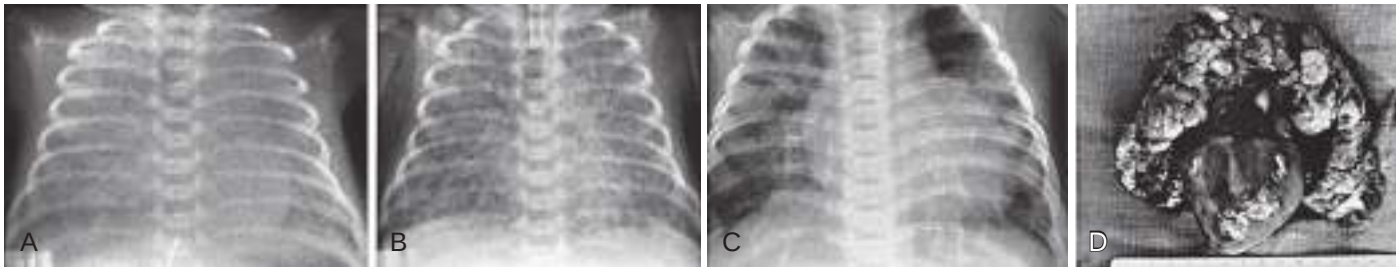

Fig. 127.1 Pulmonary changes in infants treated with prolonged, intermittent positive pressure breathing with air containing 80–100% oxygen in the immediate postnatal period for the clinical syndrome of hyaline membrane disease. **A,** A 5-day-old infant with nearly complete opacification of the lungs. **B,** A 13-day-old infant with "bubbly lungs" simulating the radiographic appearance of the Wilson-Mikity syndrome. **C,** A 7-month-old infant with irregular, dense strands in both lungs, hyperinflation, and cardiomegaly suggestive of chronic lung disease. **D,** Large right ventricle and a cobbly, irregular aerated lung of an infant who died at 11 months of age. This infant also had a patent ductus arteriosus. *(From Northway WH Jr, Rosan RC, Porter DY. Pulmonary disease following respiratory therapy of hyaline-membrane disease. N Engl J Med. 1967;276:357–368.)*

Table 127.1 Definition of Bronchopulmonary Dysplasia: Diagnostic Criteria*

	GESTATIONAL AGE	
	<32 Wk	**≥32 Wk**
Time point of assessment	36 wk PMA or discharge home, whichever comes first Treatment with >21% oxygen for at least 28 days **plus**:	>28 days but <56 days postnatal age or discharge home, whichever comes first Treatment with >21% oxygen for at least 28 days **plus**:
Mild BPD	Breathing room air at 36 wk PMA or discharge home, whichever comes first	Breathing room air by 56 days postnatal age or discharge home, whichever comes first
Moderate BPD	Need† for <30% oxygen at 36 wk PMA or discharge home, whichever comes first	Need† for <30% oxygen at 56 days postnatal age or discharge home, whichever comes first
Severe BPD	Need† for ≥30% oxygen and/or positive pressure (PPV or nCPAP) at 36 wk PMA or discharge home, whichever comes first	Need† for ≥30% oxygen and/or positive pressure (PPV or nCPAP) at 56 days postnatal age or discharge home, whichever comes first

*BPD usually develops in neonates being treated with oxygen and PPV for respiratory failure, most frequently respiratory distress syndrome (RDS). Persistence of the clinical features of respiratory disease (tachypnea, retractions, crackles) is considered common to the broad description of BPD and has not been included in the diagnostic criteria describing the severity of BPD. Infants treated with >21% oxygen and/or PPV for nonrespiratory disease (e.g., central apnea or diaphragmatic paralysis) do not have BPD unless parenchymal lung disease also develops and they have clinical features of respiratory distress. A day of treatment with >21% oxygen means that the infant received >21% oxygen for >12 hr on that day. Treatment with >21% oxygen and/or PPV at 36 wk PMA or at 56 days postnatal age or discharge should not reflect an "acute" event; rather, it should reflect the infant's usual daily therapy for several days preceding and after 36 wk PMA, 56 days postnatal age, or discharge.

†A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a pulse oximetry saturation range.

BPD, Bronchopulmonary dysplasia; nCPAP, nasal continuous positive airway pressure; PMA, postmenstrual age; PPV, positive pressure ventilation.

From Jobe AH, Bancalari E. Bronchopulmonary dysplasia. *Am J Respir Crit Care Med.* 2001;163:1723–1729.

(physiologic definition of BPD). This test is highly reliable and correlated with discharge home on oxygen, length of hospital stay, and hospital readmissions in the first year of life. The risk of neurodevelopmental impairment and pulmonary morbidity and the severity of BPD are directly correlated.

Despite its simplicity, the current severity-based definition of BPD has limitations. Because of incomplete or inaccurate data related to hospital transfer or early discharge, in a significant number of infants the diagnosis of BPD is either not documented or misapplied. Additionally, those infants requiring O_2 support at relatively high flow (>2 L/min) or very low (<0.25 L/min) or those receiving other modes of noninvasive ventilation are not well characterized. Calculation of *effective oxygen* may be helpful but is cumbersome and not well validated. Clinical trials have relied on the need for supplemental O_2 at 36 weeks PMA to define BPD. Although this definition can diagnose BPD in the highest percentage of infants, it cannot discriminate between infants with milder BPD from those with most severe forms of BPD. A National Institute of Child Health and Human Development (NICHD) workshop on BPD developed a definition of BPD that would address some of the concerns mentioned earlier (Table 127.2). Specifically, it incorporates the diverse forms of respiratory support used, distinguishes infants who are receiving invasive vs noninvasive positive pressure ventilation (PPV), and introduces the term "lethal BPD" or grade III(A) severe BPD to identify infants who die from this disease before 36 weeks' PMA.

PREVENTION

In general, there remains a lack of effective interventions that prevent BPD. Avoidance of mechanical ventilation with the early use of nCPAP and early, selective surfactant replacement therapy with rapid extubation decrease the incidence of BPD modestly. The avoidance of mechanical ventilation achieved by the combination of early rescue surfactant by the INSURE, MIST, or LISA method with nasal continuous positive airway pressure (nCPAP) has been associated with a modest reduction in BPD (see Chapter 126). Gentle ventilation strategies, including volume-targeted ventilation and high-frequency oscillatory ventilation (HFOV), have also been associated with small, inconsistent reductions in BPD. Caffeine therapy for apnea of prematurity has also been associated with a decreased risk of BPD. Although the mechanisms are unknown, caffeine likely supports effective spontaneous respiration and decreases the likelihood that an infant will need invasive mechanical ventilation.

Table 127.2 New Definition of Bronchopulmonary Dysplasia Based on the 2016 NICHD Executive Workshop on Bronchopulmonary Dysplasia

For infants born <32 wk gestation, with radiographic evidence of parenchymal lung disease, who at 36 wk require one of the following F_{IO_2}/oxygen levels/oxygen concentrations for ≥3 consecutive days to maintain Sp_{O_2} in the 90–95% range

	INVASIVE IPPV	nCPAP, NIPPV, OR NASAL CANNULA ≥3 L/MIN	NASAL CANNULA 1-3 L/MIN	NASAL CANNULA <1 L/MIN
Grade I BPD	No	21% F_{IO_2}	22–29% F_{IO_2}	22–70% F_{IO_2}
Grade II BPD	21% F_{IO_2}	22–29% F_{IO_2}	≥30% F_{IO_2}	≥70% F_{IO_2}
Grade III BPD	>21% F_{IO_2}	≥30% F_{IO_2}		
Grade III(A) BPD	Infants who die between 14 days to 36 wk PMA from respiratory failure secondary to severe parenchymal lung disease not attributable to other neonatal morbidities			

NICHD, National Institute of Child Health and Human Development; BPD, bronchopulmonary dysplasia; IPPV, invasive positive pressure ventilation; nCPAP, nasal continuous positive airway pressure; NIPPV, noninvasive positive pressure ventilation.
Adapted from Higgins RD, Jobe AH, Koso-Thomas M, et al. Bronchopulmonary dysplasia: executive summary of a workshop. *J Pediatr*. 2018;197:300–308.

Systemic corticosteroids (dexamethasone) given either early (<7 days of age to ventilated infants at risk of BPD) or late (>7 days of age to infants with progressing lung disease) prevent both mortality and BPD significantly, but because of the increased risk of cerebral palsy (CP) and neurodevelopmental impairment, their routine use is not recommended. The risk of neurodevelopmental impairment related to systemic corticosteroid use may be offset by the risk associated with BPD. A systematic review suggested that systemic corticosteroid therapy, when directed to infants with a ≥65% risk of developing BPD, may actually reduce the risk of neurodevelopmental impairment and CP. Although predictive models that use clinical characteristics have been described with promising accuracy, randomized trials using them to guide corticosteroid therapy have not been performed.

Inhaled corticosteroids administered to VLBW infants requiring mechanical ventilation at 7-14 days of age did not prevent BPD significantly. However, early, prolonged administration to mechanically ventilated extremely preterm infants until they no longer require oxygen or positive pressure support has been shown to reduce the risk of BPD, but with a concerning trend toward increased mortality. Experience with local delivery of corticosteroids by spiking surfactant with budesonide is emerging, and early data suggest that endotracheal administration of corticosteroids may reduce pulmonary inflammation and the risk of BPD and death. However, additional evidence is needed before widespread use is implemented. The routine use of antibiotics, inhaled bronchodilators, or diuretics has not been shown to *prevent* BPD.

TREATMENT

Treatment of evolving and established BPD is supportive. The basic tenets of therapy should include appropriate support of ventilation and aggressive nutritional support to optimize linear growth and encourage normal lung repair and development. Available evidence suggests short-term benefits (improved pulmonary mechanics, modest reductions in respiratory support parameters) without an indication of impact on clinically relevant outcomes (survival, need for long-term respiratory support, recurrent hospitalization). Currently, available evidence does not support the routine use of any pharmacologic agents in infants with evolving or established BPD. Treatment decisions must weigh the perceived benefit against the potential harm.

Diuretics and Fluid Restriction

Infants with BPD often have excessive pulmonary interstitial fluid that compromises lung function and increases work of breathing. Diuretic therapy (usually with furosemide or chlorothiazide) has been associated with short-term, temporary improvements in pulmonary compliance and the ability to wean respiratory support. Furosemide (1 mg/kg/dose IV or 2 mg/kg/dose orally [PO] every 12-24 hours) has been demonstrated to decrease pulmonary interstitial edema and pulmonary vascular resistance (PVR), improve pulmonary function, and facilitate weaning from mechanical ventilation and oxygen. Adverse effects of long-term furosemide therapy are common and include hyponatremia, hypokalemia, alkalosis, azotemia, hypocalcemia, hypercalciuria, cholelithiasis, renal stones, nephrocalcinosis, and ototoxicity. Sodium and potassium chloride supplementation is often necessary. Thiazide diuretics (e.g., chlorothiazide, 5-10 mg/kg/dose every 12 hours) have been used as an alternative to avoid hypercalciuria, limit nephrocalcinosis, and preserve bone development. Although avoidance of excessive fluid administration in the first few weeks of age is associated with a reduced risk of BPD, there is no evidence that fluid restriction (130-140 mL/kg/day) in established BPD has any impact. Whether using diuretics or fluid restriction, careful attention to maintaining appropriate electrolyte levels as well as providing adequate caloric intake (often >120-130 kcal/kg/day) is paramount to avoid negatively impacting nutrition.

Bronchodilators

Inhaled bronchodilators improve lung mechanics by decreasing airway resistance. **Albuterol** is a specific β_2-agonist used to treat bronchospasm in infants with BPD. Albuterol may improve lung compliance by decreasing airway resistance secondary to smooth muscle cell relaxation but can exacerbate bronchomalacia. Changes in pulmonary mechanics may last 4-6 hours. Hypertension and tachycardia are adverse effects. Ipratropium bromide is a muscarinic antagonist related to atropine, but the bronchodilator effect is more potent. Use of ipratropium bromide in BPD has been associated with improved pulmonary mechanics. Compared with either agent used alone, combined use of albuterol and ipratropium bromide may be more effective. Few adverse effects have been noted. With current aerosol administration strategies, exactly how much medication is delivered to the airways and lungs of infants with BPD, especially if they are ventilator dependent, is unclear.

Corticosteroids

Systemic corticosteroids have been used to treat evolving and established BPD. In mechanically ventilated infants, systemic corticosteroids improve pulmonary mechanics, allow weaning of ventilator support and supplemental O_2, and facilitate extubation. When given at >7 days of age, long-term benefits include a reduced need for O_2 at 36 weeks PMA, improved survival, and decreased need for home O_2. Short-term adverse effects include hyperglycemia, hypertension, and transient hypertrophic obstructive cardiomyopathy. Long-term adverse effects include osteopenia, severe retinopathy of

prematurity (ROP), abnormal neurologic examination, poor brain growth, neurodevelopmental impairment, and CP. A strategy that utilizes a low cumulative dose (0.89 mg/kg of dexamethasone given over 10-day taper) in preterm infants who remain ventilator dependent after 7 days of age (and therefore have a high risk of developing BPD) facilitates weaning of ventilator and oxygen support and promotes successful extubation without an impact on long-term outcomes, including the incidence of BPD or neurodevelopmental impairment. The controversy concerning the appropriate use of systemic corticosteroids to prevent and/or treat BPD is ongoing, and until additional evidence is available, their use remains limited to infants with severe respiratory failure (ventilator dependent at >7-14 days of age with significant respiratory and oxygen support needs) at high risk for imminent death.

Inhaled corticosteroids (budesonide, fluticasone, and beclomethasone) have been described as an alternative therapy in evolving or established BPD. Small randomized controlled trials (RCTs) and case reports in infants with established moderate to severe BPD have not shown a significant benefit for pulmonary mechanics or reduction in the need for ventilator or oxygen support. Inhaled fluticasone propionate (corticosteroid) combined with salmeterol (long-acting β_2-agonist) may be beneficial.

Pulmonary Vasodilators

Many infants with evolving or established moderate and severe BPD demonstrate increased PVR caused by pulmonary microvascular maldevelopment and abnormal vasoreactivity. In infants *with* BPD with pulmonary hypertension, acute exposure to even modest levels of hypoxemia can cause PAP to increase abruptly. Maintaining infants with established BPD and pulmonary hypertension at higher So_2 targets (92–96%) can lower PAP effectively. For infants in whom appropriate O_2 supplementation and support of ventilation are ineffective, the use of low-dose inhaled nitric oxide (iNO) may improve oxygenation anecdotally. Despite its frequent use, there is no evidence to support the use of iNO to improve lung function, cardiac function, or oxygenation in evolving BPD. Several case series have reported on the use of the phosphodiesterase-5 inhibitor sildenafil in treating pulmonary hypertension in established moderate to severe BPD. Despite its widespread use, no RCTs are evaluating the safety and efficacy of sildenafil in preterm infants with BPD. However, many experts would recommend a trial of low-dose sildenafil (1 mg/kg/dose every 8 hours) for infants with evidence of pulmonary hypertension and persistent respiratory instability despite appropriate oxygen and ventilator support.

Chronic Respiratory Support

Experience suggests that maintaining functional residual capacity (FRC) with appropriate positive pressure support (with noninvasive support whenever possible) promotes optimal lung growth and development. Provision of nCPAP until respiratory status improves and oxygen dependence resolves, with subsequent transition directly to room air, may be beneficial. Continuation of caffeine therapy may facilitate spontaneous breathing and weaning from support. Established severe BPD with cystic, heterogeneous lung disease often requires prolonged mechanical ventilation. A long inspiratory time is required to adequately ventilate diseased lung units, and appropriate expiratory time is required to allow exhalation. The use of a low rate (<20-30 breaths/min), long inspiratory time (≥0.6 seconds) strategy is usually required. To attain appropriate minute ventilation, larger tidal volumes (10-15 mL/kg) may be necessary. Higher PEEP (often >6-8 cm H_2O) may be needed to attain adequate expansion and minimize gas-trapping caused by dynamic airway collapse. Gradual weaning of ventilator settings should be attempted as the infant grows and lung disease improves, but the incidence of death or tracheostomy placement for chronic ventilation may be as high as 20%. By 2-3 years of age, the majority of infants who undergo tracheostomy for severe BPD are successfully liberated from mechanical ventilation.

PROGNOSIS

Compared with extremely preterm infants without BPD, infants with BPD have higher rates of neurodevelopmental impairment, lung diffusion impairment, wheezing and airflow obstruction, rehospitalization, and mortality. The risk of these complications increases with BPD severity. Infants with grade III BPD are most likely to either die or have long-term respiratory morbidity. Prolonged mechanical ventilation, intraventricular hemorrhage (IVH), pulmonary hypertension, cor pulmonale, and oxygen dependence beyond 1 year of life are poor prognostic signs. Mortality in infants with BPD ranges from 10–25% and is highest in infants who remain ventilator dependent for >6 months. Cardiorespiratory failure associated with cor pulmonale and acquired infection (respiratory syncytial virus [RSV]) are common causes of death. Infants are at risk for severe RSV infections and must receive prophylactic therapy (see Chapter 307).

Pulmonary function slowly improves in most survivors because of ongoing lung repair and the natural period of lung growth and alveolarization. *Rehospitalization* for impaired pulmonary function is most common during the first 3 years of life and is much more common in infants requiring respiratory support at discharge. The incidence of physician-diagnosed asthma, use of bronchodilators, and wheezing is elevated. Despite a gradual decrease in symptom frequency, persistence of respiratory symptoms and abnormal pulmonary function test results are measurable in children, adolescence, and young adults. Although not always clinically apparent, pulmonary function testing consistently reveals impaired exercise capacity, reduced pulmonary diffusing capacity, and persistent expiratory flow obstruction. High-resolution chest CT scanning or MRI studies in children and adults with a history of BPD reveal lung abnormalities that correlate directly with the degree of pulmonary function abnormality. The ultimate long-term pulmonary health of survivors of BPD is unknown. As trajectories of developing lung function remain abnormal in survivors of BPD, concerns have been raised highlighting the potential for pulmonary emphysema, chronic obstructive pulmonary disease, and pulmonary vascular disease resulting in early debilitating lung dysfunction.

Other complications of BPD include growth failure, neurodevelopmental impairment, and parental stress, as well as sequelae of therapy, such as nephrolithiasis, osteopenia, and electrolyte imbalance. Airway problems such as vocal cord paralysis, subglottic stenosis, and tracheomalacia are common and may aggravate or cause pulmonary hypertension. Subglottic stenosis may require tracheotomy or an anterior cricoid split procedure to relieve upper airway obstruction. Cardiac complications of BPD include pulmonary hypertension, cor pulmonale, systemic hypertension, left ventricular hypertrophy, and development of aortopulmonary collateral vessels, which, if large, may cause heart failure.

Chapter 128

Transient Tachypnea of the Newborn

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

INCIDENCE

Transient tachypnea of the newborn (TTN) is a clinical syndrome of self-limited tachypnea associated with delayed clearance of fetal lung fluid. Although the actual incidence is likely underreported, it is estimated at 3-6 per 1,000 term infant births, making TTN the most common etiology of tachypnea in the newborn. Twin gestation, maternal asthma, maternal hypertension, late prematurity, precipitous delivery, perinatal depression, gestational diabetes, macrosomia, and cesarean delivery, particularly without labor, are common risk factors.

ETIOLOGY AND PATHOPHYSIOLOGY

TTN is believed to result from ineffective clearance of fetal lung fluid. Retained fetal lung fluid decreases pulmonary compliance and impedes gas exchange. Clearance of fetal lung fluid occurs through increased expression of epithelial sodium channels (ENaCs) and sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) that drive active sodium (and thereby fluid) reabsorption. There is evidence that the channels involved in fluid clearance differ for infants with TTN. Additional lung fluid is cleared via compressive forces at the time of delivery and hydrostatic forces with the infant's first breaths (see Chapter 124.1). Decreased respiratory effort can delay fluid clearance and increase the risk for TTN.

CLINICAL MANIFESTATIONS

TTN is characterized by the early onset of tachypnea (>60 breaths/min), sometimes with retractions or expiratory grunting and occasionally with cyanosis that is relieved by minimal O_2 supplementation (<40%). The chest generally sounds clear without crackles or wheeze, and the chest radiograph shows prominent perihilar pulmonary vascular markings, fluid in the intralobar fissures, and rarely small pleural effusions (Fig. 128.1). Hypercapnia and acidosis are uncommon. Respiratory failure requiring positive pressure support (either with nasal continuous positive airway pressure [nCPAP] or mechanical ventilation) also is uncommon, but when it occurs usually resolves rapidly (<12-24 hours). Most infants recover with supportive care alone, and over the first 24-72 hours the tachypnea and O_2 requirements slowly resolve.

DIAGNOSIS

Distinguishing TTN from respiratory distress syndrome (RDS) and other respiratory disorders (e.g., pneumonia) may be difficult, and transient tachypnea is frequently a diagnosis of exclusion. The distinctive features of TTN are rapid recovery of the infant and the absence of radiographic findings for RDS (low lung volumes, diffuse reticulogranular pattern, air bronchograms) and other lung disorders. Other respiratory disorders to consider include meconium aspiration syndrome (see Chapter 129), persistent pulmonary hypertension of the newborn (see Chapter 130), congenital lung anomalies, and spontaneous air leak (see Chapter 132). **Primary ciliary dyskinesia (PCD)** often presents in the newborn period and may resemble TTN or RDS. PCD in the newborn often lasts longer than TTN and requires a longer duration of oxygen therapy (Chapter 455).

PREVENTION

Prevention of TTN generally focuses on avoidance of modifiable risk factors. As prematurity increases the risk of TTN, the American College of Obstetrics and Gynecology recommends against nonmedically indicated deliveries, either vaginal or cesarean, before 39 weeks. They further state that documentation of fetal lung maturity, previously accomplished via amniocentesis with amniotic fluid testing, should not be used to guide early delivery as this does not ensure appropriate maturation of physiologic processes. When late-preterm delivery is medically indicated or threatened, the use of a single course of antenatal steroids is associated with a decreased risk of TTN and may be considered. Use of antenatal steroids at increasing gestational ages must be balanced against an increased risk of hypoglycemia in the neonate postpartum.

TREATMENT

Treatment for TTN is supportive. Based on the degree of symptoms and progression of those symptoms over the first 2 hours after birth, transfer to a facility with appropriate neonatal intensive care unit (NICU) care may be required. Supplemental oxygen should be provided to maintain saturations over 90%. nCPAP can be used to support infants with more significant work of breathing or oxygen requirements. Further evaluation with chest radiograph or blood gas analysis can be undertaken when distress is more significant, or the diagnosis is in question. Infants with significant tachypnea may be unable or unsafe to feed orally and can be supported with intravenous fluids or nasogastric feedings. Generally, TTN is unrelated to an underlying infection; however, antibiotic coverage may be initiated in patients with additional risk factors. Further evaluation for an alternate diagnosis should be undertaken if symptoms are not resolving by 72 hours of age.

Inhaled β_2-agonists such as albuterol (salbutamol) increase expression and activation of ENaC and Na^+,K^+-ATPase and facilitate fluid clearance. Emerging evidence suggests that when given early in the course of TTN, albuterol may improve oxygenation, shorten the duration of supplemental O_2 therapy, and expedite recovery; however, more data are needed before employing this method.

PROGNOSIS

Infants with a history of TTN do have an increased risk of developing a wheezing diagnosis during childhood. This association persists even after stratifying for the underlying risk factor of maternal asthma.

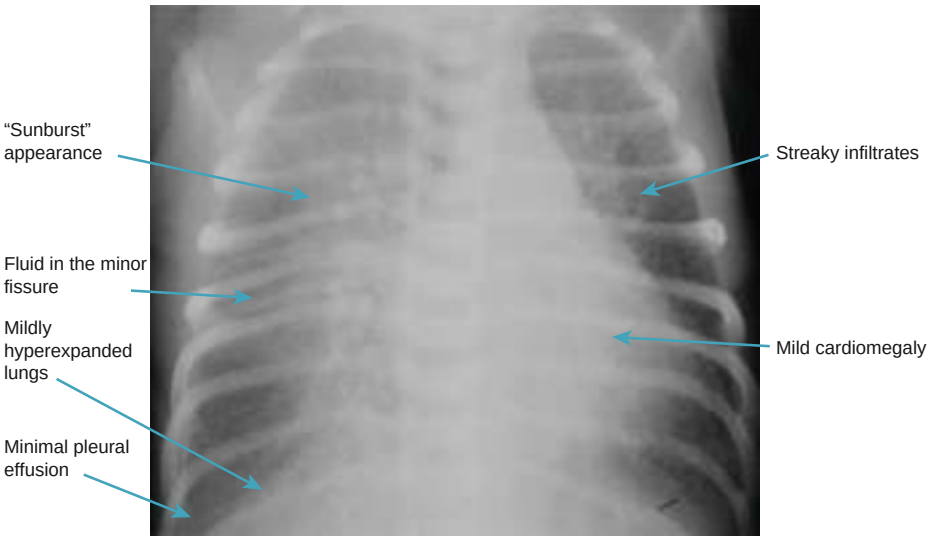

Fig. 128.1 Chest radiograph of an infant with transient tachypnea of the newborn. Notable features include increased pulmonary markings particularly in the perihilar region and fluid in the fissure. This contrasts with the radiograph of an infant with respiratory distress syndrome, which generally includes a homogenous ground glass appearance and hypoinflation. *(From Alhassen Z, Vali P, Guglani L, Lakshminrusimha S, Ryan RM. Recent advances in pathophysiology and management of transient tachypnea of newborn. J Perinatol. 2021;41:6–16. Fig. 5.)*

Chapter 129

Aspiration of Foreign Material (Meconium Aspiration Syndrome, Aspiration Pneumonia)

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Aspiration in the neonate can occur intrapartum often as a result of fetal distress or aspiration may occur postpartum, which can be related to a number of conditions including cardiopulmonary dysfunction, gastroesophageal reflux, aerodigestive tract anomalies, neurodevelopmental impairment, and craniofacial abnormalities.

INTRAPARTUM ASPIRATION

With fetal distress, the fetus often initiates vigorous respiratory movements in utero because of interference with the supply of oxygen through the placenta. Under such circumstances, the infant may aspirate amniotic fluid containing vernix caseosa, epithelial cells, meconium, blood, or material from the birth canal, which may block the smallest airways and interfere with alveolar exchange of O_2 and CO_2. Pathogenic bacteria may accompany the aspirated material, and pneumonia may ensue, but even in noninfected cases, respiratory distress accompanied by radiographic evidence of aspiration is seen (Fig. 129.1). The most relevant consequences of intrapartum aspiration are pneumonia and meconium aspiration syndrome (MAS).

Early-Onset Sepsis and Neonatal Pneumonia

Pneumonia as a presentation of early-onset sepsis typically arises following aspiration of infected amniotic fluid (see Chapter 149). The incidence of early-onset sepsis is 0.5 per 1,000 among term infants and increases to 1 per 1,000 among late preterm infants. The mortality rate is 2–3%. The most common causative agent is group B streptococcus (GBS; 40–45% of cases). Other causative agents include *Escherichia coli* and other gram-negative rods (10–15% of cases), *Enterococcus faecalis*, *Staphylococcus aureus*, and *Listeria monocytogenes*.

Bacteria within the airways causes direct mucosa injury, surfactant dysfunction, pulmonary edema, mechanical airway obstruction due to inflammation and debris, and can trigger vasoconstriction and pulmonary hypertension. Infants are particularly susceptible to infection due to immaturity of their innate and adaptive immune systems, a risk factor that is more pronounced in premature or growth-restricted infants. Additional risk factors for infection include being male, known maternal colonization with GBS, maternal fever, and prolonged rupture of membranes (>18 hours).

Diagnosis of neonatal pneumonia includes radiographic evidence of infiltrate, and consolidation, and less often cavitation or pneumatocele. Infants will display hypoxic and hypercarbic respiratory failure with frequent need for invasive ventilation; hypotension is common. Temperature instability, particularly hypothermia, is also common. White blood cell counts and single values of inflammatory markers have limited predictive potential. Blood cultures are indicated, and cerebrospinal fluid should be obtained if the blood culture is positive.

Treatment of neonatal pneumonia includes the prompt initiation of empiric broad-spectrum antibiotics. Commonly, ampicillin and an aminoglycoside (gentamicin) are used as first-line therapy with the substitution of a cephalosporin or meropenem in place of the aminoglycoside when meningitis is a concern or in cases of suspected antibiotic resistance. Therapy is typically 7-14 days in duration and should be completed parenterally.

Prevention of early-onset sepsis has largely involved the targeted intrapartum antibiotic prophylaxis of mothers known to be colonized with GBS. GBS prophylaxis, generally penicillin, is indicated for women who screen positive for colonization via vaginal-rectal culture at 36-37 weeks' gestation, have a history of an infant affected by GBS disease, or for preterm labor when GBS status is unknown. Additional broad-spectrum antibiotic therapy is indicated for women with intrapartum fever to decrease risk of ascending infection.

For more information on early-onset sepsis see Chapter 149.

Meconium Aspiration Syndrome

Meconium-stained amniotic fluid is found in 10–15% of births and usually occurs in term or postterm infants. MAS develops in 5% of such infants; 30% require mechanical ventilation, and 3–5% die. Usually, but

Fig. 129.1 Anteroposterior chest radiograph of a term infant with meconium aspiration syndrome shows the typical pattern of mixed atelectasis and local emphysema. An endotracheal tube is seen in good position. Two chest tubes are present in the right chest without persistent pneumothorax. *(From Rodriguez NE. Assessment of the neonatal and pediatric patient. In Heuer AJ, ed. Wilkins' Clinical Assessment in Respiratory Care, 9th ed. Philadelphia: Elsevier; 2022: Fig. 12.17)*

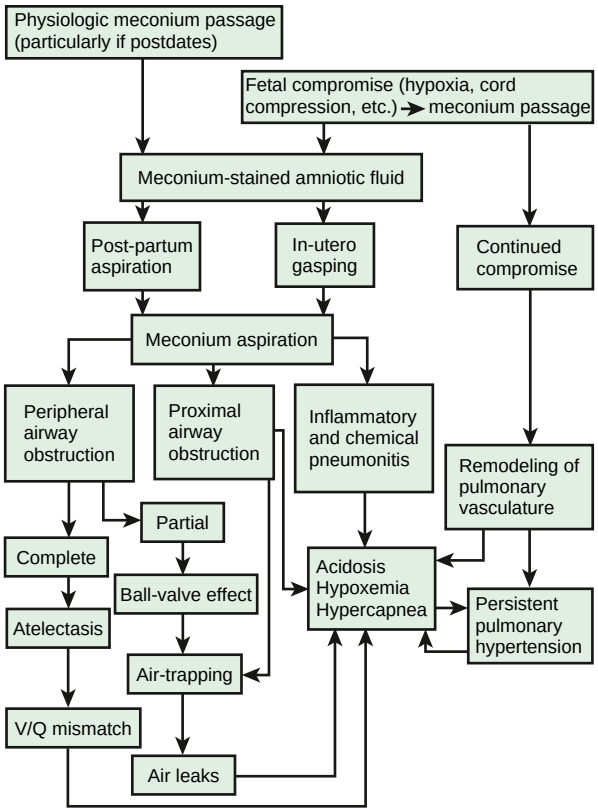

Fig. 129.2 Pathophysiology of meconium passage and the meconium aspiration syndrome. V/Q, ventilation-perfusion ratio. *(From Wiswell TE, Bent RC. Meconium staining and the meconium aspiration syndrome: unresolved issues. Pediatr Clin North Am. 1993;40:955–981.)*

not invariably, fetal distress and hypoxia occur before the passage of meconium into amniotic fluid. The infants are meconium stained and may be depressed and require resuscitation at birth. Either in utero or with the first breath, thick, particulate meconium is aspirated into the lungs. Partial obstruction of some airways may lead to pneumomediastinum, pneumothorax, or both. Overdistention of the chest may be prominent. Meconium within the lungs causes a chemical pneumonitis leading to surfactant dysfunction and inflammation (Fig. 129.1). The combination of airway obstruction and chemical injury can contribute to the development of persistent pulmonary hypertension of the newborn (PPHN; see Chapter 130). The pathophysiology of MAS is further described in Figure 129.2.

The clinical presentation of MAS is that of respiratory distress and cyanosis. In cases where in utero hypoxia was present, the presentation of MAS may be compounded by hypoxic ischemic encephalopathy and multiorgan dysfunction (including myocardial injury). The condition usually improves within 72 hours, but when its course requires assisted ventilation, it may be severe, prolonged, and with a risk for mortality. Tachypnea may persist for many days or even several weeks. The typical chest radiograph is characterized by patchy infiltrates, coarse streaking of both lung fields, increased anteroposterior diameter, and flattening of the diaphragm with possible pneumothorax (see Fig. 129.1).

The risk of meconium aspiration may be decreased by rapid identification of fetal distress and initiation of prompt delivery. Intrapartum nasopharyngeal suctioning in infants with meconium-stained amniotic fluid does not reduce the risk for MAS. Routine intubation and aspiration of depressed infants (those with hypotonia, bradycardia, or decreased respiratory effort) born through meconium-stained fluid is not effective in reducing the MAS or other major adverse outcomes and is not recommended for neonatal resuscitation. The risk of meconium-stained amniotic fluids increases with increasing gestational age. Additionally, among those infants with meconium-stained fluids, the risk for MAS increases with increasing gestational age (4.8% at >42 weeks vs 2.6% at 40 weeks) therefore limiting significantly postterm deliveries (>42 weeks) decreases the incidence of MAS.

Treatment of MAS includes supportive care and standard management for respiratory distress. The beneficial effect of mean airway pressure on oxygenation must be weighed against the risk of pneumothorax. Administration of exogenous surfactant and/or inhaled nitric oxide (iNO) to infants with MAS and hypoxemic respiratory failure, or pulmonary hypertension requiring mechanical ventilation, decreases the need for extracorporeal membrane oxygenation (ECMO), which is required by the most severely affected infants who show no response to therapy. In infants with MAS who demonstrate no other signs of sepsis, there is no role for continued antibiotic therapy. Severe meconium aspiration may be complicated by persistent pulmonary hypertension. Patients with MAS refractory to conventional mechanical ventilation may benefit from high-frequency ventilation (HFV) or ECMO (see Chapter 130). Management may also include concurrent treatment for hypoxic injury as discussed in Chapter 120.

The mortality rate of meconium-stained infants is considerably higher than that of nonstained infants. The decline in neonatal deaths caused by MAS is related to improvements in obstetric and neonatal care. Residual lung problems are rare but include symptomatic cough, wheezing, and persistent hyperinflation for up to 5-10 years. The ultimate prognosis depends on the extent of central nervous system injury from asphyxia and the presence of associated problems such as pulmonary hypertension.

POSTPARTUM ASPIRATION

Aspiration in the newborn after birth can be globally divided into categories of anatomic abnormalities and swallowing dysfunction. Regardless of the cause, the consequences of aspiration include pneumonia, chemical pneumonitis, and airway swelling.

Anatomic Causes of Postpartum Aspiration

Abnormalities of the aerodigestive tract can contribute to the passage of oral secretions and milk into the lungs. Obstruction or narrowing of the nasal cavity or nasopharynx can interrupt the normal

suck-swallow-breath cycle of the infant and increase the risk of aspiration. These conditions include genetic disorders associated with midface hypoplasia, choanal atresia, and congenital nasal masses or tumors. Infants with nasal obstruction will present with stertor, cyanosis improved with crying, and an inability to pass a nasal feeding tube. Oral sources of aspiration include micrognathia/retrognathia and oral masses that compromise airway protection. Cleft lip and palate can impair velopharyngeal closure and increase nasal regurgitation of milk with subsequent aspiration. Anatomic causes of aspiration at the level of the larynx include laryngomalacia due to increased work of breathing with poorer airway protective mechanisms, laryngotracheoesophageal clefts, and vocal fold paralysis or paresis where aspiration occurs as the vocal folds are unable to adduct and protect the airway. Tracheoesophageal fistula (TEF) contributes to aspiration via a direct connection between the esophagus and the airway. TEF can be divided into five types based on the location of the fistula and presence of esophageal atresia. Prenatal diagnosis may occur after the recognition of polyhydramnios and a small fetal stomach. Postnatal symptoms include excessive salivation that worsen with feeding attempts, choking, cough, cyanosis, respiratory distress, and an inability to pass an orogastric (OG) tube. TEF should prompt an evaluation for other anomalies.

When an anatomic abnormality is believed to be contributing to aspiration, initial management should include cessation of feeding pending an evaluation. Some conditions including vocal fold paresis and laryngomalacia may resolve spontaneously, and modified feeding strategies, often under the direction of a speech language pathologist, can allow delivery of nutrition until the condition improves with time and growth. Cleft palate can often be managed with feeding modification until surgical repair in infancy. Other conditions including choanal atresia and TEF require surgical intervention in the newborn period. In some cases, tracheostomy is required for infants unable to adequately protect their airway. Although reflux alone is not the cause of aspiration in these cases, decreasing the acidity of the aspirate may decrease airway swelling, and antireflux medications can be considered in select populations.

Swallowing Dysfunction

Swallowing dysfunction is another cause of aspiration in the newborn. Swallowing is a complex process and must be coordinated with respirations. Infants with neurologic injury may display abnormalities in the swallowing reflex or in the recognition and prevention of aspiration. Infants with pulmonary or cardiovascular disease leading to tachypnea will have more trouble coordinating a suck-swallow-breath cycle. Premature infants are more likely to have swallowing dysfunction because of prematurity-related pulmonary insufficiency and because of immaturity of the swallow mechanism, which begins to mature between 32 and 34 weeks. Hypotonic infants due to neuromuscular diseases or as a sequalae of hypoxic-ischemic encephalopathy are at increased risk of aspiration.

Evaluation of the swallow in at-risk infants often occurs with the assistance of a speech language pathologist and may include video fluoroscopic swallow studies to evaluate swallowing pattern and document aspiration. A fiberoptic endoscopic evaluation of the swallow (FEES) is another strategy whereby a speech language pathologist and ear, nose, and throat doctor observe a small-volume swallow via direct endoscopic visualization. Neurologic imaging may be indicated to assess for the underlying etiology of an ineffective or uncoordinated swallow.

Treatment strategies include feeding modifications such as pacing (tilting the bottle down every three to five sucks to allow recovery time), modified feeding position, or using a slower flow nipple. In cases where feeding modification does not adequately improve swallow safety, a percutaneous gastric tube for feeding may be indicated.

Chapter 130

Persistent Pulmonary Hypertension of the Newborn (Persistent Fetal Circulation)

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Persistent pulmonary hypertension of the newborn (PPHN) predominantly occurs in term and postterm infants. Predisposing factors include birth asphyxia, meconium aspiration syndrome (MAS), early-onset sepsis, respiratory distress syndrome (RDS), hypoglycemia, polycythemia, maternal use of nonsteroidal antiinflammatory drugs with in utero constriction of the ductus arteriosus, maternal late trimester use of selective serotonin reuptake inhibitors, and pulmonary hypoplasia caused by diaphragmatic hernia (Table 130.1). PPHN is often idiopathic. Some patients with PPHN have low plasma arginine and nitric oxide (NO) metabolite concentrations and polymorphisms of the carbamoyl phosphate synthase gene, findings suggestive of a possible subtle defect in NO production. The incidence is 1 in 500-1,500 live births, with a wide variation among clinical centers. Regardless of etiology of PPHN, profound hypoxemia from right-to-left shunting and normal or elevated $Paco_2$ are present (Fig. 130.1).

PATHOPHYSIOLOGY

Persistence of the fetal circulatory pattern of right-to-left shunting through the patent ductus arteriosus (PDA) and foramen ovale after birth is a result of excessively high pulmonary vascular resistance (PVR). Fetal PVR is usually elevated relative to fetal systemic or postnatal pulmonary pressure. This fetal state normally permits shunting of oxygenated umbilical venous blood to the left atrium (and brain) through the foramen ovale, from which it bypasses the lungs through the ductus arteriosus and passes to the descending aorta. After birth, PVR normally declines rapidly as a consequence of vasodilation secondary to lung inflation, a rise in postnatal Pao_2, a reduction in $Paco_2$, increased pH, and release of vasoactive substances. Increased neonatal PVR may be (1) **maladaptive** from an acute injury (not demonstrating normal vasodilation in response to increased O_2 and other changes after birth); (2) the result of increased pulmonary artery medial muscle thickness and extension of smooth muscle layers into the usually nonmuscular, more peripheral pulmonary arterioles in response to chronic fetal hypoxia; (3) a consequence of **pulmonary hypoplasia** (diaphragmatic hernia, Potter syndrome); or (4) **obstructive** as a result of polycythemia, total anomalous pulmonary venous return (TAPVR), or congenital diffuse development disorders of acinar lung development.

CLINICAL MANIFESTATIONS

PPHN usually manifests in the delivery room or within the first 12 hours after birth. Idiopathic PPHN or PPHN related to polycythemia, hypoglycemia, hypothermia, or asphyxia may result in severe cyanosis and respiratory distress. In some cases, however, initial signs of respiratory distress may be minimal. Infants who have PPHN associated with meconium aspiration, group B streptococcal pneumonia, diaphragmatic hernia, or pulmonary hypoplasia usually exhibit cyanosis, grunting, flaring, retractions, tachycardia, and shock. Multiorgan involvement may be present. Myocardial ischemia, papillary muscle dysfunction with mitral and tricuspid regurgitation, and biventricular dysfunction produce cardiogenic shock with decreases in pulmonary blood flow, tissue perfusion, and O_2 delivery.

Table 130.1 Etiology of Persistent Pulmonary Hypertension of the Newborn in Neonates

Maladaptation of pulmonary vasculature (abnormal, "reactive" pulmonary vasoconstriction)
- Parenchymal lung diseases, such as meconium aspiration syndrome (MAS), respiratory distress syndrome (RDS), and pneumonia
- In response to systemic disorders, such as hypothermia, sepsis, fetal hypoxia/distress, hypercapnia, acidosis, and hyperviscosity
- Toxic/pharmacologic exposure in utero (maternal selective serotonin reuptake inhibitor (SSRI) use)

Maldevelopment of pulmonary vasculature (remodeling of pulmonary vasculature)
- In utero closure of ductus arteriosus (maternal cyclooxygenase inhibitor use)
- Sustained pulmonary over circulation in congenital heart disease with large left-to-right shunts
- Intrauterine growth restriction
- Genetic/chromosomal anomalies (trisomy 21, alveolar-capillary dysplasia, surfactant protein deficiency)

Underdevelopment of pulmonary vasculature (hypoplastic pulmonary vessels; ↓ cross-sectional area)
- Congenital diaphragmatic hernia
- Pulmonary hypoplasia (premature prolonged rupture of membranes, oligohydramnios and anhydramnios, space-occupying lesions in the chest).

From Sharma M, Callan E, Konduri GG. Pulmonary vasodilator therapy in persistent pulmonary hypertension of the newborn. *Clin Perinatol*. 2022;49:103–105. Box 1.

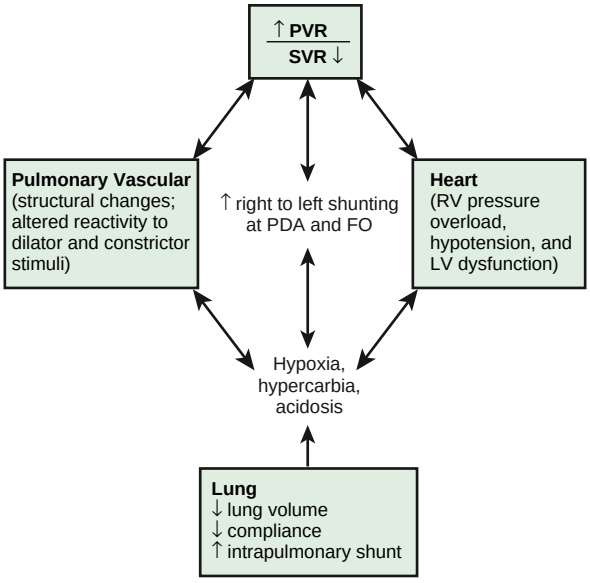

Fig. 130.1 Cardiopulmonary interactions in persistent pulmonary hypertension of the newborn (PPHN). FO, Foramen ovale; LV, left ventricle; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; RV, right ventricle; SVR, systemic vascular resistance. *(From Kinsella JP, Abman SH. Recent developments in the pathophysiology and treatment of persistent pulmonary hypertension of the newborn. J Pediatr. 1995;126:853–864.)*

Hypoxemia is often labile and out of proportion to the findings on chest radiographs. In PPHN due to asphyxia and idiopathic PPHN, chest x-ray findings are often normal, whereas in PPHN associated with pneumonia and diaphragmatic hernia, parenchymal opacification and bowel/liver in the chest, respectively, are seen.

DIAGNOSIS

Independent of the prenatal history, PPHN should be suspected in all term infants who have cyanosis. Hypoxemia is universal and intermittently unresponsive to 100% O_2 given by oxygen hood or nasal

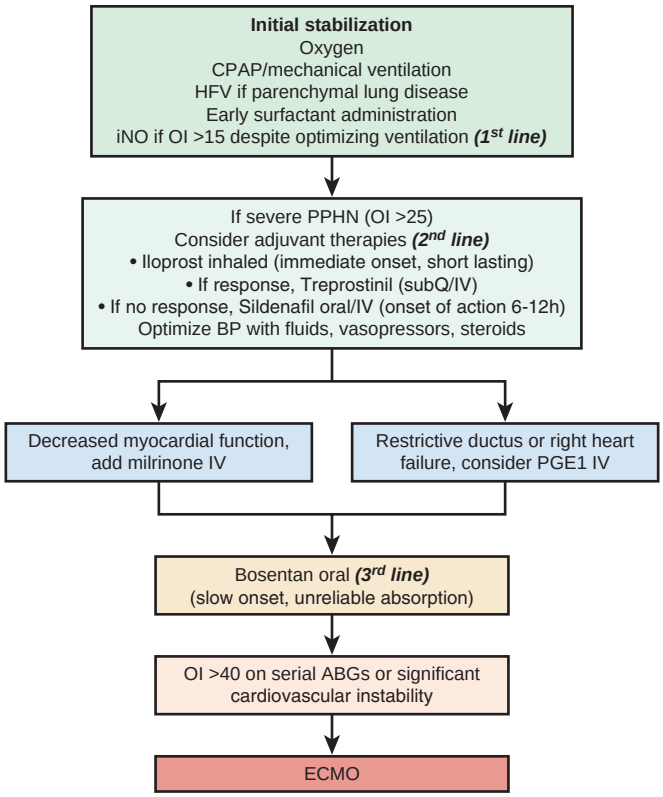

Fig. 130.2 Algorithm for the suggested approach and timing of interventions for the management of hypoxic respiratory failure (HRF)/persistent pulmonary hypertension of the newborn (PPHN). It is important to consider cardiopulmonary system to be one fully integrated unit and optimize lung recruitment, pulmonary vasodilation, and cardiac function to facilitate successful transition. The algorithm focuses on vasodilator agents and is not meant to be inclusive of all therapies used in the management of PPHN. ABG, Arterial blood gas; BP, blood pressure; CPAP, continuous positive airway pressure; ECMO, extracorporeal membrane oxygenation; HFV, high-frequency ventilation; iNO, inhaled nitric oxide; IV, intravenous; OI, oxygenation index; PGE1, prostaglandin E1; subQ, subcutaneous. *(From Sharma M, Callan E, Konduri GG. Pulmonary vasodilator therapy in persistent pulmonary hypertension of the newborn. Clin Perinatol. 2022;49:103–105, Fig. 3.)*

cannula. A Pao_2 or Sao_2 gradient between a preductal (right radial artery) and a postductal (umbilical artery) site of blood sampling suggests right-to-left shunting through the ductus arteriosus. Intracardiac shunting through the patent foramen ovale does not lead to a Pao_2 or Sao_2 gradient.

Real-time echocardiography combined with Doppler flow imaging is very helpful in evaluating PPHN. Systolic flattening of the interventricular septum as the right ventricular systolic pressure approaches the left ventricular systolic pressure can be used to estimate the degree of pulmonary hypertension. The peak velocity of the tricuspid valve regurgitation jet, when present, yields a quantitative estimate of the right ventricular systolic pressure. Likewise, the direction and velocity of a shunt across the PDA provides a quantitative comparison between the aortic and pulmonary artery pressures. In advanced cases, right-to-left or bidirectional shunting across a PDA and a patent foramen ovale can be observed.

The differential diagnosis of PPHN includes cyanotic heart disease (especially obstructed TAPVR), idiopathic pulmonary vein stenosis, congenital surfactant (protein) deficiency syndromes, pulmonary artery thrombosis, and congenital diffuse development disorders of acinar lung development (acinar dysplasia, congenital alveolar dysplasia, and alveolar capillary dysplasia with misalignment of the pulmonary veins).

Alveolocapillary dysplasia (ACD) is a rare, lethal autosomal recessive disorder of distal lung development characterized by immature lobular development and reduced capillary density. Infants with ACD

present with idiopathic PPHN, demonstrating little or no parenchymal lung disease and profound hypoxemia. Over 60% of infants with ACD manifest hypoxemia and respiratory failure within 48 hours of birth, while some with milder disease present beyond 6 months of age. The diagnosis is made on autopsy in 90% of cases, and the constellation of findings include thickened alveolar septa, increased muscularization of the pulmonary arterioles, a reduced number of capillaries, with the remaining capillaries demonstrating abnormal apposition to the air interface, and misalignment of the intrapulmonary veins. In up to 80% of cases, extrapulmonary malformations of the genitourinary, gastrointestinal, or cardiovascular system are present. Pathogenic variants in the transcription factor gene *FOXFI* have been identified in up to 40% of cases, but the diagnosis continues to rest on clinical and histopathologic features. There also may be associated gastrointestinal (malrotation), genitourinary, and cardiac (hypoplastic left heart syndrome) malformations. ACD is uniformly lethal and should be suspected in infants with idiopathic PPHN who fail to respond to maximal medical therapy, or when symptoms recur after successful weaning from extracorporeal membrane oxygenation (ECMO). In a UK ECMO report, up to 14% of infants who failed ECMO ultimately were diagnosed with ACD. Regardless of the timing of presentation, ACD is uniformly fatal, and lung transplantation remains the sole, experimental therapy.

TREATMENT

Therapy for PPHN is directed toward correcting any predisposing condition (e.g., hypoglycemia, polycythemia) and improving poor tissue oxygenation by addressing the underlying pathology (Fig. 130.2). Initial management includes O_2 administration and correction of acidosis, hypotension, and hypercapnia. Persistent hypoxemia should be managed with intubation and mechanical ventilation.

Infants with PPHN are usually managed *without* hyperventilation or alkalization. Gentle ventilation with normocarbia or permissive hypercarbia and avoidance of hypoxemia result in excellent outcomes and a low incidence of chronic lung disease and ECMO use.

Because of their instability and ability to fight the ventilator, newborns with PPHN usually require sedation. Nonpharmacologic measures such as minimal noise, light, and tactile stimulation are also employed. The use of paralytic agents is controversial and reserved for the newborn who cannot be treated with sedatives alone. Muscle relaxants may promote atelectasis of dependent lung regions and ventilation-perfusion mismatch and may be associated with an increased risk of death.

Inotropic therapy is frequently needed to support blood pressure and perfusion. Whereas epinephrine is frequently used as a first-line agent, other agents, such as dobutamine and milrinone, may be helpful when myocardial contractility is poor. Many centers use echo-guided assessment of cardiac function to choose appropriate inotropic therapy. Dopamine is typically avoided due to its ability to increase PVR. Some of the sickest newborns with PPHN demonstrate hypotension refractory to vasopressor administration. This results from desensitization of the cardiovascular system to catecholamines by overwhelming illness and relative adrenal insufficiency. Hydrocortisone rapidly upregulates cardiovascular adrenergic receptor expression and serves as a hormone substitute in cases of adrenal insufficiency.

Inhaled nitric oxide (iNO) is an endothelium-derived signaling molecule that relaxes vascular smooth muscle and can be delivered to the lung by inhalation. *Use of iNO reduces the need for ECMO support by approximately 40%.* The optimal starting dose is 20 ppm. Higher doses have not been shown to be more effective and are associated with side effects, including methemoglobinemia and increased levels of nitrogen dioxide, a pulmonary irritant. Most newborns require iNO for <5 days. Although iNO has been used as long-term therapy in children and adults with primary pulmonary hypertension, prolonged dependency is rare in neonates and suggests the presence of lung hypoplasia, congenital heart disease, or ACD. The maximal safe duration of iNO therapy is unknown. The infant can be weaned to 5 ppm after 6-24 hours of therapy. The dose can then be reduced slowly and discontinued when F_{IO_2} is <0.6 and the iNO dose is 1 ppm. Abrupt discontinuation should be avoided because it may cause rebound pulmonary hypertension. iNO should be used only at institutions that offer ECMO support or have the capability of transporting an infant on iNO therapy if a referral for ECMO is necessary. Some infants with PPHN do not respond adequately to iNO. Therapy with continuous inhaled or intravenous (IV) prostacyclin (prostaglandin I_2) can improve oxygenation in infants with PPHN. The safety and efficacy of sildenafil (type 5 phosphodiesterase inhibitor) in newborns with PPHN is under investigation; initial results are promising.

In 5–10% of patients with PPHN, the response to 100% O_2, mechanical ventilation, and drugs is poor, and many of these infants benefit from ECMO. In such patients, two parameters have been used to predict mortality: the alveolar-arterial oxygen gradient ($P_A\text{-}aO_2$), and the oxygenation index (OI), calculated as F_{IO_2} (as %) × MAP/P_{aO_2}. A $P_A\text{-}aO_2$ >600 for 8-12 hours and an OI >40 unresponsive to iNO predict a high mortality rate (>80%) and are indications for ECMO. In carefully selected, severely ill infants with hypoxemic respiratory failure caused by RDS, meconium aspiration pneumonia, congenital diaphragmatic hernia, PPHN, or sepsis, ECMO significantly improves survival.

ECMO is a form of cardiopulmonary bypass that augments systemic perfusion and provides gas exchange. Most experience has been with *venoarterial bypass,* which requires carotid artery ligation and the placement of large catheters in the right internal jugular vein and carotid artery. *Venovenous bypass* avoids carotid artery ligation and provides gas exchange, but it does not support cardiac output. Blood is initially pumped through the ECMO circuit at a rate that approximates 80% of the estimated cardiac output (150-200 mL/kg/min). Venous return passes through a membrane oxygenator, is rewarmed, and returns to the aortic arch in venoarterial ECMO and to the right atrium in venovenous ECMO. Venous O_2 saturation values are used to monitor tissue O_2 delivery and subsequent extraction for infants undergoing venoarterial ECMO, whereas arterial O_2 saturation values are used to monitor oxygenation for infants receiving venovenous ECMO.

Because ECMO requires complete heparinization to prevent clotting in the circuit, its use is generally avoided in patients with existing intracranial hemorrhage or who are at high risk of developing intraventricular hemorrhage (weight <2 kg, gestational age <34 weeks). In addition, infants being considered for ECMO should have reversible lung disease, no signs of systemic bleeding, and no severe asphyxia or lethal malformations, and they should have been ventilated for <10 days. Complications of ECMO include thromboembolism, air embolization, bleeding, stroke, seizures, atelectasis, cholestatic jaundice, thrombocytopenia, neutropenia, hemolysis, infectious complications of blood transfusions, edema formation, and systemic hypertension.

PROGNOSIS

Survival in patients with PPHN varies with the underlying diagnosis but is generally ~90%. Long-term, survivors of PPHN are at risk for neurodevelopmental impairment and sensorineural deafness, which can occur in about 25% of patients. The outcome for infants with PPHN who are treated with ECMO is also favorable; >80–90% survive, and 60–75% of survivors appear normal at 1-3.5 years of age.

Chapter 131

Diaphragmatic Hernia

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

A diaphragmatic hernia is defined as a communication between the abdominal and thoracic cavities with or without abdominal contents in the thorax (Fig. 131.1). The etiology is rarely traumatic and usually congenital. The symptoms and prognosis depend on the location of the defect and associated anomalies. The defect may be at the esophageal hiatus **(hiatal hernia)**; paraesophageal, adjacent to the hiatus (**paraesophageal hernia**; see Chapter 131.2); retrosternal (**foramen of Morgagni hernia**; see Chapter 131.1); or at the posterolateral portion of the diaphragm **(Bochdalek hernia)**. In **congenital diaphragmatic hernia (CDH),** the Bochdalek hernia accounts for up to 90% of the hernias seen, with 80–90% occurring on the left side. The Morgagni hernia accounts for 2–6% of CDH. The size of the defect is highly variable, ranging from a small hole to complete agenesis of this area of the diaphragm. These lesions may cause significant respiratory distress at birth, can be associated with other congenital anomalies, and have significant mortality and long-term morbidity.

CONGENITAL DIAPHRAGMATIC HERNIA (BOCHDALEK)

Pathology and Etiology

Although CDH is characterized by a structural diaphragmatic defect, a major limiting factor for survival is the association with other anomalies, syndromes, and primarily with pulmonary hypoplasia. Lung hypoplasia was initially thought to be solely caused by the compression of the lung from the herniated abdominal contents, which impaired lung growth. However, evidence indicates that pulmonary hypoplasia, at least in some cases, may precede the development of the diaphragmatic defect.

Pulmonary hypoplasia is characterized by a reduction in pulmonary mass and the number of bronchial divisions, respiratory bronchioles, and alveoli. The pathology of pulmonary hypoplasia and CDH includes abnormal septa in the terminal saccules, thickened alveoli, and thickened pulmonary arterioles. Biochemical abnormalities include relative surfactant deficiencies, increased glycogen in the alveoli, and decreased levels of phosphatidylcholine, total DNA, and total lung protein, all of which contribute to limited gas exchange.

Epidemiology

The incidence of CDH is between 1 in 2,000 and 1 in 3,000 live births, with males affected more often than females. Defects are more common on the left (85%) and are occasionally bilateral (<5%). Pulmonary hypoplasia and malrotation of the intestine are part of the lesion, not associated anomalies. Most cases of CDH are nonsyndromic (sporadic; 60%), but familial and syndromic cases have been reported. Associated anomalies in nonsyndromic patients have been reported in up to 30% of cases, including hypoplastic left heart syndrome and accessory spleens. CDH is recognized as part of several aneuploidy syndromes: trisomies 21, 13, and 18 and those with copy number variation: del 15q26.1-q26.2, del 8p23.1, del 1q41-q42, and del 4p16.3 as well as definable single gene syndromes including Cornelia de Lange, Donnai-Barrow, Cutis Laxa, cardiac-urogenital, and Matthew-Wood syndromes.

Diagnosis and Clinical Presentation

In >50% of cases, CDH can be diagnosed on prenatal ultrasonography (US) between 16 and 24 weeks of gestation. High-speed fetal MRI can further define the lesion. US findings may include polyhydramnios, chest mass, mediastinal shift, gastric bubble or a liver in the thoracic cavity, and fetal hydrops. Certain imaging features may predict outcome including liver position in the chest, observed-to-expected total lung volume (O/E TLV), and observed-to-expected lung-to-head ratio (O/E LHR). Nonetheless, no definitive characteristic reliably predicts outcome. After delivery, a chest radiograph is needed to confirm the diagnosis (Fig. 131.2). In some infants with an echogenic chest mass, further imaging is required. The differential diagnosis may include other diaphragm disorders, such as eventration or a cystic lung lesion (pulmonary sequestration, cystic adenomatoid malformation).

Arriving at the diagnosis early in pregnancy allows for prenatal counseling, possible fetal interventions (see Chapter 118), and planning for postnatal care. A referral to a center providing high-risk obstetrics, pediatric surgery, and tertiary care neonatology is advised. Careful evaluation for other anomalies should include echocardiography and amniocentesis. To avoid unnecessary pregnancy termination and unrealistic expectations, an experienced multidisciplinary group must carefully counsel the parents of a child diagnosed with a diaphragmatic hernia.

Respiratory distress is a cardinal sign in babies with CDH. It may occur immediately after birth, or there may be a period of up to 48 hours during which the baby is relatively stable. Respiratory distress

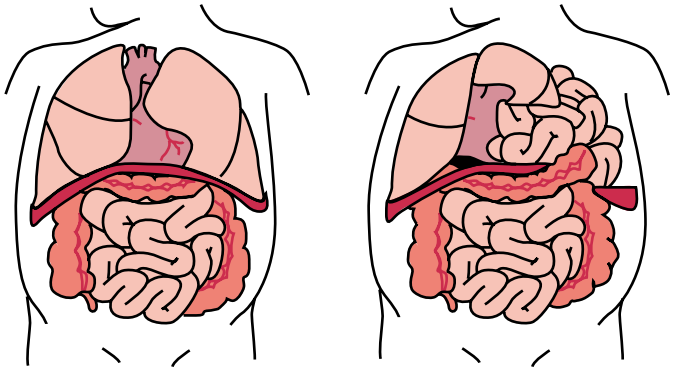

Fig. 131.1 A, Normal diaphragm separating the abdominal and thoracic cavity. B, Diaphragmatic hernia with a small lung and abdominal contents in the thoracic cavity.

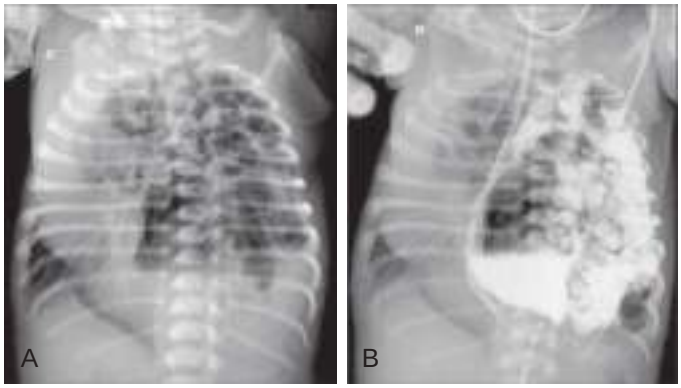

Fig. 131.2 Bochdalek hernia. A, Chest radiograph showing herniated bowel loops in the left hemithorax, displacement of the mediastinum to the contralateral side, severely reduced lung space, and unclear lung fields bilaterally. B, Upper gastrointestinal tract radiograph showing the stomach and bowel loops stained with contrast in the left hemithorax. *(From Hu X, Liu B. Bochdalek hernia. Lancet. 2018;392:60.)*

is characterized clinically by tachypnea, grunting, use of accessory muscles, and cyanosis. Children with CDH may also have a scaphoid abdomen and increased chest wall diameter. Bowel sounds may also be heard in the chest with decreased breath sounds bilaterally. The point of maximal cardiac impulse may be displaced away from the side of the hernia if mediastinal shift has occurred. A chest radiograph and passage of a gastric tube are usually sufficient to confirm the diagnosis.

A small group of infants with CDH present beyond the neonatal period. Patients with a delayed presentation may experience vomiting as a result of intestinal obstruction or mild respiratory symptoms. Occasionally, incarceration of the intestine proceeds to ischemia with sepsis and shock. Unrecognized diaphragmatic hernia is a rare cause of sudden death in infants and toddlers. Group B streptococcal sepsis has been associated with delayed onset of symptoms and a CDH (often right side).

Treatment

Initial Management

Delivery at a tertiary center with experience in the management of CDH is required to provide early, appropriate respiratory support. In the delivery room, infants with respiratory distress should be rapidly stabilized with endotracheal intubation. *Prolonged mask ventilation in the delivery room, which enlarges the stomach and small bowel and thus makes oxygenation more difficult, must be avoided and a nasogastric or orogastric tube placed immediately for decompression.* Once in the neonatal intensive care unit (NICU), central arterial and venous (umbilical) lines are placed, pre- and postductal saturations monitored, and gastric contents intermittently decompressed to prevent enlargement. A preductal arterial oxygen saturation (Spo_2) value ≥85% should be the minimum goal. An initial arterial Pco_2 >80 mm Hg is predictive of mortality in infants with CDH. Volutrauma is a significant problem. *Gentle ventilation with permissive hypercapnia* reduces lung injury, need for extracorporeal membrane oxygen (ECMO), and mortality. Factors that contribute to persistent pulmonary hypertension of the newborn (PPHN; hypoxia, acidosis, hypothermia) should be avoided (see Chapter 130). Echocardiography is important to guide therapeutic decisions by measuring pulmonary and system vascular pressures and defining the presence of cardiac dysfunction. Routine use of inotropes is indicated in the presence of left ventricular dysfunction. Neonates with CDH may be surfactant deficient. Although surfactant is frequently used, no study has proved that it is beneficial in treatment of CDH, and it may precipitate decompensation. In infants with severe respiratory failure and hypoxemia, sedation and paralysis may be required.

Ventilation Strategies

Conventional mechanical ventilation, high-frequency oscillatory ventilation (HFOV), and ECMO are the three main strategies to support respiratory failure in the newborn with CDH. The goal is to maintain oxygenation and CO_2 elimination without inducing volutrauma. Conventional ventilation using a gentle, lung protective strategy (peak inspiratory pressure [PIP] <25, positive end-expiratory pressure [PEEP] 3-5 cm H_2O) that allows for permissive hypercapnia ($Paco_2$ <65 mm Hg) is recommended. Permissive hypercapnia (as opposed to hyperventilation with high PIP) has reduced lung injury and improved survival. HFOV as a rescue therapy is indicated if a PIP >25 is required to maintain appropriate ventilation or if hypoxemia persists.

Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator. Its use reduces ductal shunting and pulmonary pressures and results in improved oxygenation. Although iNO has been helpful in PPHN, randomized trials have not demonstrated improved survival or reduced need for ECMO when iNO is used in newborns with CDH. Nonetheless, iNO is used in patients with CDH as a bridge to ECMO.

Extracorporeal Membrane Oxygenation

The availability of ECMO and the utility of preoperative stabilization has improved survival of babies with CDH. ECMO is the therapeutic option for children in whom conventional ventilation or HFOV fails. ECMO is most often used before repair of the defect. Several objective criteria for ECMO have been developed. Birthweight and the 5-minute Apgar score may be the best predictors of outcome in patients treated with ECMO. There is no strict lower weight limit for ECMO, but generally, vessels in infants <1,800 g are too small to cannulate.

The duration of ECMO for neonates with diaphragmatic hernia is longer (than for those with isolated PPHN or meconium aspiration and may last up to 2-4 weeks). Timing of repair of the diaphragm while the infant receives ECMO is controversial; some experts prefer early repair to allow a greater duration of ECMO after the repair, whereas many defer repair until the infant has demonstrated the ability to tolerate weaning from ECMO. The recurrence of pulmonary hypertension is associated with high mortality and weaning from ECMO support should be cautious. If the patient cannot be weaned from ECMO after repair of CDH, redirection of care toward comfort is usually offered to families.

Prenatal Markers of Severity and Fetal Treatment

The most studied prenatal predictor of outcome in children with CDH studied is fetal US. A prospective study of US at 24-26 weeks compared fetal LHR with mortality. There were no survivors with LHR <1, but all babies with LHR >1.4 survived. A second important consideration is the presence of liver in the thoracic cavity, which is a poor prognostic feature. Because LHR measurements increase with gestation, an O/E LHR is considered a more reliable predictor of severity irrespective of GA. O/E LHR of ≥45% is considered a good prognostic sign, whereas <25% is considered a poor prognostic sign. Fetal MRI is used at many fetal centers at 28-32 weeks for prognostication. The advantages of fetal MRI are that they are operator independent, allow measurement of both lungs, and allow better tissue contrast and better images. Normal reference values for fetal lung volumes on MRI have been published and TLV can be compared with the referent fetus. O/E TLV ≥45% is a good prognostic sign, whereas <25% is considered a poor prognostic sign.

Based on the observation that hydrostatic pressure exerted by fetal lung fluid plays a critical role in lung growth and maturity, a promising fetal therapy is in utero tracheal occlusion **(fetoscopic endoluminal tracheal occlusion [FETO])**. FETO therapy at 27–29 weeks' gestation improves survival from 15% to 40% in fetuses with severe left CDH with O/E LHR of <25%; preterm birth is a risk factor. FETO therapy is only offered at a select few centers across the United States (see Chapter 118).

Surgical Repair

Most experts plan surgery at least 48 hours after stabilization and resolution of the pulmonary hypertension. Good relative indicators of stability are the requirement for conventional ventilation only, a low PIP, and Fio_2 <50%. If the newborn is receiving ECMO, an ability to be weaned from this support should be a consideration before surgical repair. In some centers, the repair is done with the cannulas in place; in other centers the cannulas are removed. A subcostal approach is most frequently used (Fig. 131.3). This allows for good visualization of the defect, and if the abdominal cavity cannot accommodate the herniated contents, a polymeric silicone (Silastic) patch can be placed, commonly known as a silo. Both laparoscopic and thoracoscopic repairs have been reported, but these should be reserved for only the most stable infants.

The defect size and amount of native diaphragm present are variable. Whenever possible, a primary repair using native tissue is performed. If the defect is too large, a porous polytetrafluoroethylene (Gore-Tex) patch is used.

Following surgical repair, the infant must be carefully monitored for worsening pulmonary hypertension. In some patients, a postoperative course of ECMO is needed. Other recognized complications include bleeding, chylothorax, and bowel obstruction. CDH recurrence can occur in about 10% of cases, usually during the first year of life, but can occur up to the first 5 years of life. There is a higher recurrence rate of CDH in children with patches (the patch does not grow as the child grows) than in those with native tissue repairs, those with larger defects, and those with liver in the defect. A loosely fitted patch may reduce the recurrence rates.

Outcome and Long-Term Survival

Overall survival of liveborn infants with CDH is 75%. Relative predictors of a poor prognosis include an associated major anomaly and syndromes,

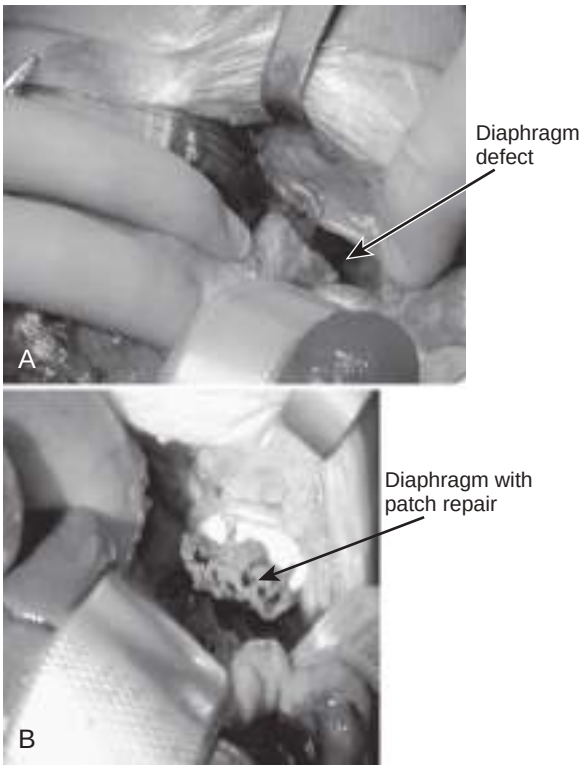

Fig. 131.3 A, Intraoperative photo of congenital diaphragmatic hernia (CDH) before repair. B, Intraoperative photo of patch repair of CDH.

severe pulmonary hypoplasia, herniation to the contralateral lung, and the need for ECMO. The size of the defect appears to be the strongest predictor of morbidity.

Pulmonary problems continue to be a source of morbidity for long-term survivors of CDH. Children receiving CDH repair who were studied at 6-11 years of age demonstrated significant decreases in forced expiratory flow at 50% of vital capacity and decreased peak expiratory flow. Chronic lung disease can occur in about 15% of patients. Both obstructive and restrictive patterns can occur. Those without severe pulmonary hypertension and volutrauma do the best. Those at highest risk include children who required ECMO and patch repair, but the data clearly show that CDH survivors who did not require ECMO also need frequent attention to pulmonary issues. At discharge, up to 20% of infants require oxygen, but only 1–2% require oxygen past 1 year of age.

Gastroesophageal reflux disease (GERD) is reported in >50% of children with CDH. GERD is more common in children whose diaphragmatic defect involves the esophageal hiatus. **Intestinal obstruction** is reported in up to 20% of children and may result from a midgut volvulus, adhesions, or a recurrent hernia that became incarcerated.

Children with CDH typically have delayed growth in the first 2 years of life. Contributing factors include poor intake, GERD, and a caloric requirement that may be higher because of the energy required to breathe. Many children normalize and "catch up" in growth by the time they are 2 years old.

Neurocognitive defects are common and may result from the disease or the interventions. The incidence of neurologic abnormalities is higher in infants who require ECMO (67% vs 24% of those who do not). The abnormalities are similar to those seen in neonates treated with ECMO for other diagnoses and include transient and permanent developmental delay, abnormal hearing or vision, and seizures. Serious hearing loss may occur in up to 28% of children who underwent ECMO. The majority of neurologic abnormalities are classified as mild to moderate.

Other long-term problems include pectus excavatum and scoliosis. Survivors of CDH repair, particularly those requiring ECMO support, have a variety of long-term abnormalities that appear to improve with time but require close monitoring and multidisciplinary support.

Health-related quality of life (HRQoL) of school-age children born with CDH is overall good and comparable to healthy children, although some children report lower quality of life. The burden of the child's diagnosis on families long-term is also reportedly low. ECMO use is associated with a lower HRQoL in certain domains, as is the need for special education services in school, and chronic respiratory problems.

131.1 Foramen of Morgagni Hernia

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

Failure of the sternal and crural portions of the diaphragm to meet and fuse produces the foramen of Morgagni hernia. These defects are usually small, with a greater transverse than anteroposterior diameter, and are more often right sided (90%) but may be bilateral. The transverse colon, small intestine, or liver is usually contained in the hernial sac. Most children with these defects are asymptomatic and are diagnosed beyond the neonatal period, often by chest radiograph performed for evaluation of another condition. The anterolateral radiograph shows a structure behind the heart, and a lateral film localizes the mass to the retrosternal area. Chest CT or MRI confirms the diagnosis. When symptoms occur, they can include recurrent respiratory infections, cough, vomiting, or reflux; in rare cases, incarceration may occur. Repair is recommended for all patients, in view of the risk of bowel strangulation, and can be accomplished laparoscopically. Prosthetic material is rarely required.

131.2 Paraesophageal Hernia

Shawn K. Ahlfeld

Paraesophageal hernia is differentiated from the hiatal hernia in that the gastroesophageal junction is in the normal location. The herniation of the stomach alongside or adjacent to the gastroesophageal junction is prone to incarceration with strangulation and perforation. A previous Nissen fundoplication and other diaphragmatic procedures are risk factors. This unusual diaphragmatic hernia should be repaired promptly after identification.

131.3 Eventration

Krishna K. Acharya, Alicia J. Sprecher, and Susan S. Cohen

Eventration of the diaphragm is an abnormal elevation consisting of a thinned diaphragmatic muscle that causes elevation of the entire hemidiaphragm or more often the anterior aspect of the hemidiaphragm. This elevation produces a paradoxical motion of the affected hemidiaphragm. Most eventrations are asymptomatic and do not require repair. A congenital form is the result of either incomplete development of the muscular portion or central tendon or abnormal development of the phrenic nerves. Congenital eventration may affect lung development, but it has not been associated with pulmonary hypoplasia. The differential diagnosis includes diaphragmatic paralysis, diaphragmatic hernia, traction injury, and iatrogenic injury after heart surgery. Eventration is also associated with pulmonary sequestration, congenital heart disease, spinal muscular atrophy with respiratory distress, and chromosomal trisomies. Most eventrations are asymptomatic and do not require repair. The indications for surgery include continued need for mechanical ventilation, recurrent infections, and failure to thrive. Large or symptomatic eventrations can be repaired by plication through an abdominal or thoracic approach that is minimally invasive.

Chapter 132

Pulmonary Air Leaks: Pneumothorax, Pneumomediastinum, Pulmonary Interstitial Emphysema, Pneumopericardium

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Pulmonary air leaks represent air breaching the alveolus and entering potential cavities within the chest. *Asymptomatic* pneumothorax, usually unilateral, is estimated to occur in 1–2% of all newborn infants; *symptomatic* pneumothorax and pneumomediastinum are less common. The incidence of pneumothorax is increased in infants with lung diseases such as meconium aspiration and respiratory distress syndrome (RDS); in those who receive assisted ventilation, especially if high-frequency ventilation (HFV) support is necessary; and in infants with pulmonary hypoplasia.

ETIOLOGY AND PATHOPHYSIOLOGY

The most common cause of pneumothorax is overdistention resulting in alveolar rupture. Alveolar overdistention can occur with positive pressure ventilation during neonatal resuscitation, or it may occur in association with the "ball-valve" phenomenon that results from aspiration (classically meconium) and bronchial/bronchiolar obstruction. Although spontaneous rupture of an underlying pulmonary malformation (e.g., lobar emphysema, congenital lung cyst, pneumatocele) occurs, pneumothorax usually occurs in an otherwise normal lung, and no underlying etiology is identified.

Pneumothorax associated with **pulmonary hypoplasia** is common, tends to occur during the first few hours after birth, and is caused by reduced alveolar surface area and poorly compliant lungs. It is associated with disorders of decreased amniotic fluid volume (Potter syndrome, renal agenesis, renal dysplasia, chronic amniotic fluid leak), decreased fetal breathing movement (oligohydramnios, neuromuscular disease, fetal akinesia syndrome), pulmonary space-occupying lesions (diaphragmatic hernia, pleural effusion, chylothorax), and thoracic abnormalities (thoracic dystrophies).

Gas from a ruptured alveolus escapes into the interstitial spaces of the lung, where it tracks along small conducting airways and dissects along the peribronchial and perivascular connective tissue sheaths to the hilum of the lung **(pulmonary interstitial emphysema, PIE)**. If the volume of escaped air is great enough, it may collect in the mediastinal space (pneumomediastinum) or rupture into the pleural space (pneumothorax), subcutaneous tissue **(subcutaneous emphysema)**, and/or pericardial sac **(pneumopericardium)**.

Tension pneumothorax occurs if an accumulation of air within the pleural space is sufficient to elevate intrapleural pressure above atmospheric pressure. Unilateral **tension pneumothorax** results in impaired ventilation not only in the ipsilateral lung but also in the contralateral lung because of a shift in the mediastinum toward the contralateral side. Compression of the vena cava and torsion of the great vessels may interfere with venous return.

CLINICAL MANIFESTATIONS

The physical findings of a clinically asymptomatic pneumothorax are hyperresonance and diminished ipsilateral breath sounds with or without tachypnea. Symptomatic pneumothorax is characterized by respiratory distress, which varies from merely high respiratory rate to severe dyspnea, tachypnea, and cyanosis. Irritability and restlessness or apnea may be the earliest signs. The onset is usually sudden but may be gradual; an infant may rapidly become critically ill. Physical exam findings include chest asymmetry with an increased anteroposterior diameter, hyperresonance, and diminished or absent breath sounds. The heart is displaced toward the contralateral side, resulting in displacement of the cardiac apex and point of maximal impulse. The diaphragm is displaced downward, as is the liver with right-sided pneumothorax, and may result in abdominal distention. Because pneumothorax may be bilateral in approximately 10% of patients, symmetry of findings does not rule it out. In tension pneumothorax, signs of shock are typical.

Pneumomediastinum can occur with or without a pneumothorax and itself is usually asymptomatic. The degree of respiratory distress depends on the amount of trapped gas; if great, bulging of the midthoracic area is observed, the neck veins are distended, and blood pressure is low. The last two findings are a result of tamponade of the systemic and pulmonary veins. Although often asymptomatic, **subcutaneous emphysema** in newborn infants is almost pathognomonic of pneumomediastinum. Rarely, air may embolize into the circulation (pulmonary air embolism) and cause cutaneous blanching, air in intravascular catheters, an air-filled heart and vessels on chest radiographs, and death.

PIE may precede the development of a pneumothorax or may occur independently and lead to increasing respiratory distress as a result of decreased compliance, hypercapnia, and hypoxemia. Hypoxemia is caused by an increased $P_A\text{-}aO_2$ gradient and intrapulmonary shunting. Progressive enlargement of blebs of gas may result in cystic dilation and respiratory deterioration resembling pneumothorax. In severe cases, PIE precedes the development of bronchopulmonary dysplasia (BPD). Avoidance of high inspiratory or mean airway pressures may prevent the development of PIE.

Pneumopericardium is generally associated with pneumothorax with air moving into the pericardium via areas of weakness in the pericardiac sac or via embryonic connections between the pleura and pericardium. Pneumopericardium may be asymptomatic, requiring only general supportive treatment, but it usually manifests as sudden shock with tachycardia, muffled heart sounds, and poor pulses suggesting tamponade. Air pressure within the pericardium can cause cardiac tamponade.

Preterm infants whose course is complicated by pulmonary air leaks are at increased risk for mortality, BPD (see Chapter 127), severe intracranial hemorrhage, and prolonged NICU stays.

DIAGNOSIS

Pneumothorax and other air leaks should be suspected in newborn infants who show signs of respiratory distress, are restless or irritable, or have a sudden change in condition. The diagnosis of pneumothorax is established by chest radiography, with the edge of the collapsed lung standing out in relief against the pneumothorax (Fig. 132.1). Pneumomediastinum is signified by hyperlucency around the heart border and between the sternum and the heart border and the displacement of the thymus by air, typically referred to as the "spinnaker sail" sign (Fig. 132.2). *Transillumination* of the thorax is often helpful in the emergency diagnosis of pneumothorax; the affected side transmits excessive light. In pneumopericardium, chest radiography demonstrates a halo of air around the cardiac silhouette. PIE appears as small cystic

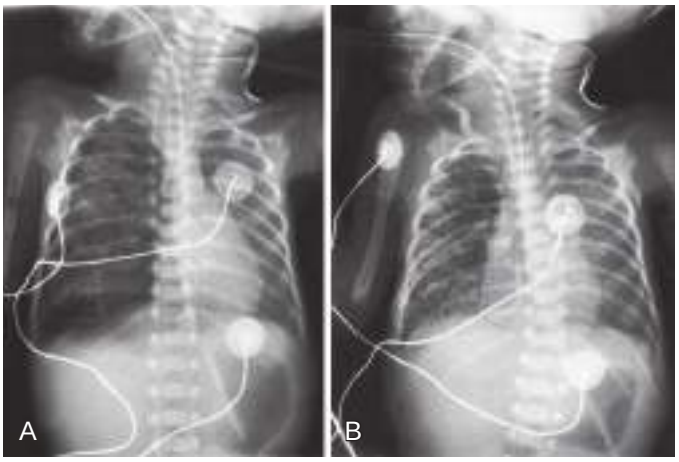

Fig. 132.1 A, Right-sided tension pneumothorax and widespread right lung pulmonary interstitial emphysema (PIE) in a preterm infant receiving intensive care. B, Resolution of pneumothorax with a chest tube in place; PIE persists. *(From Meerstadt PWD, Gyll C. Manual of Neonatal Emergency X-Ray Interpretation. Philadelphia: Saunders; 1994. p. 73.)*

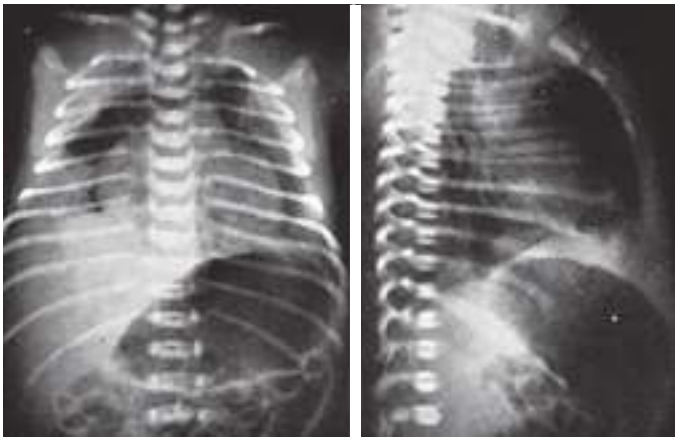

Fig. 132.2 Pneumomediastinum in newborn infant. Anteroposterior view *(left)* demonstrates compression of the lungs, and lateral view *(right)* shows bulging of the sternum, each resulting from distention of the mediastinum by trapped air.

radiolucencies along the interstitium often with hyperexpansion and is typically only seen in premature infants with preexisting lung disease.

PREVENTION

Early recognition of patients at risk for air leak is essential. Infants with oligohydramnios, extreme prematurity, or congenital pulmonary malformations are at increased risk. Surfactant therapy for RDS (see Chapter 126) reduces the incidence of **pneumothorax**. Avoidance of high inspiratory or mean airway pressures may prevent the development of air leaks.

TREATMENT

Without a continued air leak, small asymptomatic and mildly symptomatic pneumothorax, pneumomediastinum, and pneumopericardium require only close observation. Conservative management of a pneumothorax is effective even in selected infants requiring ventilatory support. Frequent small feedings may prevent gastric dilation and minimize crying, which can further compromise ventilation and worsen the pneumothorax. Breathing 100% oxygen in term infants may accelerate the resorption of free pleural air into blood by reducing the nitrogen tension in blood and producing a resultant nitrogen pressure gradient from the trapped gas in the blood; however, this is no longer practiced given the risks of oxygen toxicity.

When a pneumothorax is large, expanding, or with severe respiratory or circulatory embarrassment, emergency decompression by needle thoracentesis and/or chest tube placement is indicated. Needle thoracentesis is typically accomplished with the use of an angiocath or a 23-gauge butterfly needle attached to a stopcock and syringe to withdraw air. It can be inserted into the second intercostal space of the anterior chest. After the needle thoracentesis a chest radiograph should be obtained to evaluate and monitor for reaccumulation.

Chest tube placement should be undertaken in cases of recurrent pneumothorax after needle decompression or as a primary intervention in select patients at risk for ongoing air leak (i.e., on high-pressure invasive ventilation). In studies comparing needle decompression with primary chest tube placement there are no differences in mortality; however, approximately 30% of patients receiving a needle thoracentesis eventually required chest tube placement. **Chest tube placement** should occur under sterile conditions whenever possible and be preceded by appropriate analgesia. Pigtail catheters are the preferred type of chest tube in infants because of higher success rates and low complication rates. These catheters are placed using the Seldinger technique by introducing a needle, aspirating free air, and subsequently introducing a guidewire over which a pigtail catheter is advanced. Ideally the chest tube should be introduced into the fourth intercostal space (generally at the level of the nipple) in the anterior axillary line. Following placement, the chest tube should be attached to underwater seal drainage or continuous suction (−5 to −20 cm H_2O). Serial chest radiographs should be obtained for all infants with a chest tube in place.

Pneumopericardium with clinical symptoms (tamponade) requires prompt evacuation of entrapped air via pericardiocentesis. **Pericardiocentesis** should be performed using sterile technique and analgesia whenever possible. Ideally an echocardiogram should be completed before undertaking the procedure and cardiology or cardiothoracic surgery involvement is encouraged. Continuous cardiopulmonary monitoring is essential during the procedure. A 20–23-gauge butterfly needle is introduced into the chest to the left of the subxiphoid process at a 30–45-degree angle pointing toward the right shoulder. The needle is advanced until air returns and the pericardium is subsequently evacuated of air. The provider should stop aspirating once air no longer returns, if there is blood return, or if ectopy is observed. Following the procedure an echocardiogram should be obtained.

Treatment of PIE may include bronchoscopy in patients with evidence of mucous plugging, selective intubation and ventilation of the uninvolved bronchus, oxygen, general respiratory care, and use of HFV.

Chapter 133

Pulmonary Hemorrhage

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Massive pulmonary hemorrhage is a relatively uncommon, but catastrophic complication with a high risk of morbidity and mortality. Some degree of pulmonary hemorrhage occurs in about 10% of extremely preterm infants. However, massive pulmonary hemorrhage is less common and can be fatal. Autopsy demonstrates massive pulmonary hemorrhage in 15% of neonates who die in the first 2 weeks of life. The reported incidence at autopsy varies from 1-4 per 1,000 live births. Approximately 75% of affected patients weigh <2,500 g at birth. Prophylactic indomethacin in extremely low birthweight (ELBW) infants reduces the incidence of pulmonary hemorrhage.

Most infants with pulmonary hemorrhage have had symptoms of respiratory distress that are indistinguishable from those of respiratory distress syndrome (RDS). The onset may occur at birth or may be delayed several days. **Hemorrhagic pulmonary edema** is the source of blood in many cases and is associated with significant ductal shunting and high pulmonary blood flow or severe left-sided heart failure resulting from hypoxia. In severe cases, sudden cardiovascular collapse, poor lung compliance, profound cyanosis, and hypercapnia may be present. Radiographic findings are varied and nonspecific, ranging from minor streaking or patchy infiltrates to massive consolidation.

The risk of pulmonary hemorrhage is increased in association with acute pulmonary infection, severe asphyxia, RDS, assisted ventilation, patent ductus arteriosus (PDA), congenital heart disease, erythroblastosis fetalis, hemorrhagic disease of the newborn, thrombocytopenia, inborn errors of ammonia metabolism, and cold injury. Pulmonary hemorrhage is the only severe complication in which the rate is *increased* with surfactant treatment. Pulmonary hemorrhage is seen with all surfactants; the incidence ranges from 1–5% of treated infants and is higher with natural surfactant. Bleeding is predominantly alveolar in approximately 65% of cases and interstitial in the rest. Bleeding into other organs is observed at autopsy of severely ill neonates, suggesting an additional bleeding diathesis, such as disseminated intravascular coagulation. In preterm infants, often intraventricular hemorrhage can occur at the same time. Acute pulmonary hemorrhage may rarely occur in previously healthy full-term infants. The cause is unknown. Pulmonary hemorrhage may manifest as hemoptysis or blood in the nasopharynx or airway with no evidence of upper respiratory or gastrointestinal bleeding. Patients present with acute, severe respiratory failure requiring mechanical ventilation. Chest radiographs usually demonstrate bilateral alveolar infiltrates. The condition usually responds to intensive supportive treatment (see Chapter 458).

Treatment of pulmonary hemorrhage includes blood replacement, suctioning to clear the airway, intratracheal administration of epinephrine, and tamponade with increased mean airway pressure (often requiring high-frequency ventilation [HFV]). Although surfactant treatment has been associated with the development of pulmonary hemorrhage, administration of exogenous surfactant after the bleeding has occurred can improve lung compliance, because the presence of intraalveolar blood and protein can inactivate surfactant.

Digestive System Disorders

Robert M. Kliegman

Signs and symptoms suggestive of gastrointestinal (GI) tract pathology in the newborn may reflect immaturity, disorders specific to the GI tract, or systemic diseases affecting the GI tract as part of a multisystem disorder (Table 134.1; see Chapter 121).

Feeding intolerance in the very low birthweight neonate may be due to immaturity of GI motility but also to anatomic lesions from the esophagus to the anus, as well as systemic, metabolic (galactosemia, etc.), or inflammatory processes (sepsis, hemophagocytic lymphohistiocytosis). Recognizing other organ system abnormalities and abnormal laboratory findings (anemia, thrombocytopenia, leukocytosis, neutropenia, elevated inflammatory markers, acidosis, hypoglycemia) may help identify the specific disease.

Table 134.1 Differential Diagnosis of Gastrointestinal Symptoms

SYMPTOM	GI DISORDERS	SYSTEMIC DISORDERS
Emesis	Reflux Volvulus Pyloric stenosis Hirschsprung disease Imperforate anus NEC Meconium plug	Sepsis Inborn error of metabolism Congenital adrenal hyperplasia Increased intracranial pressure
Jaundice	Hepatitis Biliary atresia GALD PFIC Alagille syndrome	Physiologic Hemolysis HLH Sepsis HSV Inborn error of metabolism
Abdominal distention	Feeding intolerance GI obstruction Meconium plug Ileus Meconium ileus NEC Pseudoobstruction Inguinal hernia	Sepsis Hypokalemia Hydronephrosis Ascites Hypermagnesemia

Chapter 133

Pulmonary Hemorrhage

Alicia J. Sprecher, Krishna K. Acharya, and Susan S. Cohen

Massive pulmonary hemorrhage is a relatively uncommon, but catastrophic complication with a high risk of morbidity and mortality. Some degree of pulmonary hemorrhage occurs in about 10% of extremely preterm infants. However, massive pulmonary hemorrhage is less common and can be fatal. Autopsy demonstrates massive pulmonary hemorrhage in 15% of neonates who die in the first 2 weeks of life. The reported incidence at autopsy varies from 1-4 per 1,000 live births. Approximately 75% of affected patients weigh <2,500 g at birth. Prophylactic indomethacin in extremely low birthweight (ELBW) infants reduces the incidence of pulmonary hemorrhage.

Most infants with pulmonary hemorrhage have had symptoms of respiratory distress that are indistinguishable from those of respiratory distress syndrome (RDS). The onset may occur at birth or may be delayed several days. **Hemorrhagic pulmonary edema** is the source of blood in many cases and is associated with significant ductal shunting and high pulmonary blood flow or severe left-sided heart failure resulting from hypoxia. In severe cases, sudden cardiovascular collapse, poor lung compliance, profound cyanosis, and hypercapnia may be present. Radiographic findings are varied and nonspecific, ranging from minor streaking or patchy infiltrates to massive consolidation.

The risk of pulmonary hemorrhage is increased in association with acute pulmonary infection, severe asphyxia, RDS, assisted ventilation, patent ductus arteriosus (PDA), congenital heart disease, erythroblastosis fetalis, hemorrhagic disease of the newborn, thrombocytopenia, inborn errors of ammonia metabolism, and cold injury. Pulmonary hemorrhage is the only severe complication in which the rate is *increased* with surfactant treatment. Pulmonary hemorrhage is seen with all surfactants; the incidence ranges from 1–5% of treated infants and is higher with natural surfactant. Bleeding is predominantly alveolar in approximately 65% of cases and interstitial in the rest. Bleeding into other organs is observed at autopsy of severely ill neonates, suggesting an additional bleeding diathesis, such as disseminated intravascular coagulation. In preterm infants, often intraventricular hemorrhage can occur at the same time. Acute pulmonary hemorrhage may rarely occur in previously healthy full-term infants. The cause is unknown. Pulmonary hemorrhage may manifest as hemoptysis or blood in the nasopharynx or airway with no evidence of upper respiratory or gastrointestinal bleeding. Patients present with acute, severe respiratory failure requiring mechanical ventilation. Chest radiographs usually demonstrate bilateral alveolar infiltrates. The condition usually responds to intensive supportive treatment (see Chapter 458).

Treatment of pulmonary hemorrhage includes blood replacement, suctioning to clear the airway, intratracheal administration of epinephrine, and tamponade with increased mean airway pressure (often requiring high-frequency ventilation [HFV]). Although surfactant treatment has been associated with the development of pulmonary hemorrhage, administration of exogenous surfactant after the bleeding has occurred can improve lung compliance, because the presence of intraalveolar blood and protein can inactivate surfactant.

Chapter 135

Meconium Ileus, Peritonitis, Intestinal Obstruction, and Gastroschisis

Eric C. Eichenwald

Meconium consists of bile salts, bile acids, and debris shed from the intestinal mucosa in the intrauterine period. More than 90% of full-term newborn infants and 80% of very low birthweight (VLBW) infants pass meconium within the first 24 hours. The possibility of intestinal obstruction should be considered in any infant who does not pass meconium by 24-36 hours.

MECONIUM PLUGS

Meconium plugs syndrome refers to intestinal obstruction, usually in the distal colon, rectum, and anal canal, caused by meconium plugs (Fig. 135.1). Resulting from a disproportionately low amount of water in the intestinal lumen, meconium plugs are a rare cause of intrauterine intestinal obstruction and meconium peritonitis unrelated to cystic fibrosis (CF). **Anorectal plugs** may also cause mucosal ulceration from bowel wall erosion and subsequent intestinal perforation. **Meconium plugs** are associated with small left colon syndrome in infants of diabetic mothers, infants with CF (40%) and Hirschsprung disease (40%), maternal opiate use, and magnesium sulfate therapy for preeclampsia and tocolysis. Up to 30% of patients can have spontaneous resolution. Initial treatment may include administration of a glycerin suppository or rectal irrigation with isotonic saline. In up to 95% of patients, a Gastrografin enema (meglumine diatrizoate, a hyperosmolar, water-soluble, radiopaque solution containing 0.1% polysorbate 80 [Tween 80] and 37% organically bound iodine) will be both diagnostic and therapeutic, inducing passage of the plug, presumably because the high osmolarity (1,900 mOsm/L) of the solution draws fluid rapidly into the intestinal lumen and loosens the inspissated material. Such rapid loss of fluid into the bowel may result in acute fluid shifts with dehydration and shock, so it is advisable to dilute the contrast material with an equal amount of water and provide intravenous (IV) fluids, during and for several hours after the procedure, sufficient to maintain normal vital signs, urine output, and electrolytes. After removal of a meconium plug, the infant should be observed closely, and consideration given to performing diagnostic testing to identify **Hirschsprung disease** (congenital aganglionic megacolon; see Chapter 378.4) and CF (see Chapter 454).

MECONIUM ILEUS

Meconium ileus, or impaction of inspissated meconium in the distal small bowel, accounts for up to 30% of cases of neonatal intestinal obstruction. It is common in patients with CF in whom the lack of fetal pancreatic enzymes inhibits digestive mechanisms, and meconium becomes viscid and mucilaginous. Clinically, neonates present with intestinal obstruction with or without perforation. Abdominal distention is prominent, and vomiting, often bilious, becomes persistent, although occasionally inspissated meconium stools may be passed shortly after birth. Meconium ileus can present as early as in utero, in which the fetus develops acute intestinal obstruction resulting in volvulus or perforation, peritoneal ascites, meconium peritonitis, and hydrops; if untreated, fetal loss may occur.

Meconium ileus is primarily associated with cystic fibrosis transmembrane regulator (CFTR) pathologic variants F508del, G542X, W1282X, R553X, and G551D. Patients with two copies of the F508del variant have a 25% chance of presenting with meconium ileus. F508del plus any other CF mutation confers 17% risk, and two other CF variants confer a 12% risk of meconium ileus. In addition, non-CFTR genetic modifier genes influence meconium ileus. In families who already have at least one child with CF complicated by meconium ileus, there is a 39% risk for meconium ileus in subsequent children, which is more than the rates expected with autosomal recessive inheritance. In a twin study, 82% of monozygotic twins showed concordance for meconium ileus, whereas only 22% of dizygotic and 24% of two affected siblings showed concordance. Positive newborn screening for CF should prompt sweat testing when the infant weighs >2 kg and is at least 36 weeks of corrected gestational age. Genetic testing confirms the diagnosis of CF (see Chapter 454). In ~20% of patients with meconium ileus, there is no evidence of CF; in some of these patients, pathogenic variants in *GUCY2C* are identified.

The differential diagnosis involves other causes of intestinal obstruction, including intestinal pseudoobstruction, and other causes of pancreatic insufficiency (see Chapter 398). Prenatal diagnosis is readily achieved by ultrasound with identification of enlarged bowel loops or a mass with distention of the proximal small bowel. Clinically the diagnosis can be made with a history of CF in

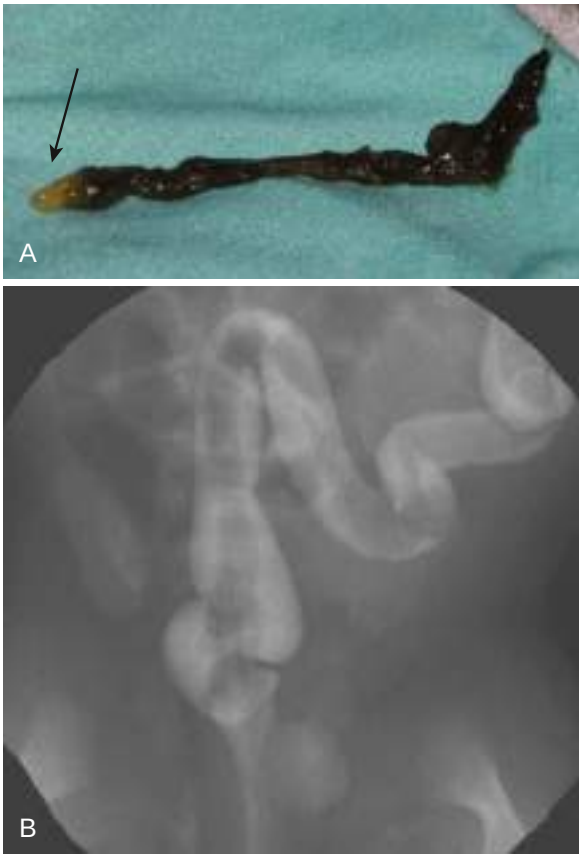

Fig. 135.1 Meconium plug. **A,** Meconium plug evacuated after a diagnostic contrast enema demonstrated the distinctive white tip *(arrow)*. **B,** Image from a contrast enema in a term neonate with vomiting and bowel distension demonstrates the long filling defect characteristic of meconium plug syndrome. The child was relieved of the obstruction after evacuation of the plug, without recurrence of symptoms. *(From Hernanz-Schulman M. Congenital and neonatal disorders. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging. 12th ed. Philadelphia: Elsevier; 2013: Fig. 106-14.)*

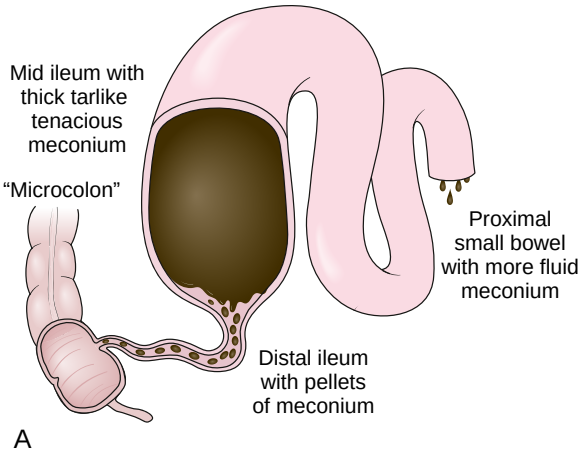

Fig. 135.2 Meconium ileus. **A,** Schematic drawing of uncomplicated meconium ileus. Pellets of inspissated meconium fill the terminal ileum proximal to a microcolon. Several loops of more proximal ileum contain thick, tenacious meconium. **B,** Enterotomy of proximal bowel and the nature of the thick and tenacious meconium. Note the dilated proximal loops of bowel filled with meconium and the progressively small caliber of the distal bowel leading to the microcolon. *(A from Leonidas JC, Berdon WE, et al. Meconium ileus and its complications: a reappraisal of plain film roentgen diagnostic criteria. Am J Roentgenol Radium Ther Nucl Med. 970;108[3]:598–609; B courtesy Dr. Wallace W. Neblett III, Nashville, TN.)*

a sibling, by palpation of doughy or cordlike masses of intestines through the abdominal wall, and from the radiographic appearance. Plain radiographs reveal small bowel obstruction. Air-fluid levels may not be apparent because of the thickened meconium.

In contrast to the generally evenly distended intestinal loops above an atresia, the loops may vary in width and are not as evenly filled with gas. At points of heaviest meconium concentration, the infiltrated gas may create a bubbly, granular appearance (Figs. 135.2 and 135.3).

Treatment for simple meconium ileus is a high-osmolarity Gastrografin enema, as described for meconium plugs. If the procedure is unsuccessful or perforation of the bowel wall is suspected, a laparotomy is performed and the ileum opened at the point of largest diameter of the impaction. Approximately 50% of these infants have associated intestinal atresia, stenosis, or volvulus that requires surgery. The inspissated meconium is removed by gentle and patient irrigation with warm isotonic sodium chloride or *N*-acetylcysteine (Mucomyst) solution through a catheter passed between the impaction and

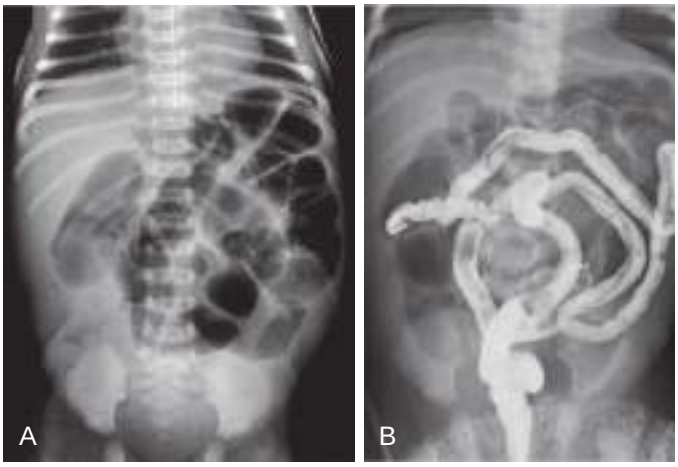

Fig. 135.3 Uncomplicated meconium ileus. **A,** Abdominal radiograph in 3-day-old infant with abdominal distention and bilious aspirates shows dilation of multiple loops of bowel. No calcifications are seen on the radiograph to suggest complicated meconium ileus. Orogastric tube near the gastroesophageal junction was subsequently advanced. **B,** Contrast enema demonstrates a microcolon, with multiple meconium plugs, consistent with the diagnosis of meconium ileus. *(From Hernanz-Schulman M. Congenital and neonatal disorders. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging. 13th ed. Philadelphia: Elsevier; 2019: Fig. 102-36)*

the bowel wall. Some patients will require bowel resection with a temporary double-barrel enterostomy followed by serial irrigations and distal refeeding, or primary anastomosis at the initial operation. Most infants with meconium ileus survive the neonatal period. If meconium ileus is associated with CF, the long-term prognosis depends on the severity of the underlying disease (see Chapter 454). In ~20% of patients with meconium ileus, there is no evidence of CF; in some of these patients pathogenic variants in *GUCY2C* are identified.

MECONIUM PERITONITIS

Perforation of the intestine may occur in utero or shortly after birth. Frequently, the intestinal perforation seals naturally with relatively little meconium leakage into the peritoneal cavity. Perforations occur most often as a complication of meconium ileus in infants with CF but occasionally result from a meconium plug or in utero intestinal obstruction of another cause.

Cases at the most severe end of the spectrum may be diagnosed on prenatal ultrasound with fetal ascites, polyhydramnios, bowel dilation, intraabdominal speckled calcifications, and hydrops fetalis (Fig. 135.4). At the other end are cases in which an intestinal perforation may seal spontaneously and patients remain asymptomatic, except when meconium becomes calcified and is later discovered on radiographs. Alternatively, the clinical picture may be dominated by signs of intestinal obstruction (as in meconium ileus) with abdominal distention, vomiting, and absence of stools or chemical peritonitis presenting with sepsis. Treatment consists primarily of elimination of the intestinal obstruction and drainage of the peritoneal cavity with a timely surgical intervention proved to result in high survival rate and favorable outcome even in complicated meconium peritonitis.

GASTROSCHISIS

Gastroschisis is the herniation of abdominal contents (usually small intestine) through a defect in the anterior abdominal wall lateral to the umbilical cord (Fig. 135.5). The etiology is unknown, but it has been

Fig. 135.4 Complicated meconium ileus. **A,** Abdominal radiograph in 2-day-old girl with abdominal distention and bilious aspirates shows absence of bowel gas in the right abdomen with a partly calcified mass displacing gas-filled dilated loops of bowel to the left. **B,** Ultrasound image demonstrates the subhepatic, partly calcified mass with internal debris and fluid-fluid level *(arrowhead)*. **C,** Additional ultrasound image shows a portion of the cyst wall *(arrows)* and multiple, abnormal, hyperechoic loops of bowel. **D,** Abdominal radiograph in different 1-day-old infant shows a calcified mass in right upper quadrant, shown at sonography to represent a loculated complex meconium collection. **E,** Radiograph a few hours later of the same infant shown in **D** shows a persistent perforation with gas entering into the right upper quadrant collection *(arrows)*. *(From Hernanz-Schulman M. Congenital and neonatal disorders. In Coley BD, ed. Caffey's Pediatric Diagnostic Imaging. 13th ed. Philadelphia: Elsevier; 2019: Fig. 102-37)*

Fig. 135.5 Intraoperative view of a complex gastroschisis with intestinal atresia. Note the severe bowel matting in the complex gastroschisis. *(Modified from Vinit N, Talbotec C, De Tristan MA, et al. Predicting factors of protracted intestinal failure in children with gastroschisis. J Pediatr. 2022;243:122–129. Fig. 1B.)*

associated with young maternal age and possible opioid use; the incidence is ~2-5 infants in 10,000 births.

Gastroschisis is usually an isolated anomaly but has a high morbidity and mortality especially in complex lesions associated with intestinal atresias and necrosis resulting in short bowel syndrome and intestinal failure (see Chapter 385.6). Treatment requires resection of atretic or necrotic tissue and long-term parenteral alimentation until enteral nutrition can be established.

Chapter 136

Necrotizing Enterocolitis

Sagori Mukhopadhyay and Misty Good

Necrotizing enterocolitis (NEC) is the most common life-threatening emergency of the gastrointestinal (GI) tract in the newborn period. The disease is characterized by various degrees of mucosal or transmural necrosis of the intestine followed by local and systemic inflammation. The cause of NEC remains unclear but is most likely multifactorial.

DEFINITION

NEC is clinically identified using a combination of clinical and radiographic signs and staged by categorizing NEC into suspected (stage I), definite (stage II, clinical signs of abdominal pathology with an abnormal abdominal radiograph showing pneumatosis intestinalis, portal venous gas, or ileus), and advanced (stage III, signs of stage II plus severe systemic signs of inflammation and acidosis with or without signs of intestinal perforation). In addition, NEC is also categorized into *medical and surgical NEC* defined by the type of acute intervention required. These criteria have been criticized for categorizing conditions with heterogeneous origins as the same disease. For example, conditions such as spontaneous intestinal perforation, septic ileus, and allergic enterocolitis can present with signs similar to NEC, but they arise from differing pathogenesis and may have differing outcomes. Similarly, term infants often present with NEC attributable to coexisting conditions such as congenital heart disease or gastroschisis, and likely do not share identical pathogenesis with NEC occurring in preterm infants. To minimize the heterogeneity of presentations that get diagnosed as NEC, a definition of "preterm NEC" has been proposed for use in clinical research. **Preterm NEC** in clinical research is defined by the presence of (1) clinical sign of abdominal distention and/or hematochezia; (2) onset between 10 days after birth to 36 weeks' postmenstrual age with the highest risk period being 30-32 weeks'

postmenstrual age; and (3) one of the following—pneumatosis intestinalis or portal venous gas by radiograph or ultrasound, histopathologic evidence of intestinal necrosis, or evidence of vasculitis, coagulopathy, or inflammation in the absence of infection.

EPIDEMIOLOGY

Epidemiologic studies have reported changes in NEC incidence in the past decade. Among 473,895 very low birthweight infants (VLBW, birthweight <1,500 g) admitted to one of 820 centers in the United States (2006-2017), the overall rate of NEC was 7.6%. From 2006–2017, there was a significant reduction in the prevalence of medical but not surgical NEC; mortality with NEC also decreased from 20.7% to16.8% among infants with medical NEC, and 36.6% to 31.6% for neonates with surgical NEC.

PATHOLOGY AND PATHOGENESIS

Many factors contribute to the development of the pathologic findings of NEC, including mucosal ischemia and subsequent necrosis; gas accumulation in the submucosa of the bowel wall **(pneumatosis intestinalis)**; and progression of the necrosis to perforation, peritonitis, sepsis, and death. An overview of common hypothesized pathogenic mechanisms, related clinical presentation, and management is shown in Figure 136.1. The distal part of the ileum and the proximal segment of the colon are involved most frequently; in fatal cases, transmural necrosis may extend from the stomach to the rectum **(NEC totalis)**. The pathogenesis of NEC is not fully understood, but three major risk factors have been implicated: prematurity, bacterial colonization of the gut, and enteral feeding. NEC develops primarily in premature infants with exposure to a nutritional substrate in the context of immature intestinal motility, and immunity, microbial dysbiosis, and mucosal ischemia. An underlying genetic predisposition is recognized with variants in genes regulating immunomodulation and inflammation (e.g., toll-like receptor-4, interleukin [IL]-4 receptor α chain, IL-6), apoptosis and cellular repair (e.g., platelet-activating factor), and oxidant stress (e.g., vascular endothelial growth factor, arginine, nitric oxide). *The greatest risk factor for NEC is prematurity, with a mean onset between 30 and 32 weeks' postmenstrual age.* Other risk factors include small for gestational age, polycythemia, and conditions resulting in in utero hypoxia. NEC rarely occurs before the initiation of enteral feeding and is much less common in infants fed human milk.

CLINICAL MANIFESTATIONS

Infants with NEC have a variety of signs and symptoms and may have an insidious or sudden catastrophic onset (Table 136.1). Age of onset is inversely related to gestational age. The first signs of impending disease may be nonspecific, including lethargy and temperature instability, or related to GI pathology, such as abdominal tenderness and distention, feeding intolerance, and bloody stools. Because of nonspecific signs, sepsis may be suspected before NEC. The spectrum of illness is broad, ranging from mild disease with only guaiac-positive stools to severe illness with bowel perforation, peritonitis, systemic inflammatory response syndrome, shock, and death. Laboratory findings may include neutropenia, anemia, thrombocytopenia, coagulopathy, and metabolic acidosis. Hypotension and respiratory failure are common. Progression may be rapid, but it is unusual for the disease to progress from mild to severe after 72 hours.

DIAGNOSIS

A very high index of suspicion in treating preterm at-risk infants is crucial. Plain abdominal radiographs are essential to make a diagnosis of NEC. The finding of pneumatosis intestinalis confirms the clinical suspicion of NEC and is diagnostic; 50–75% of patients have pneumatosis when treatment is started (Fig. 136.2). Portal venous gas is a sign of severe disease, and pneumoperitoneum indicates a perforation (Figs. 136.3 and 136.4). Ultrasound may be useful to evaluate for free fluid, abscess, pneumatosis intestinalis, and bowel wall thickness, peristalsis, and perfusion (Fig. 136.5). Doppler flowmetry studies can be used to assess flow in superior mesenteric artery and portal vein.

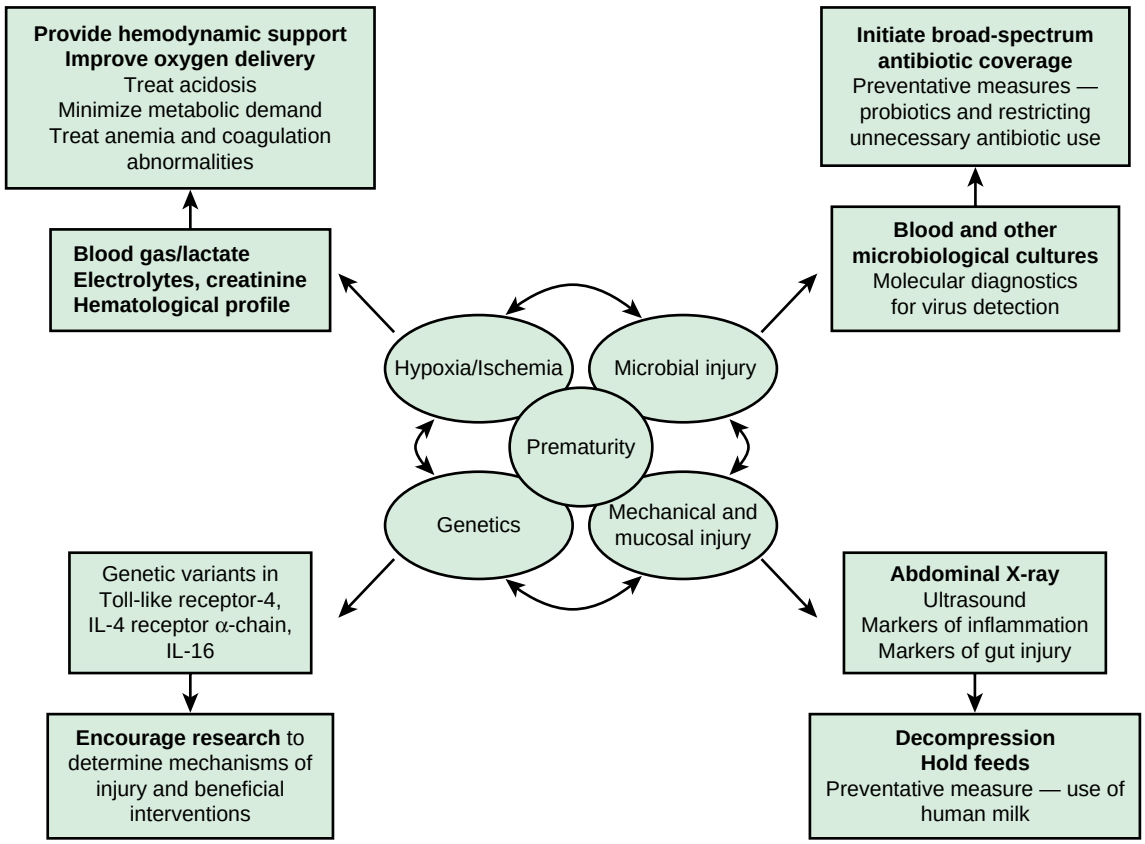

Fig. 136.1 Overview of risk factors and mechanisms of injury in necrotizing enterocolitis–associated presentation and management approaches. **Bold** indicates interventions that are common first-line interventions for NEC. IL, Interleukin. (*Figure created by authors using BioRender.com.*)

Table 136.1 Signs and Symptoms Associated with Necrotizing Enterocolitis

GASTROINTESTINAL	SYSTEMIC
Abdominal distention	Lethargy
Abdominal tenderness	Apnea/respiratory distress
Feeding intolerance	Temperature instability
Delayed gastric emptying	Acidosis (metabolic and/or respiratory)
Emesis	Glucose instability
Occult/gross blood in stool	Poor perfusion/shock
Change in stool pattern/diarrhea	Thrombocytopenia
Abdominal mass	Disseminated intravascular coagulopathy
Erythema of abdominal wall	

From Kanto WP Jr, Hunter JE, Stoll BJ. Recognition and medical management of necrotizing enterocolitis. *Clin Perinatol.* 1994;21:335–346.

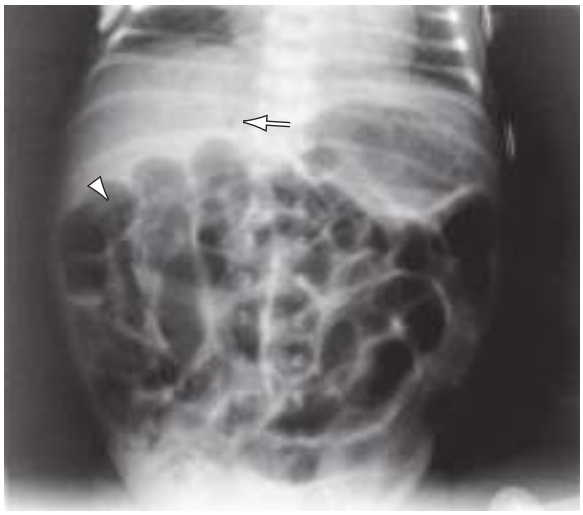

Fig. 136.2 Necrotizing enterocolitis (NEC). Kidney-ureter-bladder film demonstrates abdominal distention, hepatic portal venous gas *(arrow),* and a bubbly appearance of pneumatosis intestinalis (*arrowhead;* right lower quadrant). The latter two signs are thought to be pathognomonic for neonatal NEC.

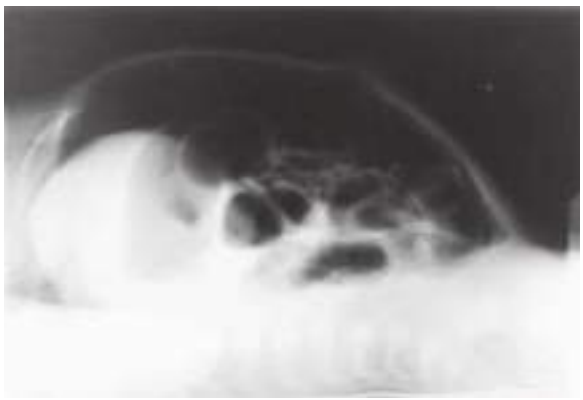

Fig. 136.3 Intestinal perforation. Cross-table abdominal radiograph in patient with neonatal necrotizing enterocolitis demonstrates marked distention and massive pneumoperitoneum, as evidenced by the free air below the anterior abdominal wall.

The differential diagnosis of NEC includes septic ileus, GI obstruction, volvulus, and isolated intestinal perforation. **Idiopathic focal intestinal perforation** can occur spontaneously or can be associated with the early use of postnatal corticosteroids and indomethacin. Pneumoperitoneum develops in such patients, but they are usually less ill than those with NEC. Occasional clusters of NEC cases have been attributed to viral infections, specifically norovirus, enterovirus, and rotavirus. Stool viral testing and infectious disease consultation should be considered when multiple cases occur together.

Fig. 136.4 Necrotizing enterocolitis (NEC). Plain abdominal x-ray film of an infant with perforated NEC showing pneumoperitoneum. *(From Tam PKH, Chung PHY, St Peter SD, et al. Advances in paediatric gastroenterology. Lancet. 2017;390:1072–1082. Fig. 4)*

TREATMENT

Rapid initiation of therapy is required for infants with suspected, as well as proven NEC. There is no specific treatment for established NEC, so therapy is directed at providing supportive care and preventing further injury with cessation of feeding, nasogastric decompression, and administration of intravenous fluids and antibiotics (see Fig. 136.1). Careful attention to the respiratory status, coagulation profile, and acid-base and electrolyte balances are important. Ventilation should be assisted in the presence of apnea or if abdominal distention is contributing to hypoxia and hypercapnia. Intravascular volume replacement with crystalloid or blood products, cardiovascular support with fluid boluses and/or inotropes, and correction of hematologic, metabolic, and electrolyte abnormalities are essential to stabilize the infant with NEC. Umbilical arterial catheters are reported to reduce blood flow in the mesenteric blood vessels and should be removed if they remain in place after a diagnosis of NEC. Maintaining reliable intravenous access for ongoing hemodynamic support and medication administration is critical.

Approximately 16% of definite NEC cases may be associated with bacteremia detected within 72 hours of its diagnosis, most frequently with a gram-negative organism. NEC with associated bacteremia has a higher risk for requiring surgical intervention and mortality. Once blood has been drawn for culture, systemic antibiotics (with broad coverage based on the antibiotic sensitivity patterns in the particular neonatal ICU) should be started immediately. The addition of anaerobic coverage with antibiotics such as metronidazole or clindamycin is variably practiced. Management of NEC with anaerobic coverage is

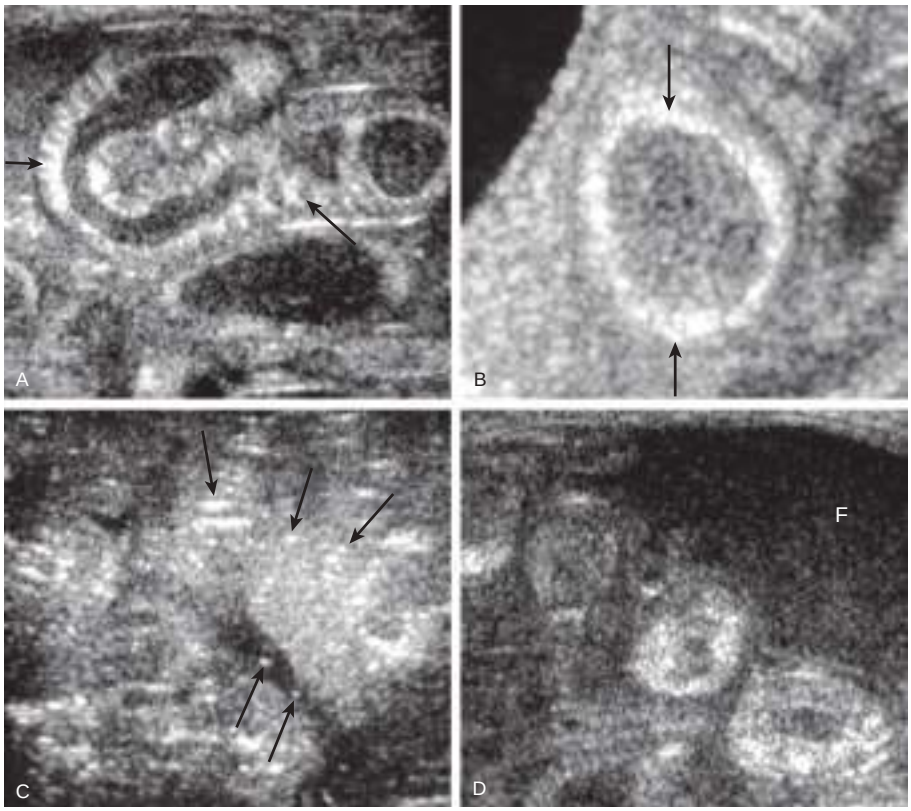

Fig. 136.5 Necrotizing enterocolitis. **A,** Mucosal and submucosal thickening *(arrows)*. **B,** Intramural gas (pneumatosis intestinalis) creates an echogenic ring *(arrows)*. **C,** Widespread echogenic bubbles of gas in the portal veins *(arrows)*. **D,** Fluid with echogenic debris (F) lies adjacent to thick loops. *(From John SD, Hollingsworth C: The pediatric gastrointestinal tract. In Levine D, Rumack CM, Wilson SR, Charboneau JW, eds. Diagnostic Ultrasound, 4th ed. Philadelphia: Elsevier, 2014. Fig 55.29.)*

associated with slightly lower risk of mortality and higher risk of subsequent strictures.

The patient's course should be monitored closely by means of frequent physical assessments in the NICU; sequential anteroposterior and cross-table lateral or lateral decubitus abdominal radiographs to detect intestinal perforation; and serial determinations of hematologic, electrolyte, and acid-base status. A surgeon should be consulted early in the course of treatment. The only *absolute* indication for surgery is evidence of perforation on an abdominal radiograph (pneumoperitoneum). However, this is present in less than half of infants with perforation or necrosis at operative exploration. Progressive clinical deterioration despite maximum medical management, a single fixed bowel loop on serial radiographs, and abdominal wall erythema are relative indications for exploratory laparotomy. Ideally, surgery should be performed after intestinal necrosis develops but before perforation and peritonitis occur. The optimal surgical approach, however, remains controversial. The options for surgical treatment include primary peritoneal drainage (PPD) or exploratory laparotomy with resection of the necrotic intestine and usually stoma creation. Laparotomy is usually the initial therapy in the majority of VLBW infants with surgical NEC, even in those <1,000 g. Randomized clinical trials comparing these approaches failed to demonstrate significant differences in survival, nutritional outcomes, or length of stay. However, among those with a diagnosis of NEC *(as opposed to intestinal perforation)*, 69% died or had neurodevelopmental impairment (NDI) when managed with initial laparotomy versus 85% when managed with PPD. In contrast, among infants with a diagnosis of *intestinal perforation*, death or NDI occurred 69% and 63% after initial management with laparotomy or PPD, respectively. When the diagnosis is confirmed NEC, initial management with laparotomy is more likely to reduce risk of death or NDI compared to PPD. However, the ultimate surgical approach for an individual case also depends on the surgeon's assessment and physiologic status of the patient.

PROGNOSIS

In patients with pneumatosis intestinalis at NEC diagnosis, disease progression is nonresponsive to medical management alone in approximately 20–40%; of these that require surgery, 20–50% die. Early postoperative complications include wound infection, dehiscence, and stomal problems (prolapse, necrosis). Later complications include intestinal strictures, which occur in approximately 25–35% of surgically or medically managed patients. After massive intestinal resection, complications from postoperative NEC include short bowel syndrome (malabsorption, growth failure, malnutrition), complications related to central venous catheters (sepsis, thrombosis), and cholestatic jaundice. Preterm infants with NEC who require surgical intervention are at increased risk for adverse growth and neurodevelopmental outcomes.

PREVENTION

The most effective preventive strategy for NEC is the use of human milk (maternal or donor); newborns exclusively fed breast milk have a reduced risk of NEC. However, because human milk does not provide complete nutritional support for very preterm infants, nutritional fortification is usual practice. Some studies have suggested that an "exclusive human milk diet" using human rather than bovine fortifiers may further reduce the risk of NEC. An optimal feeding protocol (rapid vs slow volume increments) has not been discovered; it is important to note that strict adherence to a NICU-specific feeding protocol reduces the risk of NEC. Additionally, while extensive data and meta-analyses would support the use of probiotics to prevent NEC, there is no clear consensus on the safest, most effective formulation, timing of administration, or length of therapy. Other preventive strategies using prebiotics and synbiotics have also been studied, with variable outcomes. Inhibitors of gastric acid secretion (H_2-receptor blockers, proton pump inhibitors), high osmolality enteral fluids, or prolonged empirical antibiotics in the early neonatal period have been associated with increased risk of NEC and should be avoided.

Chapter 137

Jaundice and Hyperbilirubinemia in the Newborn

Kelsey S. Ryan and Robert M. Kliegman

Hyperbilirubinemia is a common and, in most cases, benign problem in neonates. **Jaundice** is observed during the first week after birth in approximately 60% of term infants and 80% of preterm infants. The yellow color usually results from the accumulation of unconjugated, nonpolar, lipid-soluble bilirubin pigment in the skin. This unconjugated bilirubin (designated **indirect-acting** by nature of the van den Bergh reaction) is an end product of heme-protein catabolism from a series of enzymatic reactions by heme-oxygenase and biliverdin reductase and nonenzymatic reducing agents in the reticuloendothelial cells. It may also be partly caused by deposition of pigment from conjugated bilirubin, the end product from indirect, unconjugated bilirubin that has undergone conjugation in the liver cell microsome by the enzyme uridine diphosphoglucuronic acid (UDP)–glucuronyl transferase to form the polar, water-soluble glucuronide of bilirubin **(direct-reacting).** Although bilirubin may have a physiologic role as an antioxidant, elevations of indirect, unconjugated bilirubin are potentially neurotoxic. Even though the conjugated form is not neurotoxic, direct hyperbilirubinemia indicates potentially serious hepatic disorders or a systemic illness.

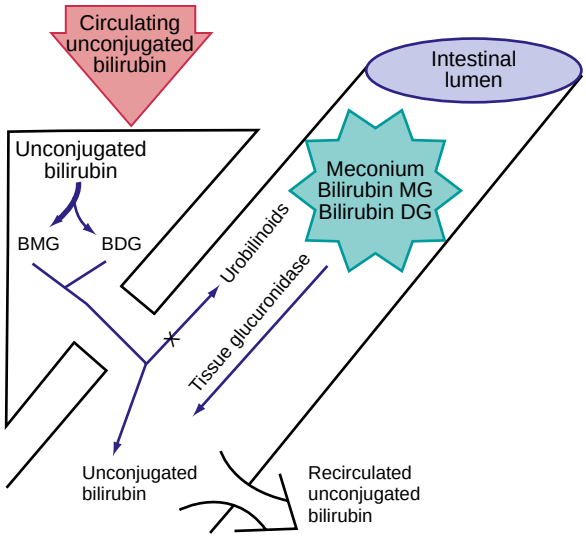

Fig. 137.1 Metabolism of bilirubin in the neonatal period. Neonatal production rate of bilirubin is 6-8 mg/kg/24 hr (in contrast to 3-4 mg/kg/24 hr in adults). Water-insoluble bilirubin is bound to albumin. At the plasma-hepatocyte interface, a liver membrane carrier (bilitranslocase) transports bilirubin to a cytosolic binding protein (ligandin or Y protein, now known to be glutathione *S*-transferase), which prevents back-absorption to plasma. Bilirubin is converted to bilirubin monoglucuronide (BMG). Neonates excrete more BMG than adults. In the fetus, conjugated lipid-insoluble BMG and bilirubin diglucuronide (BDG) must be deconjugated by tissue β-glucuronidases to facilitate placental transfer of lipid-soluble unconjugated bilirubin across the placental lipid membranes. After birth, intestinal or milk-containing glucuronidases contribute to the enterohepatic recirculation of bilirubin and possibly to the development of hyperbilirubinemia.

ETIOLOGY

During the neonatal period, metabolism of bilirubin is in transition from the *fetal stage,* during which the placenta is the principal route of elimination of the lipid-soluble, unconjugated bilirubin, to the *adult stage,* during which the water-soluble conjugated form is excreted from hepatic cells into the biliary system and gastrointestinal tract. **Unconjugated hyperbilirubinemia** may be caused or increased by any factor that (1) increases the load of bilirubin to be metabolized by the liver (hemolytic anemias, polycythemia, bruising or internal hemorrhage, shortened RBC life as a result of immaturity or transfusion of cells, increased enterohepatic circulation, infection), (2) damages or reduces the activity of the transferase enzyme or other related enzymes (genetic deficiency, hypoxia, infection, thyroid deficiency), (3) competes for or blocks the transferase enzyme (drugs and other substances requiring glucuronic acid conjugation), or (4) leads to an absence or decreased amounts of the enzyme or to reduction of bilirubin uptake by liver cells (genetic defect, prematurity). Gene polymorphisms in the hepatic uridine diphosphate glucuronosyltransferase isoenzyme 1A1 *(UGT1A1)* and the solute carrier organic anion transporter 1B1 *(SLCO1B1)*, alone or in combination, influence the incidence of neonatal hyperbilirubinemia.

The toxic effects of elevated serum concentrations of unconjugated bilirubin are increased by factors that reduce the retention of bilirubin in the circulation (hypoproteinemia, displacement of bilirubin from its binding sites on albumin by competitive binding of drugs such as sulfisoxazole and moxalactam, acidosis, and increased free fatty acid concentration secondary to hypoglycemia, starvation, or hypothermia). Neurotoxic effects are directly related not only to the permeability of the blood-brain barrier (BBB) and nerve cell membranes but also to neuronal susceptibility to injury, all of which are adversely influenced by asphyxia, prematurity, hyperosmolality, and infection. Early and frequent feeding decreases, whereas suboptimal feedings and dehydration increases serum levels of bilirubin. Delay in passage of meconium, which contains 1 mg bilirubin/dL, may contribute to jaundice by enterohepatic recirculation after deconjugation by intestinal glucuronidase (Fig. 137.1). Drugs such as oxytocin (in the mother) and chemicals used in the nursery such as phenolic detergents may also produce unconjugated hyperbilirubinemia.

CLINICAL MANIFESTATIONS

Jaundice usually appears during the early neonatal period, depending on etiology. Whereas jaundice from deposition of indirect bilirubin in the skin tends to appear bright yellow or orange, jaundice of the obstructive type (direct bilirubin) has a greenish or muddy yellow cast. Jaundice usually becomes apparent in a cephalocaudal progression, starting on the face and progressing to the abdomen and then the feet, as serum levels increase. Dermal pressure may reveal the anatomic progression of jaundice (face, approximately 5 mg/dL; mid-abdomen, 15 mg/dL; soles, 20 mg/dL), *but clinical examination cannot reliably estimate serum levels*. Noninvasive techniques for transcutaneous measurement of bilirubin that correlate with serum levels may be used to *screen* infants, but determination of the serum bilirubin level is indicated in patients with elevated age-specific transcutaneous bilirubin measurement, progressing jaundice, or risk for hemolysis or sepsis. Infants with severe hyperbilirubinemia may present with lethargy and poor feeding and, without treatment, can progress to acute bilirubin encephalopathy (kernicterus) (see Chapter 137.1).

DIFFERENTIAL DIAGNOSIS

The distinction between *physiologic* and *pathologic* jaundice relates to the timing, rate of rise, and extent of hyperbilirubinemia, because some of the same causes of physiologic jaundice (e.g., large RBC mass, decreased capacity for bilirubin conjugation, increased enterohepatic circulation) can also result in pathologic jaundice. Evaluation should be determined on risk factors, clinical appearance, and severity of the hyperbilirubinemia (Tables 137.1-137.3). Jaundice that is present at birth or appears within the first 24 hours after birth should be considered **pathologic** and requires immediate attention. Potential diagnoses would include erythroblastosis fetalis, concealed hemorrhage, sepsis, or congenital

Table 137.1 Risk Factors for Severe Neonatal Hyperbilirubinemia

GENETIC FACTORS
• Gilbert syndrome
• Crigler-Najjar syndrome
• Alagille syndrome
• β thalassemia
• Glucose-6-phosphate dehydrogenase deficiency
• Bilirubin glucuronosyltransferase polymorphism
• Pyruvate kinase deficiency
• Erythrocyte structural defects (including hereditary spherocytosis and elliptocytosis)
• Galactosemia
MATERNAL FACTORS
• Family history of severe jaundice, splenectomy, or cholecystectomy
• Primiparity
• Teenage pregnancy
• Diabetes
• Rhesus incompatibility
• ABO incompatibility
• Other blood group isoimmunization
• Use of drugs during labor (including oxytocin, promethazine, and bupivacaine)
• Exclusive breastfeeding
PERINATAL FACTORS
• Mode of deliver (breech vs vertex, instrumentation)
• Birth trauma (cephalohematoma or substantial bruising, extravasation)
• Birth asphyxia
• Congenital infections (including cytomegalovirus and syphilis)
• Sepsis
NEONATAL FACTORS
• Male sex
• Prematurity or low birthweight and small-for-gestational age
• Hypothyroidism
• Polycythemia
• Hypoglycemia
• Low intake of breast milk, dehydration, or weight loss
• Breast milk jaundice
• Jaundice in the first day of life
• Trisomy 21
• Infant of diabetic mother
• Cephalohematoma, other bruising
OTHER RISK FACTORS AND MARKERS
• Previous sibling received phototherapy or exchange transfusion
• Predischarge total serum bilirubin or transcutaneous bilirubin concentration in the high zone
• Use of hemolytic agents (e.g., naphthalene or menthol-based products) in glucose-6-phosphate dehydrogenase deficient population groups
• Folate deficiency
• Aflatoxins
• Hypothermia
• Birth outside of a healthcare facility

CMV, Cytomegalovirus; CBC, complete blood count; HSV, herpes simplex virus; PCR, polymerase chain reaction; INR, international normalized ratio; TORCH, toxoplasmosis, other, rubella, CMV, herpes.

infections, including syphilis, cytomegalovirus (CMV), rubella, and toxoplasmosis. Significant hemolysis is suggested by a rapid rise in serum bilirubin concentration (>0.5 mg/dL/hr), anemia, pallor, reticulocytosis, hepatosplenomegaly, and a positive family history. An unusually high proportion of direct-reacting bilirubin may characterize jaundice in infants who have received intrauterine transfusions for erythroblastosis fetalis. Jaundice that first appears on the second or third day is usually **physiologic** but may represent a more severe form. Familial nonhemolytic icterus **(Crigler-Najjar syndrome)** and early-onset breastfeeding (suboptimal intake) jaundice are seen initially on the second or third day. Jaundice *appearing* after the third day and within the first week suggests bacterial sepsis or urinary tract infection; it may also be caused by other infections, notably syphilis, toxoplasmosis, CMV, herpes simplex virus (HSV), and enterovirus. Jaundice secondary to extensive ecchymosis or blood extravasation may occur during the first day or later, especially in premature infants. Polycythemia may also lead to early jaundice.

There is a long differential diagnosis for jaundice first recognized *after* the first week of life, including breast milk jaundice, septicemia, congenital atresia or paucity of the bile ducts, hepatitis, galactosemia, hypothyroidism, cystic fibrosis (CF), pyloric stenosis, and congenital hemolytic anemia crises related to RBC morphology and enzyme deficiencies (Fig. 137.2). The differential diagnosis for persistent jaundice during the first month of life includes hyperalimentation-associated cholestasis, hepatitis, CMV, syphilis, toxoplasmosis, familial nonhemolytic icterus, biliary atresia, galactosemia and other inborn errors of metabolism, and inspissated bile syndrome following hemolytic disease of the newborn. Rarely, physiologic jaundice may be prolonged for several weeks, as in infants with hypothyroidism or pyloric stenosis.

Regardless of gestation or time of appearance of jaundice, patients with *significant* hyperbilirubinemia *and* those with symptoms or signs require a complete diagnostic evaluation, which includes review of risks (Table 137.1), determination of direct and indirect bilirubin fractions, hemoglobin, reticulocyte count, blood type, direct antiglobulin/antibody test (DAT) (Coombs test), and examination of a peripheral blood smear. Indirect hyperbilirubinemia, reticulocytosis, and a smear with evidence of RBC destruction suggest hemolysis (see Table 137.2). In the absence of blood group incompatibility, non–immunologically-induced hemolysis should be considered. If the reticulocyte count, Coombs test result, and direct bilirubin value are normal, physiologic or pathologic indirect hyperbilirubinemia may be present (see Fig. 137.2). If direct hyperbilirubinemia is present, diagnostic possibilities include hepatitis, congenital bile duct disorders (biliary atresia, paucity of bile ducts, Byler disease), cholestasis, inborn errors of metabolism, CF, congenital hemosiderosis, sepsis, and neonatal hepatic failure syndromes (Table 137.4).

Table 137.3 Diagnostic Features of the Various Types of Neonatal Jaundice

DIAGNOSIS	VAN DEN BERGH REACTION	JAUNDICE		PEAK BILIRUBIN CONCENTRATION		BILIRUBIN RATE OF ACCUMULATION (mg/dL/day)	COMMENTS
		APPEARS	DISAPPEARS	MG/DL	AGE IN DAYS		
"Physiologic jaundice"							Usually relates to degree of maturity
Full-term	Indirect	2-3 days	4-5 days	10-12	2-3	<5	
Premature	Indirect	3-4 days	7-9 days	15	6-8	<5	
Hyperbilirubinemia caused by metabolic factors							Metabolic factors: hypoxia, respiratory distress, lack of carbohydrate
Full-term	Indirect	2-3 days	Variable	>12	First wk	<5	Hormonal influences: hypothyroidism, hormones, Gilbert syndrome
Premature	Indirect	3-4 days	Variable	>15	First wk	<5	Genetic factors: Crigler-Najjar syndrome, Gilbert syndrome
Hemolytic states and hematoma	Indirect	May appear in first 24 hr	Variable	Unlimited	Variable	Usually >5	Erythroblastosis: Rh, ABO, Kell congenital hemolytic states: spherocytic, nonspherocytic Infantile pyknocytosis Drug: vitamin K Enclosed hemorrhage—hematoma
Mixed hemolytic and hepatoxic factors	Indirect and direct	May appear in first 24 hr	Variable	Unlimited	Variable	Usually >5	Infection: bacterial sepsis, pyelonephritis, hepatitis, toxoplasmosis CMV HSV Rubella, syphilis
Hepatocellular damage	Indirect and direct	Usually 2-3 days; may appear by second wk	Variable	Unlimited	Variable	Variable, can be >5	Biliary atresia; paucity of bile ducts, familial cholestasis, galactosemia; hepatitis, infection, hepatic failure syndromes*

PHYSIOLOGIC JAUNDICE (ICTERUS NEONATORUM)

Under normal circumstances, the level of indirect bilirubin in umbilical cord serum is 1-3 mg/dL and rises at a rate of <5 mg/dL/24 hr; thus jaundice becomes visible on the second or third day, usually peaking between the second and fourth days at 5-6 mg/dL and decreasing to <2 mg/dL between the fifth and seventh days after birth. Jaundice associated with these changes is designated *physiologic* and is believed to be the result of increased bilirubin production from the breakdown of fetal RBCs combined with transient limitation in the conjugation of bilirubin by the immature neonatal liver.

Overall, 6–7% of full-term infants have indirect bilirubin levels >13 mg/dL, and <3% have levels >15 mg/dL. Risk factors for elevated indirect bilirubin include maternal age, ethnicity (Chinese, Japanese, Korean, Native American), maternal diabetes, prematurity, drugs, altitude, polycythemia, male, trisomy 21, cutaneous bruising, blood extravasation (cephalohematoma), oxytocin induction, breastfeeding, weight loss (dehydration or caloric deprivation), delayed bowel movement, and a family history of, or a sibling who had, physiologic jaundice (see Table 137.1). In infants without these variables, indirect bilirubin levels rarely rise >12 mg/dL, whereas infants with several risk factors are more likely to have higher bilirubin levels. A combination of breastfeeding, variant-glucuronosyltransferase activity (1A1), subclinical glucose-6-phosphate dehydrogenase (G6PD) deficiency, and alterations of the organic anion transporter-2 gene increases the risk of hyperbilirubinemia. Predicting which neonates are at risk for exaggerated physiologic jaundice can be based on *hour-specific* bilirubin levels in the first 24-72 hours of life (Fig. 137.3). Transcutaneous measurements of bilirubin are linearly correlated with serum levels and can be used for screening. Indirect bilirubin levels in full-term infants decline to adult levels (1 mg/dL) by 10-14 days of life. Persistent indirect hyperbilirubinemia beyond 2 weeks suggests hemolysis, hereditary glucuronyl transferase deficiency, breast milk jaundice, hypothyroidism, or intestinal obstruction. Jaundice associated with pyloric stenosis may be the result of caloric deprivation, relative deficiency of hepatic UDP–glucuronyl transferase, or an increase in the enterohepatic circulation of bilirubin from an ileus. In premature infants, the rise in serum bilirubin tends to be the same or somewhat slower but of longer duration than in term infants. Peak levels of 8-12 mg/dL are not usually reached until the fourth to seventh day, and jaundice is infrequently observed after the 10th day, corresponding to the maturation of mechanisms for bilirubin metabolism and excretion.

The diagnosis of physiologic jaundice in term or preterm infants can be established only by excluding known causes of jaundice based on the history, clinical findings, and laboratory data (see Table 137.3). In general, a search to determine the cause of jaundice should be made if (1) it appears in the first 24-36 hours after birth, (2) serum bilirubin is rising at a rate faster than 5 mg/dL/24 hr, (3) serum bilirubin is >12 mg/dL in a full-term infant (especially in the absence of risk factors) or 10-14 mg/dL in a preterm infant, (4) jaundice persists after 10-14 days after birth, or (5) direct bilirubin fraction is >2 mg/dL at any time. Other factors suggesting a pathologic cause of jaundice are family history of hemolytic disease, pallor, hepatomegaly, splenomegaly, failure of phototherapy to lower the bilirubin level, vomiting, lethargy, poor feeding, excessive weight loss, apnea, bradycardia, abnormal vital signs (including hypothermia), light-colored stools, dark urine positive for bilirubin, bleeding disorder, and signs of kernicterus (see Chapter 137.1).

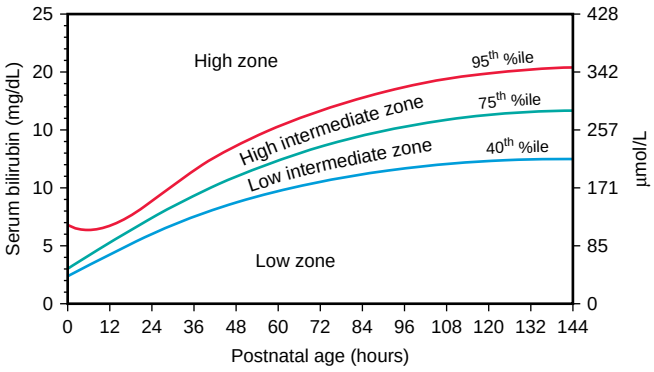

Fig. 137.3 Neonatal bilirubin nomogram. Percentile designation of well newborns ≥35 weeks' gestational age based on their hour-specific serum bilirubin values. The high zone is subdivided by the 95th percentile track. The intermediate zone is subdivided into upper and lower zones by the 75th percentile track. The low zone has been electively and statistically defined by the 40th percentile track. *(Modified from Bahr TM, Henry E, Christensen RD, et al. A new hour-specific serum bilirubin nomogram for neonates ≥35 weeks of gestation. J Pediatr. 2021;236:28–33. Fig. 2.)*

PATHOLOGIC HYPERBILIRUBINEMIA

Jaundice and its underlying hyperbilirubinemia are considered pathologic if the time of appearance, duration, or pattern varies significantly from that of physiologic jaundice, or if the course is compatible with physiologic jaundice but other reasons exist to suspect that the infant is at special risk for neurotoxicity. It may not be possible to determine the precise cause of an abnormal elevation of unconjugated bilirubin, but many infants with this finding have associated risk factors such as ethnicity, prematurity, breastfeeding, and weight loss. Frequently, the terms *exaggerated physiologic jaundice* and *hyperbilirubinemia of the newborn* are used in infants whose primary problem is probably a deficiency or inactivity of bilirubin glucuronyl transferase **(Gilbert syndrome)** rather than an excessive load of bilirubin for excretion (see Table 137.1). *The combination of G6PD deficiency and a pathogenic variant of the promoter region of UDP-glucuronyl transferase-1 produces indirect hyperbilirubinemia in the absence of signs of hemolysis.*

The greatest risk associated with indirect hyperbilirubinemia is the development of bilirubin-induced neurologic dysfunction, which typically occurs with high indirect bilirubin levels (see Chapter 137.1). The development of kernicterus **(bilirubin encephalopathy)** depends on the level of indirect bilirubin, duration of exposure to bilirubin elevation, the cause of jaundice, and the infant's well-being. Neurologic injury including kernicterus may occur at lower bilirubin levels in preterm infants and in the presence of asphyxia, sepsis, meningitis, intraventricular hemorrhage, hemolysis, or drugs that displace bilirubin from albumin. *The exact serum indirect bilirubin level that is harmful for very low birthweight (VLBW) infants is unclear.*

JAUNDICE ASSOCIATED WITH BREASTFEEDING

Significant elevation in unconjugated bilirubin **(breast milk jaundice)** develops in an estimated 2% of breastfed term infants after the seventh day, with maximal concentrations as high as 10-30 mg/dL reached during the second to third week. If breastfeeding is continued, the bilirubin gradually decreases but may persist for 3-10 weeks at lower levels. Phototherapy may be of benefit (see Chapter 137.1). Although very uncommon, kernicterus can occur in patients with breast milk jaundice. The etiology of breast milk jaundice is not entirely clear, although intestinal β-glucuronidase resulting in deconjugation of bilirubin and increased enterohepatic circulation and other factors in breast milk that might interfere with bilirubin conjugation (e.g., pregnanediol, free fatty acids) have been implicated.

The late jaundice associated with breast milk should be distinguished from an *early onset*, accentuated unconjugated hyperbilirubinemia known as suboptimal intake hyperbilirubinemia or **breastfeeding jaundice**, which occurs during the first week after birth in breastfed infants, who normally have higher bilirubin levels than formula-fed infants (Fig. 137.4). Lower milk intake before breast milk production is established can result in various degrees of dehydration, which hemoconcentrates bilirubin, while also causing fewer bowel movements, which in turn increases the enterohepatic circulation of bilirubin. Prophylactic supplements of glucose water to breastfed infants are associated with higher bilirubin levels, in part because of reduced intake of the higher–caloric density breast milk and *are not indicated*. Frequent breastfeeding (>10 in 24 hours), rooming-in with night feeding, and ongoing lactation support may reduce the incidence of

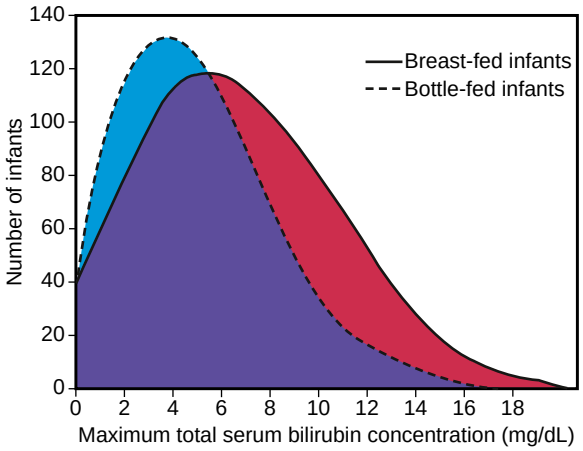

Fig. 137.4 Distribution of maximal bilirubin levels during the first week of life in breastfed and formula-fed White infants weighing >2,500 g. *(From Maisels MJ, Gifford K. Normal serum bilirubin levels in the newborn and the effect of breast-feeding. Pediatrics. 1986;78:837–843.)*

early breastfeeding jaundice. In addition, supplementation with formula or more preferred expressed breast milk is appropriate if the intake seems inadequate, weight loss is excessive, or the infant appears dehydrated.

NEONATAL CHOLESTASIS

See Chapter 404.

CONGENITAL ATRESIA OF THE BILE DUCTS

See Chapter 404.1.

Jaundice persisting for >2 weeks or associated with acholic stools and dark urine suggests biliary atresia. All infants with such findings require immediate diagnostic evaluation, including determination of direct bilirubin.

137.1 Kernicterus and Therapy of Hyperbilirubinemia

Kelsey S. Ryan and Robert M. Kliegman

Kernicterus, or **bilirubin encephalopathy**, is a neurologic syndrome resulting from the deposition of unconjugated (indirect) bilirubin in the basal ganglia and brainstem nuclei. The pathogenesis of kernicterus is multifactorial and involves an interaction between unconjugated bilirubin levels, albumin binding and unbound bilirubin levels, passage across the BBB, and neuronal susceptibility to injury. Disruption of the BBB by disease, asphyxia, infection, and other factors and maturational changes in BBB permeability affect risk.

The precise blood level above which indirect-reacting bilirubin or free bilirubin will be toxic for an individual infant is unpredictable. In a large series, however, kernicterus occurred only in infants with a bilirubin >20 mg/dL (more often >25-30 mg/dL), 90% of whom were previously healthy, predominantly breastfed, term and near-term infants. The duration of exposure to high bilirubin levels needed to produce toxic effects is unknown; the more immature the infant, and possibly age (day 1 vs day of life ≥4), the greater the susceptibility to kernicterus.

CLINICAL MANIFESTATIONS

Signs and symptoms of kernicterus usually appear 2-5 days after birth in term infants and as late as the seventh day in preterm infants, but hyperbilirubinemia may lead to encephalopathy at any time during the neonatal period. The early signs may be subtle and indistinguishable from those of sepsis, asphyxia, hypoglycemia, intracranial hemorrhage, apnea, and other acute systemic illnesses in a neonate. Lethargy, poor feeding, and loss of the Moro reflex are common initial signs. Subsequently, the infant may appear gravely ill and prostrate, with diminished tendon reflexes and respiratory distress. Opisthotonos with a bulging fontanel, twitching of the face or limbs, and a shrill, high-pitched cry may follow. In advanced cases, convulsions and spasm occur, with affected infants stiffly extending their arms in an inward rotation with the fists clenched (Table 137.5). Rigidity is rare at this late stage.

Table 137.5 Clinical Features of Kernicterus

ACUTE FORM
Phase 1 (first 1-2 days): poor suck, stupor, hypotonia, seizures
Phase 2 (middle of first week): hypertonia of extensor muscles, opisthotonos, retrocollis, fever
Phase 3 (after the first week): hypertonia
CHRONIC FORM
First year: hypotonia, active deep tendon reflexes, obligatory tonic neck reflexes, delayed motor skills
After first year: movement disorders (choreoathetosis, ballismus, tremor), upward gaze, sensorineural hearing loss

From Dennery PA, Seidman DS, Stevenson DK. Neonatal hyperbilirubinemia. *N Engl J Med* 2001;344:581–590.

Many infants who progress to these severe neurologic signs die; the survivors usually have serious sequalae but may appear to recover and for 2-3 months show few abnormalities. Later in the first year, opisthotonos, muscle rigidity, irregular movements, and convulsions tend to recur. In the second year the opisthotonos and seizures abate, but irregular, involuntary movements, muscle rigidity, or, in some infants, hypotonia increase steadily. By 3 years of age, the complete neurologic syndrome is often apparent: bilateral choreoathetosis with involuntary muscle spasms, extrapyramidal signs, seizures, mental deficiency, dysarthric speech, high-frequency hearing loss, squinting, and defective upward eye movements. Pyramidal signs, hypotonia, and ataxia occur in a few infants. In mildly affected infants, the syndrome may be characterized only by mild to moderate neuromuscular incoordination, partial deafness, or "minimal brain dysfunction," occurring singly or in combination; these problems may be unapparent until the child enters school (see Table 137.5).

INCIDENCE AND PROGNOSIS

By pathologic criteria, kernicterus develops in 30% of infants (all gestational ages) with untreated hemolytic disease and bilirubin levels >25-30 mg/dL. The incidence at autopsy in hyperbilirubinemic preterm infants is 2–16% and is related to the risk factors discussed in this chapter. Reliable estimates of the frequency of the clinical syndrome are not available because of the wide spectrum of manifestations. Overt neurologic signs carry a grave prognosis; >75% of infants die, and 80% of affected survivors have bilateral choreoathetosis with involuntary muscle spasms. Developmental delay, deafness, and spastic quadriplegia are common.

PREVENTION

The aim of bilirubin management is prevention of kernicterus. Although kernicterus has been thought to be a disease of the past, there are reports of neurotoxic effects of bilirubin in term and near-term infants who were discharged as healthy newborns. Effective prevention requires ongoing vigilance and a practical, system-based approach to distinguish infants with benign newborn jaundice from those whose course may be less predictable and potentially harmful. Predischarge universal screening for hyperbilirubinemia and assessment of clinical risk factors for severe jaundice and bilirubin-induced neurologic dysfunction include either total serum bilirubin or transcutaneous bilirubin measurement (interchangeably), although transcutaneous instruments may be less accurate at higher bilirubin levels (>15 mg/dL) or for infants with darker skin or if phototherapy has been used. If transcutaneous levels are documented as ≥15 mg/dL or rising rapidly, confirmation with a total serum bilirubin is recommended. Serum

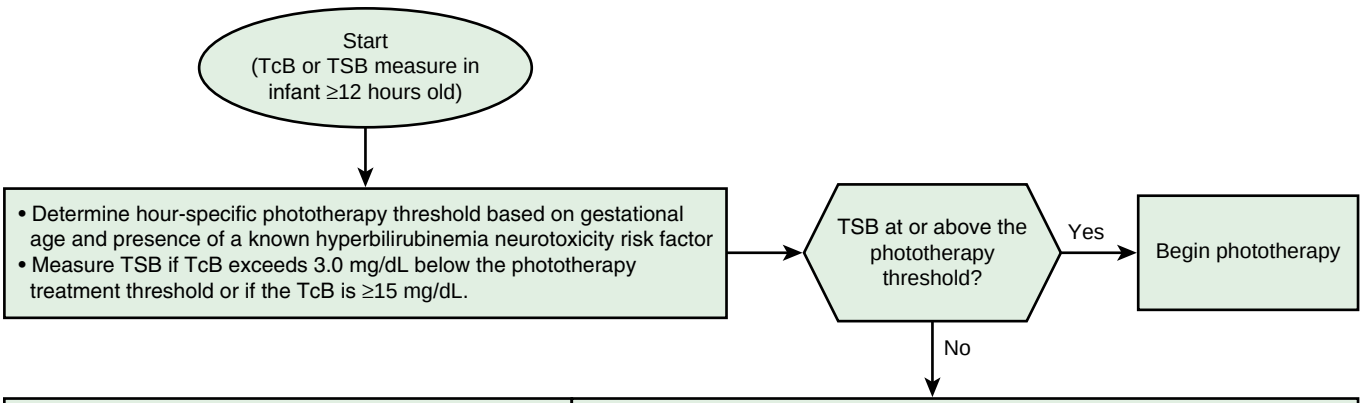
values should also be measured once infants begin phototherapy, because transcutaneous measurement may falsely underestimate total bilirubin in this setting.

Protocols using the hour-specific bilirubin nomogram (see Fig. 137.3), physical examination, and clinical risk factors have been successful in identifying patients at risk for hyperbilirubinemia and candidates for targeted management. Potentially preventable causes of kernicterus include (1) early discharge (<48 hours) with no early follow-up (within 48 hours of discharge), a problem that is particularly important in near-term infants (35-37 weeks of gestation); (2) failure to check the bilirubin level in an infant noted to be jaundiced in the first 24 hours; (3) failure to recognize the presence of risk factors for hyperbilirubinemia, especially hemolysis; (4) underestimation of the severity of jaundice by clinical (visual) assessment, which is inaccurate; (5) lack of concern regarding the presence of jaundice; (6) delay in measuring the serum bilirubin level despite marked jaundice or delay in initiating phototherapy in the presence of elevated bilirubin levels; and (7) failure to respond to parental concern regarding jaundice, poor feeding, or lethargy. Figure 137.5 provides a consensus-based (expert opinion) management plan for neonates with significant hyperbilirubinemia that relies on consensus-recommended (expert opinion) phototherapy thresholds for gestational ages ≥35 weeks (Figs. 137.6 and 137.7) in well appearing neonates.

The following approach is further recommended: (1) any infant who is jaundiced before 24 hours requires measurement of total *and* direct serum bilirubin levels and, if elevated, evaluation for possible hemolytic or primary hepatic diseases, and (2) follow-up should be provided within 2-3 days of discharge to all neonates discharged earlier than 48 hours after birth. Early follow-up is particularly important for infants <38 weeks of gestation. The timing of follow-up depends on the age at discharge and the presence of risk factors. In some cases, follow-up within 24 hours is necessary. Postdischarge follow-up is essential for early recognition of problems related to hyperbilirubinemia and disease progression. Parental communication with regard to concerns about the infant's skin color and behavioral activities should be addressed early and frequently, including education about potential risks and neurotoxicity. Ongoing lactation promotion, education, support, and follow-up services are essential throughout the neonatal period. Parents should be advised to nurse their infants 8-12 times in 24 hours and to avoid supplementation with water or glucose water to ensure adequate hydration and caloric intake.

TREATMENT OF HYPERBILIRUBINEMIA

Regardless of the cause, the goal of therapy is to prevent neurotoxicity related to indirect-reacting bilirubin while causing no undue harm. Phototherapy and, if unsuccessful, exchange transfusion remain the primary treatment modalities used to keep the maximal total serum bilirubin below pathologic levels (Table 137.6; see Figs. 137.6 and 137.7). The risk of injury to the central nervous system from bilirubin must be balanced against the potential risk of treatment. Because phototherapy may require 6-12 hours to have a measurable effect, it must be started at bilirubin levels below those indicated for exchange transfusion. When identified, underlying



Phototherapy threshold minus TcB or TSDB		Discharge recommendations
0.1-1.9 mg/dL	Age <24 hours	Delay discharge, consider phototherapy, measure TSB in 4 to 8 hours
	Age ≥24 hours	Measure TSB in 4 to 24 hours[a] Options: • Delay discharge and consider phototherapy • Discharge with home phototherapy if all considerations in the guideline are met • Discharge without phototherapy but with close follow-up
2.0-3.4 mg/dL	Regardless of age or discharge time	TSB or TcB in 4 to 24 hours[a]
3.5-5.4 mg/dL	Regardless of age or discharge time	TSB or TcB in 1-2 days
5.5-6.9 mg/dL	Discharging <72 hours	Follow-up within 2 days; TcB or TSB according to clinical judgment[b]
	Discharging ≥72 hours	Clinical judgment[b]
≥7.0 mg/dL	Discharging <72 hours	Follow-up within 3 days; TcB or TSB according to clinical judgment[b]
	Discharging ≥72 hours	Clinical judgment[b]

Fig. 137.5 Algorithm to determine postdischarge follow-up for infants who have not received phototherapy during the birth hospitalization. [a]Use clinical judgment and shared decision-making to determine when to repeat the bilirubin measure within this 4–24-hour time window. [b]Clinical judgment decisions should include physical examination, the presence of risk factors for the development of hyperbilirubinemia or hyperbilirubinemia neurotoxicity risk factors, feeding adequacy, weight trajectory, and family support. TcB, Transcutaneous bilirubin; TSB, total serum bilirubin. *(From Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2022; 150[3]:e2022058859. Fig. 7.)*

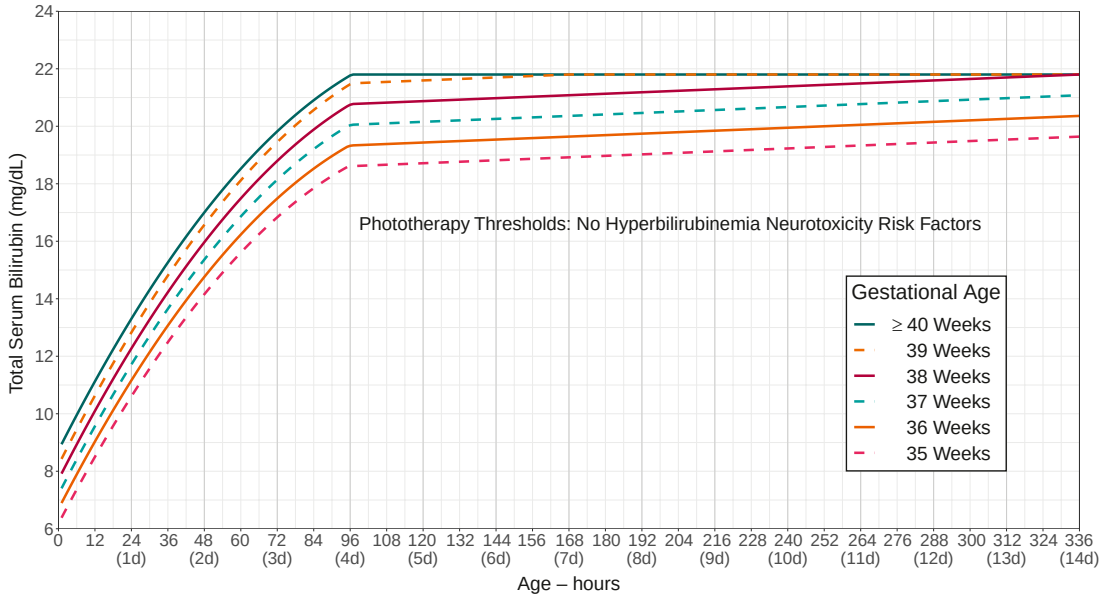


Fig. 137.6 Phototherapy thresholds by gestational age and age in hours for infants with no recognized hyperbilirubinemia neurotoxicity risk factors other than gestational age. These thresholds are based on expert opinion rather than strong evidence on when the potential benefits of phototherapy exceed its potential harms. Use total serum bilirubin concentrations; do not subtract direct-reacting or conjugated bilirubin from the total serum bilirubin. In rare cases of severe hyperbilirubinemia in which the direct-reacting or conjugated bilirubin exceeds 50% of the TSB, consult an expert. Note that infants <24 hours old with a TSB at or above the phototherapy threshold are likely to have a hemolytic process and should be evaluated for hemolytic disease. Hyperbilirubinemia neurotoxicity risk factors include gestational age <38 weeks; albumin <3.0 g/dL; isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, or other hemolytic conditions; sepsis; or any significant clinical instability in the previous 24 hours. *(From Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2022;150[3]:e2022058859. Fig. 2.)*

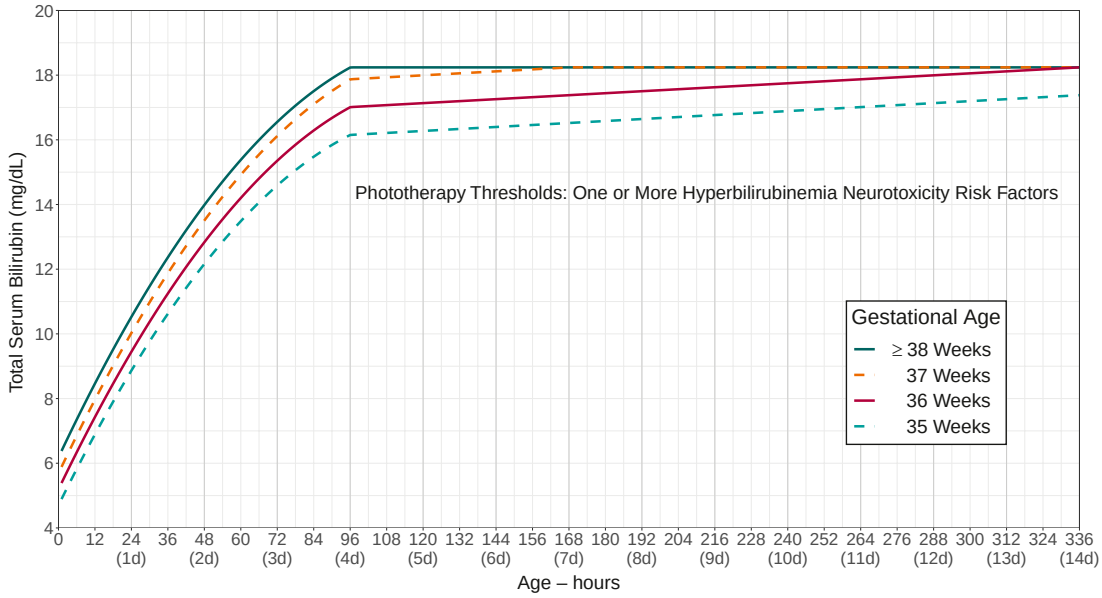

Fig. 137.7 Phototherapy thresholds by gestational age and age in hours for infants with any recognized hyperbilirubinemia neurotoxicity risk factors other than gestational age. These thresholds are based on expert opinion rather than strong evidence on when the potential benefits of phototherapy exceed its potential harms. Use total serum bilirubin concentrations; do not subtract the direct-reacting or conjugated bilirubin from the total serum bilirubin. medical causes of elevated bilirubin and physiologic factors that contribute to neuronal susceptibility should be treated, such as antibiotics for sepsis, correction of acidosis, and dehydration (Fig. 137.8).

Phototherapy

Clinical jaundice and indirect hyperbilirubinemia are reduced by exposure to high-intensity light in the visible spectrum. Bilirubin absorbs light maximally in the blue range (420-470 nm). Broad-spectrum white, blue, and special narrow-spectrum (super) blue lights have been effective in reducing bilirubin levels. Bilirubin in the skin absorbs light energy, causing several photochemical reactions. One major product from phototherapy is a result of a reversible photoisomerization reaction converting the toxic native unconjugated 4Z,15Z-bilirubin into an unconjugated configurational isomer, 4Z,15E-bilirubin, which can then be excreted in bile without conjugation. The other major product from phototherapy is lumirubin, which is an irreversible structural isomer converted from native bilirubin that can be excreted by the kidneys in the unconjugated state.

The therapeutic effect of phototherapy depends on the light energy emitted in the effective range of wavelengths, the distance between the lights and the infant, and the surface area of exposed skin, as well as the rate of hemolysis and in vivo metabolism and excretion of bilirubin. Available commercial phototherapy units vary considerably in spectral output and the intensity of radiance emitted; therefore the wattage can be accurately measured only at the patient's skin surface. Dark skin does not reduce the efficacy of phototherapy. Maximal intensive phototherapy should be used when indirect bilirubin levels approach those noted in Figures 137.6 and 137.7. Such therapy includes using LED lamps and/or putting a fiberoptic phototherapy blanket under the infant's back to increase the exposed surface area.

The use of phototherapy has decreased the need for exchange transfusion in term and preterm infants with hemolytic *and* nonhemolytic jaundice. When indications for exchange transfusion are present, phototherapy should not be used as a substitute; however, phototherapy may reduce the need for repeated exchange transfusions in infants with hemolysis. Conventional phototherapy is applied continuously (except for breastfeeding). It should be discontinued as soon as the indirect bilirubin concentration has reduced to levels considered safe with respect to the infant's age and condition. Serum bilirubin levels and hematocrit should be monitored every 4-8 hours in infants with hemolytic disease and those with bilirubin levels near toxic range. Serum bilirubin monitoring should continue for at least 24 hours after cessation of phototherapy in *patients with hemolytic disease*, because unexpected rises in bilirubin may occur, requiring further treatment. Skin color, visual assessment, or transcutaneous bilirubin levels cannot be relied on for evaluating the effectiveness of phototherapy; the skin of babies exposed to light may appear to be almost without jaundice in the presence of marked hyperbilirubinemia. Although not necessary for *all* affected infants, intravenous fluid supplementation added to oral feedings are beneficial in dehydrated patients or infants with bilirubin levels nearing those requiring exchange transfusion.

Complications associated with phototherapy include loose stools, erythematous macular rash, purpuric rash associated with transient porphyrinemia, hypothermia from exposure, and a benign condition called "bronze baby syndrome," which occurs in the presence of direct hyperbilirubinemia. Phototherapy is contraindicated in the presence of porphyria. Before phototherapy is initiated, the infant's eyes should be closed and adequately covered to prevent light exposure and corneal damage. Body temperature should be monitored, and the infant should be shielded from bulb breakage and fluorescent bulb use. Irradiance should be measured directly. In infants with hemolytic disease, care must be taken to monitor for the development

Table 137.6 Suggested Maximal Indirect Serum Bilirubin Concentrations (mg/dL) in Preterm Infants

BIRTHWEIGHT (g)	UNCOMPLICATED*	COMPLICATED*
<1,000	12-13	10-12
1,000-1,250	12-14	10-12
1,251-1,499	14-16	12-14
1,500-1,999	16-20	15-17
2,000-2,500	20-22	18-20

*Complications include perinatal asphyxia, acidosis, hypoxia, hypothermia, hypoalbuminemia, meningitis, intraventricular hemorrhage, hemolysis, hypoglycemia, or signs of kernicterus. Phototherapy is usually started at 50–70% of the maximal indirect level. If values greatly exceed this level, if phototherapy is unsuccessful in reducing the maximal bilirubin level, or if signs of kernicterus are evident, exchange transfusion is indicated.

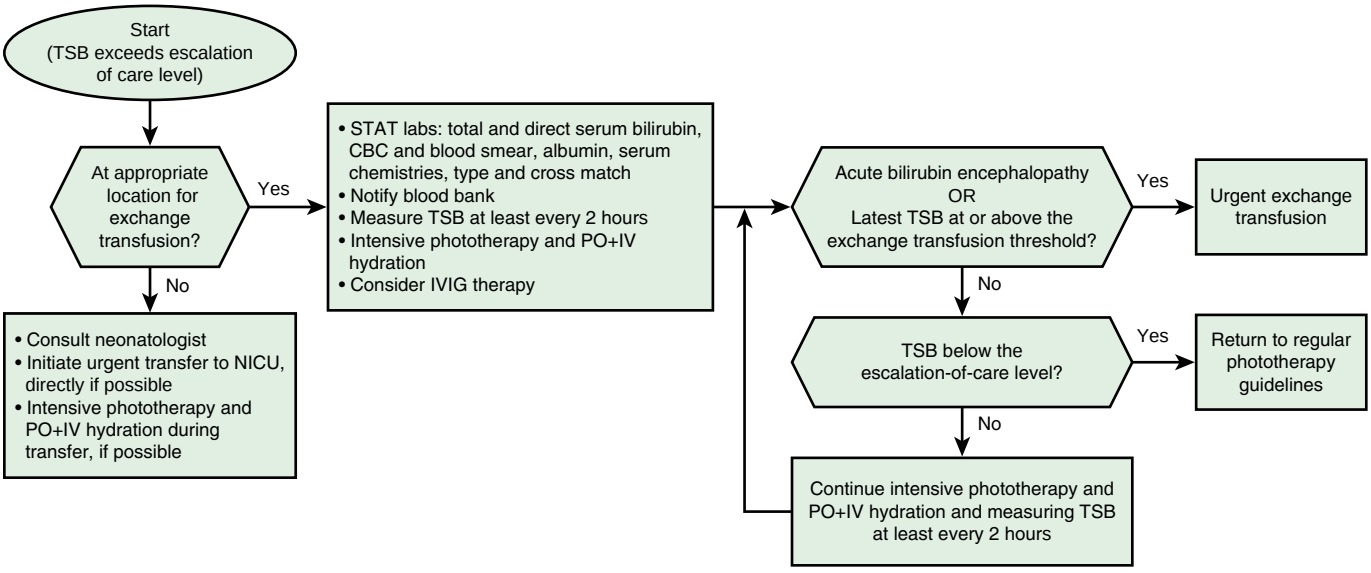

Fig. 137.8 Approach to escalation of care. The escalation-of-care threshold is 2 mg/dL below the exchange transfusion threshold. IVIG, Intravenous immunoglobulin; NICU, neonatal intensive care unit; PO, orally; TSB, total serum bilirubin. *(Modified from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2022;150[3]:e2022058859. Fig. 4.)*

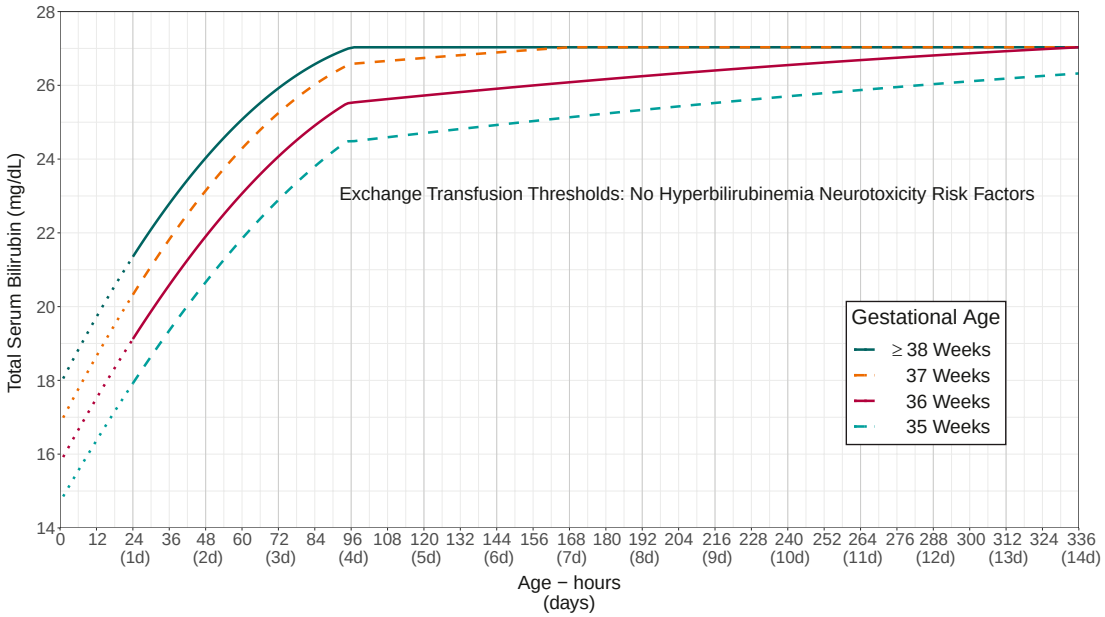

Fig. 137.9 Exchange transfusion thresholds by gestational age for infants with no recognized hyperbilirubinemia neurotoxicity risk factors other than gestational age. These thresholds are based on expert opinion rather than strong evidence on when the potential benefits of escalation of care exceed its potential harms. The stippled lines for the first 24 hours indicate uncertainty because of the wide range of clinical circumstances and responses to intensive phototherapy. Use total serum bilirubin concentrations; do not subtract direct bilirubin from the total serum bilirubin. In rare cases of severe hyperbilirubinemia in which the direct-reacting or conjugated bilirubin exceeds 50% of the TSB, consult an expert. Hyperbilirubinemia neurotoxicity risk factors include albumin <3.0 g/dL; isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, or other hemolytic conditions; sepsis; or any significant clinical instability in the previous 24 hours. *(From Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2022;150[3]:e2022058859. Fig. 5.)*

of anemia, which may require transfusion; *anemia may develop despite lowering of bilirubin levels.* Clinical experience suggests that long-term adverse biologic effects of phototherapy are absent, minimal, or unrecognized.

The term **bronze baby syndrome** refers to a dark, grayish brown skin discoloration sometimes noted in infants undergoing phototherapy. Almost all infants observed with this syndrome have had significant elevation of direct-reacting bilirubin and other evidence of obstructive liver disease. The discoloration may result from photo-induced modification of porphyrins, which are often present during cholestatic jaundice and may last for many months. Despite the bronze baby syndrome, phototherapy can continue if needed.

Intravenous Immunoglobulin

The administration of intravenous immunoglobulin (IVIG) is an adjunctive treatment for hyperbilirubinemia caused by *isoimmune hemolytic disease*. It has been used when serum bilirubin is approaching exchange levels despite maximal interventions, including phototherapy. IVIG (0.5-1.0 g/kg/dose; repeat in 12 hours) may reduce the need for exchange transfusion in both ABO and Rh hemolytic disease, presumably by reducing hemolysis. The effectiveness is unclear.

Exchange Transfusion

Double-volume exchange transfusion is performed if intensive phototherapy has failed to reduce bilirubin levels to a safe range and the risk of kernicterus exceeds the procedural risk. Potential complications from exchange transfusion are not trivial and include metabolic acidosis, electrolyte abnormalities, hypoglycemia, hypocalcemia, thrombocytopenia, volume overload, arrhythmias, necrotizing enterocolitis (NEC), infection, graft versus host disease, and death. This widely accepted treatment is repeated if necessary to keep indirect bilirubin levels in a safe range (Fig. 137.9). Ideally the exchange transfusion should be performed with leukocyte-depleted, washed fresh-packed RBC's, reconstructed with fresh-frozen plasma to a hematocrit of ~40%. It should be cross matched against the neonate and the mother.

Various factors may influence the decision to perform a double-volume exchange transfusion in an individual patient (see Fig. 137.8). The appearance of clinical signs suggesting kernicterus is an absolute indication for exchange transfusion at any level of serum bilirubin. A hydropic jaundiced neonate with erythroblastosis from Rh disease will be critically ill and requires exchange transfusion at much lower levels than recommended in Figures 137.9 and 137.10. See other risk factors affecting exchange transfusion threshold in Figure 137.10.

A healthy full-term infant with physiologic or breast milk jaundice may tolerate a bilirubin concentration slightly higher than 25 mg/dL with no apparent ill effect, whereas kernicterus may develop in a sick premature infant at a significantly lower level. A level approaching that considered critical for the individual infant may be an indication for exchange transfusion during the first or second day after birth, when a further rise is anticipated, but not typically after the fourth day in a term infant or after the seventh day in a preterm infant, because an imminent decrease in bilirubin levels may be anticipated as the hepatic conjugating mechanism becomes more effective.

Chapter 138

Blood Disorders

Christopher S. Thom and Michele P. Lambert

NORMAL ERYTHROPOIESIS AND HEMOGLOBIN FUNCTIONS

The diagnosis of anemia or polycythemia, and interpretation of laboratory values, requires understanding normal hemoglobin-oxygen binding and delivery physiology. Heterotetrameric **hemoglobin**, comprising two α-globin and two β-globin monomers, has an exquisite ability to cooperatively bind and release oxygen molecules in response to environmental conditions. Hemoglobin switching refers to the normal transitions in gene expression among embryonic, fetal, and adult globins that occur before and after birth (Fig. 138.1). Fetal hemoglobin (HbF) is the predominant hemoglobin molecule produced during late gestation. Its increased oxygen affinity compared with maternal adult hemoglobin (HbA) facilitates oxygen transfer in the hypoxic in utero environment, which lacks direct atmospheric gas exchange. Relative in utero hypoxia explains the elevated hemoglobin levels normally seen in newborns, which can be exacerbated by pathologic chronic intrauterine hypoxia.

NORMAL RED BLOOD CELL INDICES IN NEONATES AND INFANTS

Diagnosing anemia or polycythemia in infants also relies on comparisons to normal reference ranges, which vary based on gestational and postnatal age. Normal reference ranges for hemoglobin, hematocrit, and other erythrocyte indices are based on measurements from more than 25,000 preterm and term infants through the first 28 days of life (Fig. 138.2). Hemoglobin and hematocrit levels exhibit linear increases between 22 and 40 weeks of gestation.

Erythrocyte mean corpuscular volume (MCV) in neonates is typically higher than toddlers or older children, with normal values ranging from approximately 100-115 fL at birth (see Fig. 138.2C). Reasons for this finding are multifactorial. An elevated MCV can reflect an increase in circulating reticulocytes (immature erythrocytes), although a relative reticulocytosis in neonates is inadequate to fully explain the MCV elevation. Indeed, mature erythrocytes are larger in neonates than in adults. The size discrepancy may be related to the presence of different hemoglobin molecules, as mature erythrocytes containing HbF (termed F cells) may be larger than HbA-containing cells. Conversely, MCV <100 fL in a neonate should prompt suspicion for underlying α-thalassemia/thalassemia trait, maternal iron deficiency, or chronic fetal to maternal blood loss.

At any age, increased MCV can indicate hemolysis or other processes that enhance erythropoietic drive. Persistent microcytic anemia can result from thalassemia or iron deficiency.

Platelet Count Abnormalities in Pediatric Patients

Hematopoiesis, megakaryopoiesis, and thrombopoiesis produce ~10^{11} platelets per day to facilitate normal blood clotting and fulfill important vascular functions (see Chapter 495). Processes that disrupt platelet production or consumption can significantly alter steady-state platelet quantities in circulation. This can be clinically relevant and require intervention, although many etiologies are transient and/or benign. Here we describe common etiologies that increase or decrease platelet counts. Chapter 533 includes a full description of these and other platelet defects.

Thrombocytosis is defined as >450 × 10^9 platelets/L blood, although for neonates this limit can be raised to >600 × 10^9 platelets/L. Thrombocytosis can be stratified from mild to extreme, the latter defined as >1,000 × 10^9

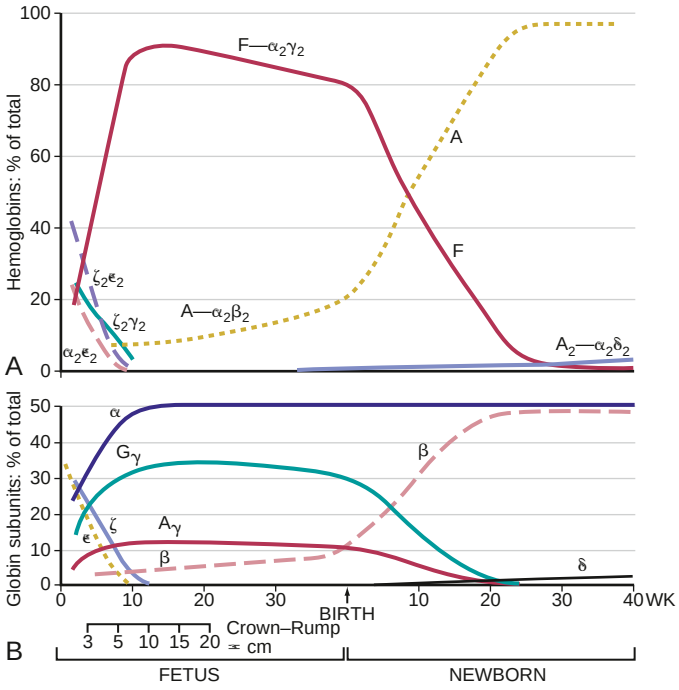

Fig. 138.1 Developmental changes in (**A**) hemoglobin tetramers and (**B**) globin subunit expression from early gestation through infancy. (*From Polin RA, Fox WW. Fetal and Neonatal Physiology. 2nd ed. Philadelphia: Saunders; 1998. p. 1769.*)

platelets/L. Immature immune or hematopoietic systems may underlie an increased rate of thrombocytosis in infants and young children.

Myeloproliferative disorders can cause primary thrombocytosis, but this is rare in children. More often, thrombocytosis reflects a secondary or reactive process as part of an acute phase response. This is usually due to an inflammatory process and does not increase thrombotic risk in children. Extreme thrombocytosis is rare, and it can be more worrisome for infection, iron deficiency, or other inflammatory pathology. However, even extremely elevated platelet counts do not seem to increase risk of hemorrhage or thrombosis. Thus most often, thrombocytosis will resolve spontaneously, or after treatment of the inciting etiology, without adverse sequelae.

Thrombocytopenia is defined as platelets count <150 × 10^9 platelets/L blood. However, increased bleeding risk does not typically occur unless platelet counts decline to <20 × 10^9 platelets/L. Congenital and acquired processes underlie a broad differential diagnosis for thrombocytopenia that is described in Chapter 533. Different immune and nonimmune processes can cause thrombocytopenia at different stages of infancy or later childhood, with wide-ranging health implications.

NEUTROPENIA

White blood cells provide innate and adaptive immune functions. The neutrophil is a key component of innate immune surveillance, and disorders that affect neutrophil number and function can result in varied clinical consequences (see Chapter 168).

Neutropenia is defined as an absolute neutrophil count (ANC) <1,500/μL blood, but typically increases infection risk only when ANC falls <500/μL. Many processes affecting the survival of neutrophils and their precursor cells can cause neutropenia, including situations wherein antineutrophil antibodies increase neutrophil destruction and clearance.

Autoimmune neutropenia results from a patient's own neutrophil-targeted antibodies. It is among the most common etiologies of neutropenia in infants and toddlers, rarely results in significant infections or complications, and generally resolves by the time the child is school age. Neonatal isoimmune neutropenia results from transplacental passage of maternal antineutrophil antibodies in a process akin to red blood cell (RBC) antigen-targeted antibodies in hemolytic disease of the fetus and newborn (see Chapter 140). Importantly, these scenarios do not typically incur additional infection risks for patients. In fact, they are typically diagnosed incidentally after noting abnormalities on a complete blood count obtained for other reasons. Reassurance, with or without repeat laboratory testing, is typically all that is required. Counts will virtually always normalize spontaneously.

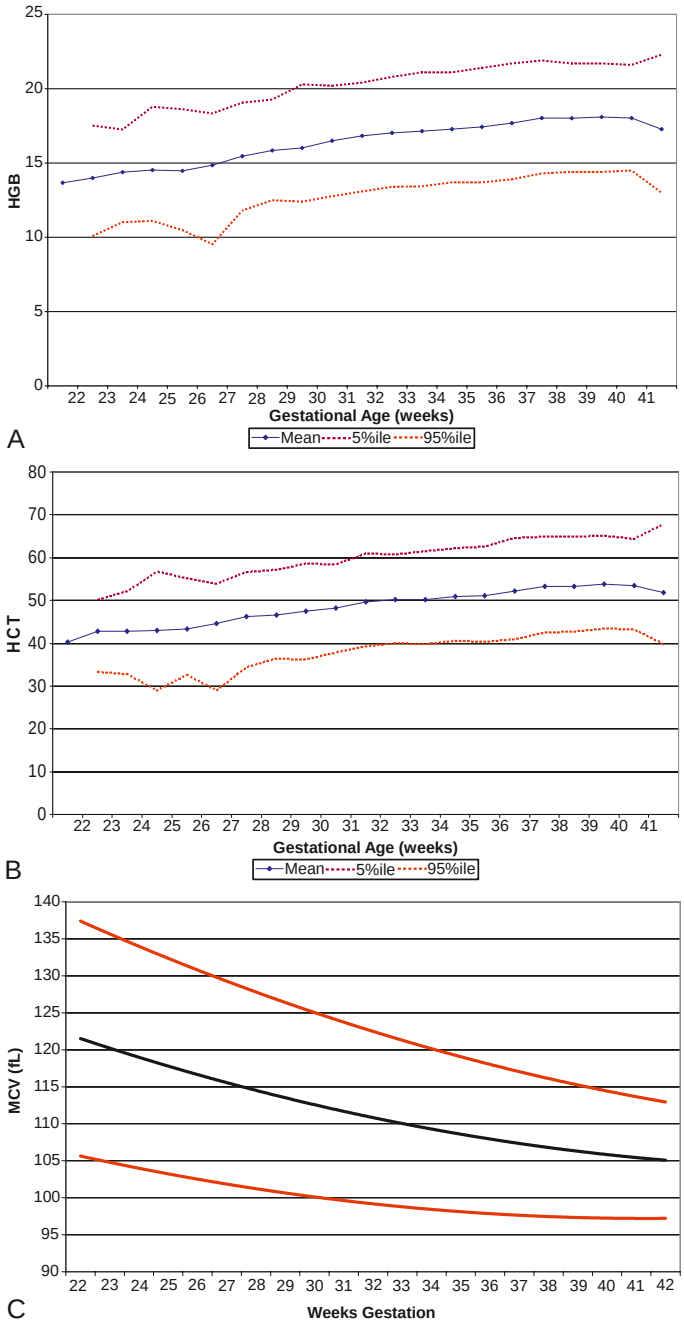

Fig. 138.2 Reference range for hematocrit (HCT) and hemoglobin (HGB) concentration according to gestational age. **A** and **B**, Reference ranges (5th percentile, mean, and 95th percentile) are shown for blood HGB (**A**) and HCT (**B**). Concentrations were obtained during the first 6 hours after birth, among patients at 22-42 weeks of gestation. Values were excluded if the diagnosis included abruption, placenta previa, or known fetal anemia, or if a blood transfusion was given before the first HGB was measured. **C**, Reference ranges for mean corpuscular volume (MCV) in neonates on first day after birth. The *lower line* shows the 5th percentile values, the *middle line* shows the mean values, and the *upper line* shows the 95th percentile values. Chapter 139

Anemia in the Newborn Infant

Christopher S. Thom and Michele P. Lambert

Anemia is extremely common worldwide, affecting an estimated 25% of the global population, and carries a broad differential diagnosis in infants and children. Etiologies may be acute or chronic, with clinical manifestations ranging from an asymptomatic laboratory finding to life-threatening signs and symptoms. Because anemia can result from decreased erythrocyte production, increased erythrocyte destruction, erythrocyte dysfunction, or blood loss, the differential diagnosis of anemia can be complex (Table 139.1). Careful consideration of details related to the patient's history and presentation can facilitate rapid diagnosis. Additional relevant details in neonates include gestational age and general health, perinatal course and delivery, and maternal health from early pregnancy through delivery and the postpartum period.

THE PHYSIOLOGIC NADIR DURING INFANCY

An abrupt increase in oxygen tension and arterial hemoglobin saturation, a shift in the oxygen dissociation curve due to a switch from high oxygen affinity fetal hemoglobin (HbF) to low oxygen affinity adult hemoglobin (HbA), increased postnatal 2,3-diphosphoglycerate (increasing oxygen delivery through cooperativity), and adaptive cardiovascular mechanisms all contribute to increased oxygen delivery to tissues and can rapidly reduce erythropoietin levels postnatally. These mechanisms result in reduced erythropoiesis in the bone marrow after a week of life. Combined with the shorter half-life of neonatal erythrocytes compared to adult erythrocytes (60 days vs 120 days), full-term infants normally experience a slow decline in hemoglobin to 9-11 g/dL over 6-10 weeks (Fig. 139.1). Eventually, the reduction in hemoglobin concentration reduces oxygen delivery enough to stimulate erythropoietic drive, and hemoglobin levels subsequently rebound to "normal" levels for later life (see Fig. 139.1). These typical developmental and physiologic processes culminating in a decreased hemoglobin level are termed the **physiologic nadir**.

Preterm infants experience a more pronounced, earlier nadir, with hemoglobin levels falling to 8-9 g/dL over 4-8 weeks. One reason for the more dramatic nadir in preterm infants is reduced iron stores, because most iron is normally transferred to the fetus during the third trimester. The nadir in preterm infants is also a consequence of a reduced starting hemoglobin at birth; iatrogenic blood loss; and more significant cardiorespiratory disease, inadequate nutrition, and infections. Still, a hemoglobin level <8 typically prompts a transfusion and/or hematologist consultation.

Normal physiologic changes in hemoglobin concentration should be considered when diagnosing anemia in neonates and early infants. For example, a neonate may be considered anemic if the hemoglobin level declines below the 5th percentile for age (see Fig. 139.1, lower dashed lines). *Interventions should occur only in response to clinical signs and symptoms that occur as disease sequelae with referral to subspecialty care for further evaluation and management as appropriate.*

ANEMIA CLASSIFICATIONS AND KEY DIAGNOSTIC MODALITIES

Anemia can result from blood loss, erythrocyte destruction (hemolysis), or underproduction of erythrocytes. Common etiologies are summarized in Table 139.1. In many cases, the clinical context, physical examination, and medical history, including review of the patient's history and clinical course, can be diagnostic. However, a simple and efficient laboratory workup can facilitate rapid definitive diagnosis and suggest an effective treatment strategy (Fig. 139.2).

In many cases, a CBC and the reticulocyte count can identify the diagnosis. Additional testing that is particularly helpful in neonatal diagnosis includes a direct antiglobulin test, serum bilirubin, infant blood type, and maternal blood type (ABO and Rh). Prenatal screening routinely includes indirect (serum) antiglobulin testing for maternal erythrocyte alloantibodies. The infant's peripheral blood smear can identify nucleated erythrocytes secondary to compensatory active erythropoiesis, as well as distinct erythrocyte morphologies (e.g., elliptocytes, acanthocytes) reflecting hemolytic anemia. Spherocytes and microspherocytes can suggest immune-mediated hemolysis or hereditary spherocytosis (HS), which can be differentiated by the direct antiglobulin test (DAT; formerly the direct Coombs test; Fig. 139.3). Importantly, neonatal blood smears often include atypical erythrocyte morphology with macrocytosis, poikilocytosis, and anisocytosis, which can result from normal erythropoiesis at that age and preclude definitive diagnosis. An experienced hematology-pathologist is needed to identify truly pathologic features (Table 139.2; see Chapter 496).

Specialized testing to diagnose various red cell membrane disorders and enzyme deficiencies, as well as hemoglobin quantitation for evaluation for specific hemoglobin disorders, may be performed in consultation with a specialist. Some states routinely screen newborns for glucose-6-phosphate-dehydrogenase (G6PD) deficiency. Further, universal screening in the United States for sickle cell disease has markedly improved health outcomes by facilitating early penicillin prophylaxis, although much work remains to be done.

Inadequate Red Blood Cell Production

Whereas normal RBC underproduction after birth results in the **physiologic nadir**, this process can be more significant in preterm infants, requiring transfusions and other supportive therapy. **Anemia of prematurity** is largely due to iatrogenic losses (phlebotomy) and is exacerbated by acute or chronic illness, comorbidities of prematurity, and decreased iron stores.

Iron-deficiency anemia is the most common cause of anemia worldwide, and can occur during infancy or in older children. Iron is required

Table 139.1 Differential Diagnosis of Neonatal Anemia

BLOOD LOSS	↑ RBC DESTRUCTION	↓ RBC PRODUCTION
• Iatrogenic blood loss (phlebotomy) • Placental hemorrhage • Placental previa • Injury of umbilical or placental vessels • Fetomaternal transfusion • Fetoplacental transfusion • Twin-twin transfusion • Acute perinatal hemorrhage (e.g., cesarean birth, other obstetric trauma) • Chronic in utero blood loss	*Immune-Mediated Hemolysis* • Rh incompatibility • ABO incompatibility • Minor antigen incompatibility *RBC Membrane Disorders* • Hereditary spherocytosis • Hereditary elliptocytosis • Hereditary pyropoikilocytosis • Hereditary stomatocytosis *RBC Enzyme Disorders* • G6PD deficiency • Pyruvate kinase deficiency	• Physiologic anemia and anemia of prematurity • Infection (rubella, CMV, parvovirus B19) • Bone marrow suppression (acute stress in perinatal period) • Hemoglobinopathy (γ-globin mutation, unstable β-hemoglobinopathy, α-thalassemia major) • Bone marrow suppression (CMV, EBV) • Diamond-Blackfan anemia • Schwachman-Diamond syndrome • Congenital dyserythropoietic anemia • Fanconi anemia • Pearson syndrome • Congenital leukemia

CMV, Cytomegalovirus, EBV, Epstein-Barr virus; G6PD, glucose-6-phosphate dehydrogenase.

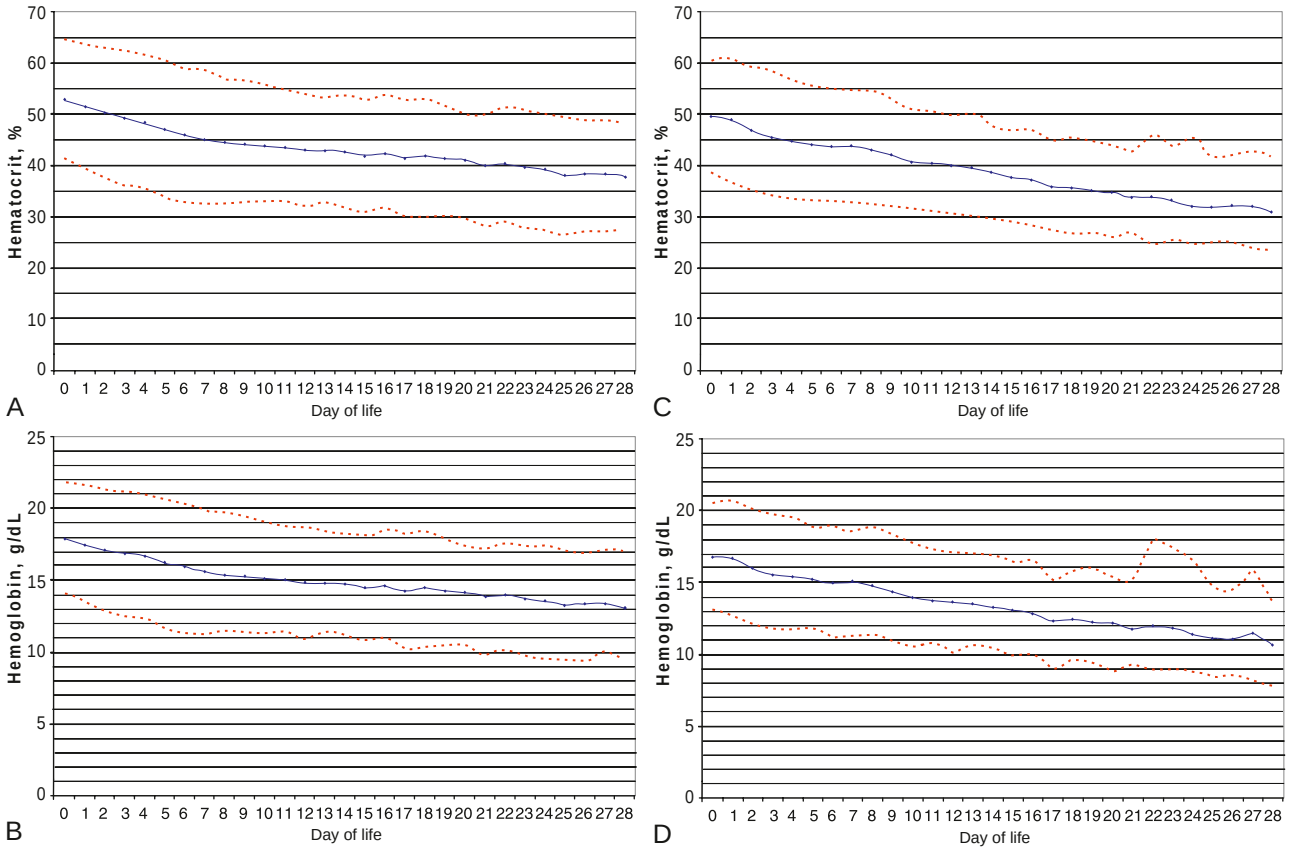

Fig. 139.1 Reference range for hematocrit and hemoglobin concentration during the first 28 days of life. **A** and **B**, Late preterm and term infants (35-42 weeks' gestation). **C** and **D**, Preterm infants (29-34 weeks' gestation). The reference ranges are shown for hematocrit (**A** and **C**) (41,957 patients) and blood hemoglobin (**B** and **D**) (39,559 patients) during the 28 days after birth. Values were divided into two groups (A/B and C/D) on the basis of gestational age at delivery. Patients were excluded when their diagnosis included abruption, placenta previa, or fetal anemia, or when a blood transfusion was given. Analysis was not possible for patients <29 weeks' gestation because virtually all these had repeated phlebotomy and erythrocyte transfusions. (*From Jopling J, Henry E, Wiedmeier SE, Christensen RD. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period: data from a multihospital health care system. Pediatrics. 2009;123[2]:e333–e337.*)

for hemoglobin tetramer construction, so erythropoiesis demands ample iron be present to form hemoglobinized RBCs. Insufficient iron stores, either through chronic blood loss or inadequate iron intake, hinder erythropoiesis. RBCs will be uniformly microcytic (mean corpuscular volume [MCV] <80 fL) and hypochromic on the blood smear. Ferritin, transferrin, and reticulocyte quantities will be low. In addition to anemia, iron deficiency predisposes to thrombocytosis. This is a result of effects on hematopoietic progenitor cell lineage commitment, among potential mechanisms. Iron supplementation at doses of 3-6 mg/kg/day can effectively treat this condition; once-daily treatment is better than divided doses due to potential induction of hepcidin with frequent iron supplementation.

Acquired conditions may also suppress bone marrow erythrocyte production in neonates and older children (Table 139.3). Numerous bacterial and viral infections may suppress erythropoiesis and contribute to anemia, from prenatal TORCH (toxoplasmosis, other viral agents, rubella, cytomegalovirus [CMV], herpes simplex) infections and parvovirus B19 to sepsis. Congenital conditions may result in anemia due to decreased red cell production. These rare disorders may manifest early in the neonatal period, but more commonly present in later infancy or early childhood. Etiologies include the bone marrow failure syndromes (Fanconi anemia, Schwachman-Diamond syndrome, Diamond-Blackfan anemia, Aase syndrome congenital dyserythropoietic anemia, dyskeratosis congenita, Pearson syndrome), the thalassemias (α, β, or HbE), and infant leukemias, among others (see Tables 139.1 and 139.3).

Increased Red Cell Destruction: The Hemolytic Anemias

Increased rates of RBC destruction cause hemolytic anemia. This most often occurs via immune-mediated mechanisms, when RBC antigen incompatibilities exist between infants and mothers, or as a result of autoimmune disease in later childhood. However, intrinsic abnormalities in the erythrocyte membrane, hemoglobin, or other enzymes can also increase hemolysis. Severe hemolytic anemias can cause hyperbilirubinemia necessitating intervention (Fig. 139.4). For example**, hemolytic disease of the fetus and newborn (HDFN),** also known as erythroblastosis fetalis, results in often severe alloimmune hemolysis from maternal antibodies targeting paternally derived RBC antigens (see Chapter 140).

Congenital erythrocyte membrane disorders can cause clinically significant hemolytic anemia and jaundice in the neonatal period and beyond. Key structural proteins and lipid components are necessary to produce durable, flexible, biconcave erythrocyte membranes capable of deforming and squeezing through tiny capillaries. Genetic abnormalities in integral membrane proteins (e.g., ankyrin, band 3, α-spectrin, β-spectrin, protein 4.2) destabilize the RBC membrane and decrease cellular deformability, increasing splenic entrapment. HS is the most common RBC membrane disorder, affecting 1 in 2,500-5,000 individuals of European descent. HS is most often caused by pathogenic variants in genes coding for ankyrin or spectrin and is characterized by spherical erythrocytes on the blood smear (see Fig. 139.3; see Chapter 507). Most infants born with HS will develop jaundice early in the newborn period. *Treatment is largely supportive. Most patients with mild disease require little intervention, whereas those with more severe hemolysis sometimes require RBC transfusions or splenectomy.* Hereditary elliptocytosis (HE), another erythrocyte membranopathy, is typically less severe than HS. HE is characterized by elliptical-shaped erythrocytes on the peripheral blood smear and may be underdiagnosed given the extremely mild clinical presentation.

A more clinically significant membranopathy is hereditary pyropoikilocytosis (HPP), an autosomal recessive disorder with striking dysmorphology (poikilocytosis) on the peripheral blood smear. HPP is most common

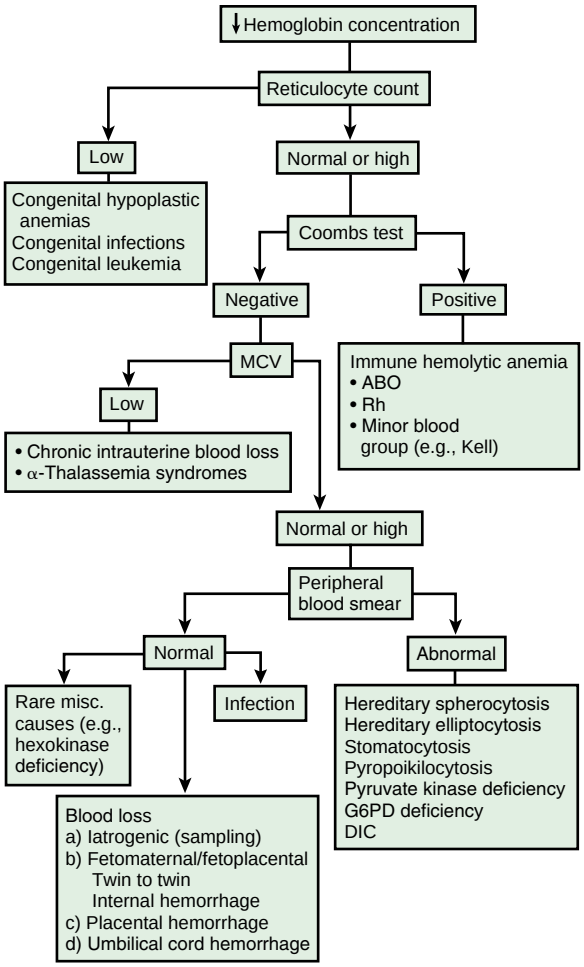

Fig. 139.2 Diagnostic algorithm showing the approach to anemia in newborn infants. DIC, Disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; MCV, mean corpuscular volume. Fig. 139.3 Microspherocytes. **A,** Neonate with ABO hemolytic disease. **B,** Neonate with hereditary spherocytosis. (*From Christensen RD. Neonatal erythrocyte disorders. In Gleason CA, Juul SE, eds. Avery's Diseases of the Newborn. 10th ed. Philadelphia: Elsevier; 2018: Fig. 81-8.*)

in infants of African descent and can be associated with severe anemia and hemolysis during infancy and throughout life. There is substantial clinical and genetic overlap between HPP and HE, because infants with HPP often have a family history of HE and may develop a milder condition resembling HE later in childhood (see Chapter 508).

In infants with significant jaundice in the first day of life without a blood type mismatch, a family history of hemolytic anemia should prompt clinical suspicion for an erythrocyte membranopathy. Beyond a negative DAT, diagnostic evaluation should include serial bilirubin and reticulocyte monitoring, along with a peripheral blood smear. Previously, osmotic fragility testing was the only way to establish the diagnosis, but it is significantly impacted by hemoglobin F concentrations. Some laboratories can instead diagnose certain membranopathies by flow cytometry based on binding of eosin-5-maleimide (EMA). Treatment is directed by the degree of anemia and hyperbilirubinemia, which can be highly variable.

Erythrocyte enzymopathies can also cause neonatal anemia. Circulating RBC survival relies on critical metabolic pathways to limit oxidative stress. Inadequate antioxidant systems can result in membrane instability and cell lysis that manifest clinically as hemolytic anemia. For example, G6PD is abundant in RBCs to limit oxidative stress. G6PD deficiency, the most common RBC enzymopathy, is an X-linked disorder affecting >400 million people worldwide. Different classes of G6PD deficiency vary in clinical severity. Although affected individuals are generally asymptomatic, some are prone to develop acute hemolytic anemia in the setting of oxidative stress triggered by sulfa drugs, infections, or certain foods like fava beans. There is an increased incidence of clinically significant jaundice in G6PD deficient neonates, who sometimes have severe and prolonged hyperbilirubinemia that can present in the first few days of life. Although severe anemia with reticulocytosis is uncommon, many infants require increased monitoring or therapy. Newborn screening for G6PD deficiency varies across the United States. G6PD activity can be tested in erythrocytes (<1–2% suggests G6PD deficiency). However, testing may be inaccurate during acute hemolysis or reticulocytosis because, for the most common variants, reticulocytes have higher enzyme activity.

Another common RBC enzymopathy is pyruvate kinase deficiency (PKD), which affects an estimated 3.2-8.5 per million individuals of European descent. Pyruvate kinase is a critical glycolytic enzyme. In its absence, metabolic derangements can cause RBC lysis and hemolytic anemia. Though clinical severity varies, PKD may be associated with sometimes life-threatening complications, prolonged jaundice, and lifelong blood transfusions.

HEMOGLOBINOPATHIES

Hemoglobinopathies result from genetic variants in γ-globin, β-globin, or α-globin genes. The clinical presentation of hemoglobin variants reflects aberrant biochemical properties of the mutated hemoglobin molecule. Individuals can be anemic (most commonly), cyanotic, polycythemic, prone to hemolysis, have high methemoglobin levels, or asymptomatic. Thousands of variants have been identified, with wide-ranging clinical severity.

Hemoglobin variants can also clinically manifest at different times according to when the affected globin chain is produced (see Fig. 138.1). The common β-hemoglobinopathies, sickle cell disease and β-thalassemia, do not typically present in the neonatal period due to protective effects from high HbF levels. In fact, novel therapeutic approaches aim to maintain HbF persistence in sickle cell patients. In contrast, infants with rare γ-globin variants can present with complications in the neonatal period that resolve in the first few months of life as normal gene expression changes to reduce or abrogate γ-globin expression.

Hemorrhage and Red Blood Cell Loss

Blood loss or hemorrhage in utero or in the newborn period can also result in anemia. In fact, iatrogenic or pathologic blood loss is the most common cause of neonatal anemia. For critically ill and/or premature infants in the neonatal intensive care unit (NICU), laboratory monitoring can require phlebotomy of 15–30% of an infant's blood volume every week (~11-22 mL/kg/week). Most other blood loss etiologies occur just before or during delivery, often from placental abruption or fetal hemorrhage (see Table 139.1). Infants can also become anemic from occult gastrointestinal blood losses due to milk protein allergy. Other causes of blood loss are restricted

Table 139.2 Morphologic Abnormalities of Erythrocytes in Neonates with Jaundice

ABNORMAL ERYTHROCYTE MORPHOLOGY	MOST LIKELY CAUSES	SUGGESTED LABORATORY TESTING/FINDINGS	OTHER FEATURES
Microspherocytes	Hereditary spherocytosis	DAT (–) EMA flow (+) Persistent spherocytosis Reticulocytosis	MCHC/MCV elevated (>36, likely >40)
	ABO hemolytic disease	DAT (+) Transient spherocytosis Reticulocytosis	MCHC/MCV normal (<36, likely <34)
Elliptocytes	Hereditary elliptocytosis	DAT (–)	MCHC normal MCV normal
Bite and blister cells	G6PD deficiency Unstable hemoglobin	G6PD enzyme activity Heinz body preparation	Typically affects males, but rarely females are also affected Ethnicity of equatorial origin
Echinocytes	PK deficiency Other glycolytic enzyme deficiency	PK enzyme activity Quantify activity of other glycolytic enzymes	Autosomal recessive, likely to have no family history
Schistocytes	DIC and/or perinatal asphyxia	Low levels of FV and FVIII, elevated levels of D-dimers	Low or falling platelet count Normal to high IPF
	Heinz body HA	Positive result of Heinz body preparation	Normal to high MPV DIC, perinatal asphyxia
	ADAMTS-13 deficiency (TTP)	Severely decreased ADAMTS-13 activity (<0.1 U/mL) high levels of LDH	ADAMTS-13 deficiency, early neonatal HUS, and giant hemangiomas all involve platelet consumption from endothelial injury and all have a similar neonatal presentation
	Neonatal hemolytic-uremic syndrome	Acute renal failure	
	Homozygous protein C deficiency	Severely decreased functional protein C activity (<1%)	
	Giant hemangioma	May be internal or external	

DAT, Direct antiglobulin test; DIC, disseminated intravascular coagulation; EMA, eosin 5-maleimide; FV, factor V; FVIII, factor VIII; G6PD, glucose-6-phosphate dehydrogenase; HA, hemolytic anemia; HUS, hemolytic uremic syndrome; IPF, immature platelet fraction; LDH, lactic dehydrogenase; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MPV, mean platelet volume; PK, pyruvate kinase; TTP, thrombotic thrombocytopenic purpura.

to older children, including celiac disease or menstrual bleeding. Diagnosis and treatment of hemorrhage in the newborn period are discussed in Chapter 142.

Fetomaternal hemorrhage (FMH) is caused by abnormal bleeding from fetal to maternal circulation before or during delivery. Although small amounts of FMH can be normal, more substantial pathologic FMH (>30 mL of fetal blood) occurs in 3 per 1,000 births. In comparison, large (>80 mL) or massive (>150 mL) FMH occurs in 0.9 and 0.2 per 1,000 births, respectively. Clinical signs of FMH vary due to differential fetal compensation. Decreased or absent fetal movement is the most common antenatal presentation and should prompt clinical suspicion. Postnatally, infant pallor, tachycardia, hypotension, and poor perfusion can indicate clinically significant anemia.

A standard diagnostic modality for FMH is the Kleihauer-Betke test, which leverages the differential stability of HbF vs HbA on acid exposure to identify fetal erythrocytes in the maternal circulation from a maternal blood smear (Fig. 139.5). However, this test requires technical skill, expert interpretation, and may not be available in a timely manner. Some laboratories now offer flow cytometry–based assays to quantify fetal RBCs in maternal circulation.

ANEMIA MANAGEMENT PRINCIPALS

Red Blood Cell Transfusions

The decision to transfuse packed RBC for anemia depends on the severity of symptoms, the hemoglobin concentration, and the presence of comorbidities that can alter oxygen delivery, such as pulmonary hypertension, bronchopulmonary dysplasia, cyanotic congenital heart disease, or other respiratory pathology. Benefits should be balanced against risks, including volume overload, hemolytic and nonhemolytic reactions, exposure to blood product preservatives and toxins, graft-versus-host reaction, and transfusion-acquired infections such as

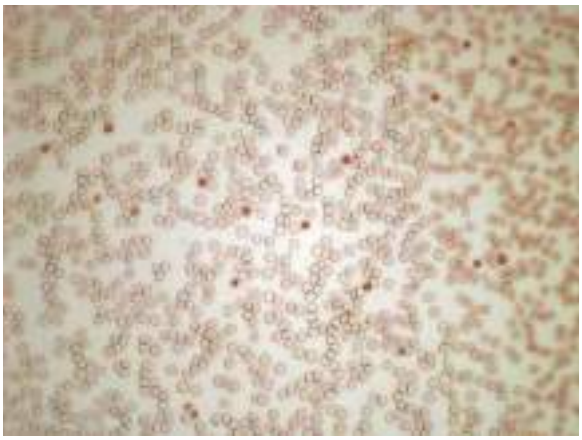

Fig. 139.5 Acid elution technique of Kleihauer (Kleihauer-Betke test). Fetal red blood cells stain with eosin and appear dark. Adult RBCs do not stain and appear as "ghosts." (*From Liley HG, Gardener G, Lopriore E, Smits-Wintjens V. Immune hemolytic disease. In Orkin SH, Nathan DG, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood. 8th ed. Philadelphia: Elsevier; 2015: Fig. 3-2.*)

Table 139.4 Suggested Transfusion Thresholds

	PRESENCE OF RESPIRATORY SUPPORT	ABSENCE OF RESPIRATORY SUPPORT
POSTNATAL AGE	HEMOGLOBIN CONCENTRATION g/dL (HEMATOCRIT %)	
Week 1	11.0 (33%)	10.0 (30%)
Week 2	10.0 (30%)	8.5 (25%)
Week 3	8.5 (25%)	7.0 (21%)

Values based on thresholds described in Kirpalani H, Bell EF, Hintz SR, et al. Higher or lower hemoglobin transfusion thresholds for preterm infants. *N Engl J Med.* 2020;383(27):2639–2651.

CMV, HIV, parvovirus, hepatitis B, and hepatitis C (see Chapter 523). Transfusion decisions should also consider the time course in which anemia developed, whether ongoing blood loss or hemolysis are anticipated, and if there are any planned surgical interventions.

Many neonates in the NICU require RBC transfusions, particularly among premature and very low birthweight (VLBW) infants. Several trials to compare restrictive (lower) to liberal (higher) transfusion thresholds have shown no significant differences in death or serious morbidity, with restrictive thresholds modestly reducing blood product exposure. These studies provide the basis for neonatal transfusion guidelines based on postnatal age and respiratory support needs (Table 139.4). *In full-term anemic infants, RBC transfusions should be similarly based on hemodynamic stability, respiratory status, clinical status, and expected clinical trajectory.*

To reduce blood product-associated CMV transmission to vulnerable infants, it is important that transfused RBCs are leukocyte reduced or CMV seronegative. There remains a small risk of transfusion-associated graft versus host disease even after RBC irradiation. Although data do not support specific transfusion volumes, the typical range is from 10-20 mL/kg. Infants at risk of volume overload, including neonates with congenital cardiac disease or who were born in the setting of chronic abruption, are typically given smaller volume transfusions (often 5 mL/kg). *One logical goal of RBC transfusions is to target a specific goal hemoglobin concentration.* Each 5 mL/kg of transfused RBCs is expected to raise the hemoglobin concentration by 1 g/dL.

Transfusion of RBCs is typically delivered at a rate of 3-5 mL/kg/hr, with a slower rate preferred for very small, acutely ill infants with a tenuous fluid status. Each transfusion should be completed within 4 hours, or before a given blood product expires.

Chapter 140

Hemolytic Disease of the Fetus and Newborn

Christopher S. Thom and Michele P. Lambert

Hemolytic disease of the fetus and newborn (HDFN), also known as **erythroblastosis fetalis**, is a broad diagnosis that applies to any fetus or neonate who develops alloimmune hemolysis caused by the transplacental passage of maternal antibodies directed against paternally derived red blood cell (RBC) antigens. Although more than 60 different RBC antigens can elicit a maternal antibody response, clinically significant disease is most often associated with incompatibility in ABO blood groups or rhesus (Rh) antigen (Table 140.1). HDFN caused by anti-RhD antibodies, occurring in RhD-positive infants born to RhD-negative mothers, is the most severe form because of the highly immunogenic nature of the RhD antigen. Less frequently, hemolytic disease may be caused by differences in other Rh system antigens, or by other RBC antigens such as C^W, C^X, D^U, K (Kell), M, Duffy, S, P, MNS, Xg, Lutheran, Diego, and Kidd. *Early recognition and diagnosis facilitate timely interventions to prevent adverse sequelae.*

HDFN CAUSED BY Rh INCOMPATIBILITY

Pathogenesis

Rh antigenic determinants are genetically transmitted from each parent and determine Rh blood type by directing the production of Rh C, c, D, E, or e proteins to be expressed on the RBC surface. RhD alloimmunization is responsible for 90% of HDFN cases involving the Rh antigen system, but other Rh antigens, particularly E and c, can be causal. Rh sensitization usually occurs in the first pregnancy when small amounts of blood (usually >1 mL) enter maternal circulation so that most instances of sensitization occur around the time of delivery. Although sensitization may occur earlier in the first pregnancy resulting in some hemolysis, HDFN rarely occurs during a first pregnancy. After sensitization, smaller doses of antigen can stimulate antibody production, so all subsequent infants expressing the cognate antigen are at risk for HDFN. For this reason, the severity of HDFN also typically worsens with successive pregnancies. *Routine administration of Rh immunoglobulin (RhoGAM) to mothers at risk for Rh alloimmunization, both at 28 and 32 weeks' gestation and within 72 hours after delivery of Rh-positive infants, has reduced initial sensitization to an estimated <0.1% of at-risk pregnancies in high-income countries.*

Clinical Manifestations

The severity of HDFN is variable, ranging from mild hemolysis without overt symptoms to severe anemia with compensatory hyperplasia of erythropoietic tissues, including massive hepatosplenomegaly. When hemolysis exceeds the compensatory regenerative capacity of the hematopoietic system, profound anemia, thrombocytopenia, coagulopathy, cardiomegaly, respiratory distress, massive anasarca, and circulatory collapse can result. Perinatal hemoglobin concentrations may be as low as 3-4 g/dL.

HDFN can also cause abnormal fluid collection in two or more fetal compartments (skin, pleura, pericardium, placenta, peritoneum, amniotic fluid), a clinical scenario termed **hydrops fetalis,** which frequently results in significant clinical morbidity or death in utero or shortly after birth. Hydrops results from heart failure along with subsequent hepatic congestion and dysfunction. This leads to reduced serum albumin and loss of intravascular oncotic pressure. Consequent edema can lead to extravascular fluid accumulation in the lungs (pleural effusion), abdomen (ascites), and elsewhere, which can compromise ventilation and lead to a range of life-threatening complications (Fig. 140.1). Hydrops is typically present when the fetal hemoglobin level is <5 g/dL but can occur when hemoglobin levels are between 7 and 9 g/dL. Hydrops does not invariably occur with low hemoglobin concentration, instead depending on the duration of anemia and the gestational age when anemia developed.

Infants affected by HDFN may not be jaundiced at birth because of effective placental clearance of lipid-soluble unconjugated bilirubin. However, in severe cases, bilirubin pigments can stain the amniotic fluid, cord, and vernix. In either case, hyperbilirubinemia is generally evident within 24 hours of birth, as hemolysis overwhelms the infant's bilirubin clearance system. Extremely high levels of unconjugated bilirubin levels present a risk of bilirubin encephalopathy **(kernicterus)**, which is worsened in patients with concomitant hypoxia or acidosis.

Hypoglycemia may further complicate clinical management of infants with severe HDFN. This may be related to islet cell hypertrophy and hyperinsulinism due to growth stimulatory effects of anti-RhD antibodies on the pancreas.

Table 140.1 Etiologies of Hemolytic Disease of the Fetus and Newborn

	Rh	ABO	KELL
BLOOD GROUPS			
Mother	Rh-negative	O (occasionally B)	K1-negative
Infant	Rh-positive (D is most common)	A (sometimes B)	K1-positive
CLINICAL FEATURES			
Occurrence in firstborn	5%	40–50%	Rare
Severity in subsequent pregnancies:	Predictable	Difficult to predict	Somewhat predictable
Stillbirth/hydrops	Frequent (less with Rh-immunoglobulin use)	Rare	10%
Severe anemia	Frequent	Rare	Frequent
Jaundice	Prominent, severe	Mild-moderate	Mild
LABORATORY TESTS			
Direct antiglobulin test (infant)	Positive	Positive or negative	Positive or negative
Reticulocyte count	Elevated	Elevated	Variable
RBC antibodies (mother)	Usually detectable Antibody titers may help predict severity of fetal disease	May not be detectable Antibody titers may not correlate with fetal disease	Usually detectable Antibody titers may not correlate with fetal disease; fetus can be affected at titers lower than for Rh-mediated hemolysis

Fig. 140.1 Hydrops fetalis. Longitudinal sonographic image of the fetus, with ascitic fluid outlining the liver *(large arrow)*. The *small arrow* shows pleural effusion above the diaphragm. *(From Wilkins I: Nonimmune hydrops. In Creasy RK, Resnick R, Iams JD, et al., eds. Creasy & Resnik's Maternal-Fetal Medicine. 7th ed. Philadelphia: Elsevier; 2014: Fig. 37-2.)*

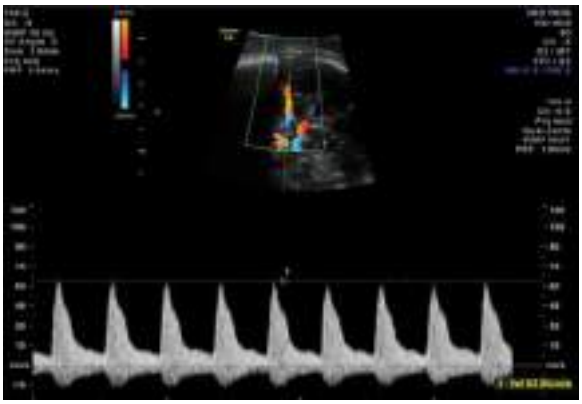

Fig. 140.2 Middle cerebral artery (MCA) Doppler study of elevated peak systolic velocity (PSV). MCA-PSV can predict fetal anemia with sufficient accuracy to determine management, including the need for intrauterine transfusion or, in the mid to late third trimester, early delivery. Fetal hemoglobin is typically measured at the start and end of intravascular transfusion to validate the prediction from MCA-PSV results. The reliability of MCA-PSV can decrease after intrauterine transfusion because of the altered rheostatic characteristics of transfused adult blood. This is now the method of choice for detecting fetal anemia. *(From Liley HG, Gardener G, Lopriore E, Smits-Wintjens V. Immune hemolytic disease. In Orkin SH, Nathan DG, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood. 8th ed. Philadelphia: Elsevier' 2015: Fig. 3-6.)*

Diagnosis, Prevention, and Treatment

Definitive diagnosis of HDFN requires demonstration of blood group incompatibility between mother and infant, and corresponding maternal antibody bound to the infant's RBCs. However, severe clinical presentations strongly suggest the diagnosis. Emergent interventions may be required before definitive test results become available.

During pregnancy, expectant parents should have blood tested for potential blood type incompatibility, including ABO and Rh antigens. If RhD incompatible, maternal anti-RhD IgG titers should be measured early in pregnancy. Paternal blood can be tested to determine the fetal risk of inheriting the cognate antigen, typically either 50% or 100% depending on whether the father is heterozygous or homozygous. However, as paternal serologic testing alone is not fully accurate, molecular genotyping may be recommended for both parents.

Fetal genotyping provides an accurate prediction for the development of HDFN in sensitized mothers. Fetal Rh status is available by isolating fetal cells or cell-free fetal DNA from the maternal circulation. These methods are replacing amniocentesis and chorionic villus sampling methods and associated risks. Elevated antibody titers, or rising titers, correspond to increased HDFN risk.

Without Rh immunoglobulin prophylaxis, any Rh-negative woman with a previous pregnancy or abortion, prior exposure to transfused blood products, or receipt of an organ transplant is at risk for Rh sensitization. If a mother has had a previously affected infant or stillbirth, the Rh-positive infant is usually equally or more severely affected than the previous infant. Although there can be poor correlation between the anti-RhD titer level and disease severity, Rh-negative mothers found to have RhD antibody titers of ≥1:16 (15 IU/mL in Europe) at any time during a subsequent pregnancy warrant close monitoring for fetal anemia.

Pregnancies at risk for HDFN should be managed by maternal-fetal specialists. In some cases, monitoring must begin at 16-24 weeks' gestation. This is typically done via noninvasive Doppler ultrasonography of middle cerebral artery (MCA) flow velocity, which can be used to monitor for increased vascular resistance in fetal arteries indicative of **fetal anemia** (Fig. 140.2). Moderate to severe anemia increases MCA blood flow, so peak MCA flow velocity can be a quantitative correlate for anemia severity. Real-time ultrasound is used to detect signs of hydrops (skin or scalp edema, pleural or pericardial effusions, and ascites) and fetal heart rate monitoring. Early ultrasonographic signs of hydrops include organomegaly (liver, spleen, heart), the double–bowel wall sign (bowel edema), and placental thickening. Progression to polyhydramnios, ascites, pleural or pericardial effusions, and skin or scalp edema may then follow. *In the setting of concerning ultrasonographic findings, percutaneous umbilical blood sampling (PUBS) can provide more direct assessment of fetal hemoglobin level and facilitate intrauterine transfusions.*

Although cord blood hemoglobin content typically varies in proportion to disease severity, hemoglobin may be within the normal range due to compensatory bone marrow and extramedullary hematopoiesis. Reticulocytosis will be present and a peripheral blood smear will show polychromasia with abundant nucleated RBCs. Thrombocytopenia may develop in severe cases. Umbilical cord bilirubin levels are generally between 3 and 5 mg/dL, including elevated direct bilirubin levels from cholestasis. Indirect-reacting bilirubin content rises rapidly in the first 6-12 hours of life.

Indications for delivery include fetal distress, complications during in utero interventions, and pulmonary maturity. Many affected infants are delivered preterm due to concerns for fetal well-being, after balancing risks of prematurity. The birth should be attended by a skilled neonatal resuscitation team familiar with the infant's prenatal course. *Because severe hemolytic anemia can cause rapid cardiovascular compromise, a team skilled in evaluation in management of HDFN should be involved when the diagnosis is suspected or confirmed, especially when there is a history of prior infants affected by HDFN.* Small packed RBC (PRBC) transfusions can be used to partially correct anemia, although volume expansion (e.g., large transfusions) risks worsening cardiac failure. Phototherapy may be necessary to treat hyperbilirubinemia in the first 24 hours of life if bilirubin levels exceed safe limits on an age-based nomogram (see Chapter 137). Although it is the indirect bilirubin fraction that crosses the blood-brain barrier to cause kernicterus, clinical decision-making is often based on total serum bilirubin levels.

Despite adequate resuscitation, phototherapy, and/or other empiric treatments, some infants with HDFN require exchange transfusions to treat anemia and/or hyperbilirubinemia. The decision to proceed with exchange transfusion is typically based on clinical status and trajectories in hemoglobin or serum bilirubin values, specifically the likelihood that serum bilirubin, plotted against postnatal hours of life, will reach a dangerous level (see Chapter 137). Signs and symptoms of kernicterus are absolute indications for exchange transfusion. Previous kernicterus or severe HDFN in a sibling, severe reticulocytosis >15%, or prematurity (with increased kernicterus risk) are additional factors to be considered in the decision to proceed with exchange transfusion (see Chapter 137).

Complications related to HDFN can also present weeks after birth, irrespective of the prenatal or perinatal course. Late anemia can present after 4-6 weeks of life, sometimes clinically manifesting as poor feeding or growth. This can result from ongoing hemolysis caused by persistent circulating maternal alloantibodies, or from hyporegenerative anemia caused by suppression of bone marrow erythropoiesis. These etiologies can be distinguished by reticulocyte count and bilirubin level, with ongoing hemolysis driving reticulocytosis and hyperbilirubinemia.

Neutropenia may also be observed in association with hyporegenerative anemia. Outpatient blood and reticulocyte counts should be monitored serially under the supervision of an expert hematologist to determine the need for interventions through bone marrow recovery. Iron supplementation or erythropoietin therapy can be helpful. In some cases, PRBC transfusions can be required for months after birth, until the infant's own erythropoietic system becomes more robust.

Hemolysis and hyperbilirubinemia can also cause late-onset complications. Jaundice typically resolves spontaneously within a few weeks or months with conservative management. Portal vein thrombosis and portal hypertension may occur in children who have been subjected to exchange transfusion as newborn infants. This complication is thought to be seen in infants with prolonged, traumatic, or septic umbilical vein catheterization. Inspissated bile syndrome is another rare complication, associated with persistent icterus and significant elevations in both direct and indirect bilirubin levels.

The outcome for Rh-incompatible fetuses varies greatly, depending on the characteristics of both the RBC antigen and the maternal antibodies. Although fetal transfusions and prenatal interventions can ameliorate some complications, those with severe hydrops remain at risk for cerebral palsy, developmental delay, and deafness, requiring medical and procedural interventions for hydrops prenatally or after birth. Infants should be monitored closely for late complications by pediatric hematologists in the outpatient setting.

HDFN CAUSED BY ABO INCOMPATIBILITY

ABO incompatibility is the most common cause of HDFN, with approximately 20% of live births at theoretical risk. Of at-risk infants, clinical manifestations develop in 1–10% and are usually less severe than Rh disease, rarely requiring aggressive clinical management or therapeutic intervention aside from phototherapy. This is because naturally occurring maternal antibodies against ABO blood group antigens are mostly IgM and therefore do not cross the placenta. However, some group O mothers will naturally produce anti-A or anti-B IgG antibodies that can cross the placenta to cause immune-mediated hemolysis. For this reason, ABO incompatibility can cause hemolysis even in a firstborn infant. Another reason for mild disease manifestations is that fetal and neonatal RBCs have relatively low ABO expression, limiting binding sites for maternal antibodies.

Clinical Manifestations

Affected infants will typically develop jaundice in the first day of life. Severe clinical manifestations, such as hydrops, severe anemia, or hepatosplenomegaly, are rare. Diagnosis requires serologic ABO incompatibility between the mother and infant, a positive DAT, and hyperbilirubinemia with or without anemia. Affected infants often have mild anemia and reticulocytosis, with peripheral blood smears showing polychromasia, nucleated RBCs, and spherocytes. *Phototherapy may be required based on bilirubin level and postnatal age, and is typically effective in lowering serum bilirubin levels* (see Chapter 137). In some cases, hemolysis can persist for weeks until maternal antibodies are cleared. Intravenous immunoglobulin (IVIG) administration can help to limit hemolysis and potentially avoid exchange transfusion and/or PRBC transfusions in cases with dangerous levels of hyperbilirubinemia or anemia, respectively. Rarely, affected infants who also have hyporegenerative anemia can require PRBC transfusions several weeks after birth. For this reason, outpatient monitoring is essential for newborns with ABO hemolytic disease. However, the persistence of hemolytic anemia or spherocytosis beyond 2 weeks of age can indicate an alternative diagnosis, such as hereditary spherocytosis (see Fig. 139.3).

OTHER ETIOLOGIES OF HDFN

Incompatibility in blood group antigens other than Rh or ABO account for <5% of HDFN. Minor RBC antigen mismatch is emerging as a common cause of HDFN in the developed countries in which anti-RhD immune globulin is routinely used. The likelihood of minor antigen mismatches is a function of population frequency, antigen surface density on RBCs, and immunogenicity in the mother. In most cases, the infant's direct antiglobulin test (DAT) will be positive and maternal serum will have alloantibodies against infant (and paternal) erythrocytes. Elution techniques can identify the antigen specificity.

Common RBC antigens that can lead to clinically relevant incompatibility include those in the Kell, Duffy, and MNS blood groups. Kell incompatibility can be the most clinically relevant, as the severity of the hemolytic anemia is difficult to predict based on previous obstetric history, amniotic fluid bilirubin determinants, or maternal antibody titer (Table 140.2). Kell-alloimmunized infants often have inappropriately low numbers of circulating reticulocytes caused by erythroid suppression, and even low maternal titers of anti-Kell antibodies may cause significant anemia due to loss of precursors expressing the antigen as well as mature erythrocytes. No pharmacologic therapies are available to prevent sensitization with these minor antigens. As with cases of Rh and ABO incompatibility, treatment is supportive, including exchange transfusion for severe presentations.

Chapter 141

Neonatal Polycythemia

Christopher S. Thom and Michele P. Lambert

Neonatal polycythemia is broadly defined as an elevated hemoglobin or hematocrit level. This can be due to primary myeloproliferative disorders (e.g., polycythemia vera) or reactive processes, such as from chronic hypoxemia or living at high altitudes.

In infants, polycythemia is inferred from a hematocrit level >2 standard deviations above the normal value for gestational and postnatal age (Figs. 138.2 and 139.1). Full-term infants are therefore considered polycythemic with a hemoglobin level above ~22 g/dL or hematocrit >65%. It is important that these values are obtained from a "central" venous or arterial puncture, as heelstick or capillary samples can report artificially elevated values. Due to fluid shifts in the newborn period, hematocrit levels typically peak at 2-3 hours of life.

Although most polycythemic individuals are asymptomatic, symptomatic blood **hyperviscosity** from polycythemia can cause sluggish blood flow that decreases tissue perfusion and leads to metabolic disturbances. Signs and symptoms are vague, including irritability, lethargy, tachypnea, respiratory distress, cyanosis, feeding disturbances, hyperbilirubinemia, hypoglycemia, and thrombocytopenia. Thus a high index of suspicion is often required for diagnosis and coincident respiratory, cardiovascular, and neurologic disorders should be investigated. Severe complications include seizures, stroke, pulmonary hypertension, necrotizing enterocolitis (NEC), renal vein thrombosis, and renal failure in newborns. Related symptoms often appear in the first hours of life but can be delayed by up to 2-3 days depending on clinical context.

Dehydration should be considered as a potential contributing cause in symptomatic polycythemic infants. Neonatal polycythemia can also result from processes that lead to passive RBC transfusion into the fetus or increased intrauterine erythropoiesis. Passive fetal RBC transfusions may occur from prolonged delayed umbilical cord clamping but can also present in recipients of twin-twin transfusions or unrecognized maternal-fetal transfusions from the placenta.

Most cases of increased fetal erythropoiesis are thought to result from chronic intrauterine hypoxia, which stimulates erythropoietin and RBC production. Increased fetal erythropoiesis is associated with polycythemia in postterm (3%) and term (1–2%) infants; small-for-gestational-age (8%) or large-for-gestational-age (3%) infants; infants of diabetic mothers; infants of hypertensive mothers or those taking propranolol; and infants with trisomy 13, 18, or 21, adrenogenital syndrome, neonatal Graves disease, hypothyroidism, or Beckwith-Wiedemann syndrome. Delayed cord clamping does not increase the incidence of polycythemia. Contraindications to delayed cord clamping include suspected chronic intrauterine hypoxia (e.g., severe growth restriction) and maternal diabetes, which independently increase RBC production. The frequency of neonatal polycythemia is also increased for births at higher altitudes (5% at high altitude vs 1–2% at sea level).

Asymptomatic polycythemia can be treated conservatively, with consideration for supplemental enteral or intravenous hydration. Treatment for symptomatic infants should also begin with supplemental hydration, after considering potential comorbidities (e.g., heart failure). All polycythemic infants should have intake and output, blood glucose, and bilirubin levels followed closely. Infants with hyperviscosity symptoms may benefit from partial exchange transfusions, particularly if the hematocrit reaches ≥75% and symptoms worsen despite aggressive intravenous hydration.

Outcomes are more closely determined by etiologies contributing to chronic intrauterine hypoxia than polycythemia per se. Although infants treated with partial exchange transfusion may be at increased risk of NEC, it is unclear whether adverse long-term speech, fine motor, cognitive, and behavioral outcomes are affected.

Chapter 142

Hemorrhage in the Newborn Infant

Christopher S. Thom and Michele P. Lambert

Congenital and acquired bleeding disorders can manifest at varying times in infants and older children. Hemorrhage in an otherwise healthy newborn may suggest an inherited coagulation defect (e.g., hemophilia) or concurrent thrombocytopenia. Bleeding in otherwise sick neonates is frequently caused by underproduction or consumption of coagulation factors and/or platelets. Common acquired hemorrhagic disorders include hemorrhage due to vitamin K deficiency (see Chapter 71 and below), disseminated intravascular coagulation (DIC: see Chapter 532), or immune-mediated thrombocytopenia (see Chapter 533).

The neonatal hemostatic system differs from older children and adults. This impacts bleeding risk and laboratory assessment, and should enter into management considerations. Plasma levels of vitamin K–dependent coagulation factors (II, VII, IX, X, protein C, protein S) and antithrombin are initially low at birth and do not reach adult ranges until approximately 6 months of age. Note that overall the neonatal hemostatic system tends toward hypercoagulability, given low levels of protein C, protein S, and antithrombin. This may explain why neonatal platelets are hypofunctional in response to some agonists, and why neonatal platelet content differs from adults (Chapters 525 and 526).

HEMORRHAGIC DISEASE OF THE NEWBORN

Bleeding from vitamin K deficiency, otherwise known as **hemorrhagic disease of the newborn**, results from transient but profound deficiencies in vitamin K–dependent coagulation factors. Vitamin K normally facilitates carboxylation of factors II, VII, IX, and X, which is necessary for enzymatic activities. Decarboxylated factors are biologically inactive. Without vitamin K, decarboxylated *proteins induced in vitamin K absence (PIVKA)* are secreted. The classic form of this disease can be prevented with intramuscular injection of vitamin K (phytonadione) just after birth.

The disease process most often affects exclusively breastfed infants who did not receive intramuscular vitamin K prophylaxis at birth. Maternal breastmilk lacks free vitamin K, and newborns lack the intestinal flora normally responsible for vitamin K synthesis. Premature infants with nutritional deficiencies are also at risk of vitamin K deficiency and bleeding.

Laboratory testing typically reveals prolonged prothrombin time (PT) and partial thromboplastin time (PTT) in affected infants, with low plasma levels of prothrombin (II) and factors VII, IX, and X. Soluble **PIVKA** measurement can also act as a laboratory marker for vitamin K status. Factors V and VIII, fibrinogen, bleeding time, clot retraction, platelet count, and platelet function will be within normal newborn ranges.

Intramuscular administration of 1 mg vitamin K_1 (phytonadione) soon after birth can prevent bleeding complications from vitamin K deficiency in most full-term infants. Low birthweight infants may be given 0.5 mg phytonadione, although weight-based dosing varies between institutions. Phytonadione is the only form of vitamin K available in the United States. Vitamin K_2, also known as menaquinones, constitutes a minority of the vitamin K consumed by humans or produced by intestinal flora. Vitamin K prophylaxis does not prevent all hemorrhagic disease of the newborn. Although rare, cases can occur in full-term infants, preterm infants with significant nutritional deficiencies, and infants with malabsorption.

Chapter 141

Neonatal Polycythemia

Christopher S. Thom and Michele P. Lambert

Neonatal polycythemia is broadly defined as an elevated hemoglobin or hematocrit level. This can be due to primary myeloproliferative disorders (e.g., polycythemia vera) or reactive processes, such as from chronic hypoxemia or living at high altitudes.

In infants, polycythemia is inferred from a hematocrit level >2 standard deviations above the normal value for gestational and postnatal age (Figs. 138.2 and 139.1). Full-term infants are therefore considered polycythemic with a hemoglobin level above ~22 g/dL or hematocrit >65%. It is important that these values are obtained from a "central" venous or arterial puncture, as heelstick or capillary samples can report artificially elevated values. Due to fluid shifts in the newborn period, hematocrit levels typically peak at 2-3 hours of life.

Although most polycythemic individuals are asymptomatic, symptomatic blood **hyperviscosity** from polycythemia can cause sluggish blood flow that decreases tissue perfusion and leads to metabolic disturbances. Signs and symptoms are vague, including irritability, lethargy, tachypnea, respiratory distress, cyanosis, feeding disturbances, hyperbilirubinemia, hypoglycemia, and thrombocytopenia. Thus a high index of suspicion is often required for diagnosis and coincident respiratory, cardiovascular, and neurologic disorders should be investigated. Severe complications include seizures, stroke, pulmonary hypertension, necrotizing enterocolitis (NEC), renal vein thrombosis, and renal failure in newborns. Related symptoms often appear in the first hours of life but can be delayed by up to 2-3 days depending on clinical context.

Dehydration should be considered as a potential contributing cause in symptomatic polycythemic infants. Neonatal polycythemia can also result from processes that lead to passive RBC transfusion into the fetus or increased intrauterine erythropoiesis. Passive fetal RBC transfusions may occur from prolonged delayed umbilical cord clamping but can also present in recipients of twin-twin transfusions or unrecognized maternal-fetal transfusions from the placenta.

Most cases of increased fetal erythropoiesis are thought to result from chronic intrauterine hypoxia, which stimulates erythropoietin and RBC production. Increased fetal erythropoiesis is associated with polycythemia in postterm (3%) and term (1–2%) infants; small-for-gestational-age (8%) or large-for-gestational-age (3%) infants; infants of diabetic mothers; infants of hypertensive mothers or those taking propranolol; and infants with trisomy 13, 18, or 21, adrenogenital syndrome, neonatal Graves disease, hypothyroidism, or Beckwith-Wiedemann syndrome. Delayed cord clamping does not increase the incidence of polycythemia. Contraindications to delayed cord clamping include suspected chronic intrauterine hypoxia (e.g., severe growth restriction) and maternal diabetes, which independently increase RBC production. The frequency of neonatal polycythemia is also increased for births at higher altitudes (5% at high altitude vs 1–2% at sea level).

Asymptomatic polycythemia can be treated conservatively, with consideration for supplemental enteral or intravenous hydration. Treatment for symptomatic infants should also begin with supplemental hydration, after considering potential comorbidities (e.g., heart failure). All polycythemic infants should have intake and output, blood glucose, and bilirubin levels followed closely. Infants with hyperviscosity symptoms may benefit from partial exchange transfusions, particularly if the hematocrit reaches ≥75% and symptoms worsen despite aggressive intravenous hydration.

Outcomes are more closely determined by etiologies contributing to chronic intrauterine hypoxia than polycythemia per se. Although infants treated with partial exchange transfusion may be at increased risk of NEC, it is unclear whether adverse long-term speech, fine motor, cognitive, and behavioral outcomes are affected.

Chapter 142

Hemorrhage in the Newborn Infant

Christopher S. Thom and Michele P. Lambert

Congenital and acquired bleeding disorders can manifest at varying times in infants and older children. Hemorrhage in an otherwise healthy newborn may suggest an inherited coagulation defect (e.g., hemophilia) or concurrent thrombocytopenia. Bleeding in otherwise sick neonates is frequently caused by underproduction or consumption of coagulation factors and/or platelets. Common acquired hemorrhagic disorders include hemorrhage due to vitamin K deficiency (see Chapter 71 and below), disseminated intravascular coagulation (DIC: see Chapter 532), or immune-mediated thrombocytopenia (see Chapter 533).

The neonatal hemostatic system differs from older children and adults. This impacts bleeding risk and laboratory assessment, and should enter into management considerations. Plasma levels of vitamin K–dependent coagulation factors (II, VII, IX, X, protein C, protein S) and antithrombin are initially low at birth and do not reach adult ranges until approximately 6 months of age. Note that overall the neonatal hemostatic system tends toward hypercoagulability, given low levels of protein C, protein S, and antithrombin. This may explain why neonatal platelets are hypofunctional in response to some agonists, and why neonatal platelet content differs from adults (Chapters 525 and 526).

HEMORRHAGIC DISEASE OF THE NEWBORN

Bleeding from vitamin K deficiency, otherwise known as **hemorrhagic disease of the newborn**, results from transient but profound deficiencies in vitamin K–dependent coagulation factors. Vitamin K normally facilitates carboxylation of factors II, VII, IX, and X, which is necessary for enzymatic activities. Decarboxylated factors are biologically inactive. Without vitamin K, decarboxylated *proteins induced in vitamin K absence (PIVKA)* are secreted. The classic form of this disease can be prevented with intramuscular injection of vitamin K (phytonadione) just after birth.

The disease process most often affects exclusively breastfed infants who did not receive intramuscular vitamin K prophylaxis at birth. Maternal breastmilk lacks free vitamin K, and newborns lack the intestinal flora normally responsible for vitamin K synthesis. Premature infants with nutritional deficiencies are also at risk of vitamin K deficiency and bleeding.

Laboratory testing typically reveals prolonged prothrombin time (PT) and partial thromboplastin time (PTT) in affected infants, with low plasma levels of prothrombin (II) and factors VII, IX, and X. Soluble **PIVKA** measurement can also act as a laboratory marker for vitamin K status. Factors V and VIII, fibrinogen, bleeding time, clot retraction, platelet count, and platelet function will be within normal newborn ranges.

Intramuscular administration of 1 mg vitamin K_1 (phytonadione) soon after birth can prevent bleeding complications from vitamin K deficiency in most full-term infants. Low birthweight infants may be given 0.5 mg phytonadione, although weight-based dosing varies between institutions. Phytonadione is the only form of vitamin K available in the United States. Vitamin K_2, also known as menaquinones, constitutes a minority of the vitamin K consumed by humans or produced by intestinal flora. Vitamin K prophylaxis does not prevent all hemorrhagic disease of the newborn. Although rare, cases can occur in full-term infants, preterm infants with significant nutritional deficiencies, and infants with malabsorption.

Table 142.1 Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)

	EARLY-ONSET DISEASE	CLASSIC DISEASE	LATE-ONSET DISEASE
Age	0-24 hr	2-7 days	1-6 mo
Potential sites of hemorrhage	Cephalohematoma Subgaleal Intracranial Gastrointestinal Umbilicus Intraabdominal	Gastrointestinal Ear-nose-throat-mucosal Intracranial Post circumcision Cutaneous Injection sites	Intracranial Gastrointestinal Cutaneous Ear-nose-throat-mucosal Injection sites Thoracic
Etiology/risks	Maternal drugs (phenobarbital, phenytoin, warfarin, rifampin, isoniazid) that interfere with vitamin K levels or absorption Inherited coagulopathy	Vitamin K deficiency Exclusive breastfeeding	Cholestasis: malabsorption of vitamin K (biliary atresia, cystic fibrosis, hepatitis) Abetalipoprotein deficiency Idiopathic in Asian breastfed infants Warfarin ingestion
Prevention	Avoidance of high-risk medication Possibly antenatal vitamin K to treatment of mother (20 mg) before birth and postnatal administration to infant soon after birth	Prevented by parenteral vitamin K at birth Oral vitamin K regimens require repeated dosing	Prevented by parenteral and high-dose oral vitamin K during periods of malabsorption or cholestasis
Incidence	Very rare	~2% if infant not given vitamin K soon after birth	Dependent on primary disease

Infants who present with hemorrhage should be given 1-5 mg of vitamin K_1 intravenously, typically on 3 consecutive days. This regimen generally improves coagulation defects and bleeding ceases within hours. Serious bleeding, particularly in premature infants or those with liver disease, may also require intravenous transfusion of fresh-frozen plasma to correct coagulopathy. Packed RBCs (PRBCs) or whole blood transfusions may also be required to correct anemia.

Bleeding episodes most frequently occur between days of life 2 and 7. Mild bleeding may precede more severe manifestations, which are most frequently gastrointestinal, nasal, subgaleal, intracranial, or occur after circumcision.

Early-onset vitamin K deficiency bleeding can occur in the first day of life in infants born to mothers chronically treated with drugs that interfere with vitamin K absorption or function, including warfarin, phenytoin, phenobarbital, or some cholesterol-lowering medications. Usually, bleeding is promptly ameliorated by vitamin K administration, although some infants can have poor or delayed improvements in bleeding. Thus infants born to mothers who took these medications late in gestation should be given 1-2 mg intravenous vitamin K immediately after birth, and serial newborn PT monitoring should begin using cord blood. If the PT is greatly prolonged and fails to improve, or significant hemorrhage presents, fresh-frozen plasma administration can temporarily correct factor deficiencies.

Late-onset vitamin K deficiency bleeding after 2 weeks of life is most often associated with conditions that cause fat-soluble vitamin malabsorption, including cystic fibrosis, neonatal hepatitis, or biliary atresia (Table 142.1). Bleeding can be severe and is not responsive to vitamin K treatment if there is hepatocellular injury; bleeding will respond to intravenous vitamin K if there is malabsorption.

Bleeding unresponsive to vitamin K should prompt consideration for congenital clotting factor deficiencies (see Chapter 525). These conditions may present with hematomas, melena, post circumcision bleeding, or bleeding from the umbilicus. Up to 70% cases of hemophilia (factor VIII or IX deficiency) are clinically apparent in the newborn period. Congenital factor deficiency treatment requires specific factor replacement, or fresh-frozen plasma if factor concentrate is not available.

Although *oral* vitamin K administration has been investigated as an alternative to intramuscular prophylaxis, oral regimens *do not* prevent late-onset vitamin K deficiency bleeding. Thus intramuscular vitamin K prophylaxis remains the method of choice.

Prompt recognition of infants who do present with bleeding from vitamin K deficiency is critical. A presumptive diagnosis can often be made based on a complete history, even before laboratory confirmation, facilitating rapid treatment initiation. With timely therapy and supportive care, the associated mortality rate is low.

DISSEMINATED INTRAVASCULAR COAGULOPATHY

Critical illness that results in consumption of circulating coagulation factors and platelets is termed disseminated intravascular coagulation. In neonates and other patients, DIC can result in either bleeding or thrombosis. DIC occurs secondary to an array of primary processes, including but not limited to sepsis or asphyxia. Rarely, hemangiomas will cause consumption of coagulation factors and initiate this process. In addition to clinical context, coagulation studies, factor levels, and platelet counts can provide evidence of ongoing DIC. Management centers on treatment of the underlying etiology, although supportive care may include blood, plasma, vitamin K, or platelet transfusions to replace consumed factors. Usually, affected infants are critically ill, with evidence of end-organ damage. Those with DIC can have high rates of morbidity and mortality, dependent on the underlying etiology (see Chapter 532).

Diagnosis and Treatment

Diagnostic modalities for hemorrhage in neonates vary based on clinical suspicion. For example, noninvasive imaging can be used to identify hemorrhage or bleeding sequelae. Premature infants who become acutely anemic out of proportion to phlebotomy are frequently monitored for intraventricular hemorrhage or investigated for bleeding elsewhere. These diagnostic measures can help to explain the pathology leading to anemia and any related risks. In turn, diagnosis can facilitate prognostication, and in rare cases lead to potentially definitive interventions (e.g., for some vascular malformations).

Treatment for blood loss typically includes transfusion of crossmatched PRBCs, which should be given more slowly in the setting of chronic blood loss or in patients at risk of volume overload. Therapies and interventions should also focus on correcting coexisting coagulopathy and/or comorbidities that increase further bleeding risk.

Chapter 143

Nonimmune Hydrops

Dalal Taha

Nonimmune hydrops, a significant contributor to neonatal morbidity and mortality, is the leading cause of fetal hydrops. **Hydrops fetalis** is defined by ≥2 abnormal fetal fluid collections, such as ascites, pleural, pericardial, or cutaneous edema (>5 mm) (Fig. 143.1). In addition, there may be associated placental edema (>6 mm), polyhydramnios (50%), and the rare occurrence of **mirror syndrome**, in which the mother becomes edematous. In cases in which hydrops is not caused by red cell alloimmunization, it is referred to as nonimmune hydrops. Nonimmune hydrops is the result of a range of underlying etiologies, such as high-output cardiac failure secondary to anemia or fetal arrhythmia, alterations in lymphatic development, fetal inflammation, and capillary leak or elevated central venous pressure due to structural cardiac disease. Despite advances in recognition of the underlying cause, mortality remains high with prognosis dependent on the underlying cause, degree of prematurity, and extent of disease burden at birth.

INCIDENCE AND ETIOLOGY

Estimates of incidence range between 1 in 1,700 pregnancies and 1 in 4,000 pregnancies. Population studies provide lower estimates, but this may be an underrepresentation due to a lack of information on fetuses who died in utero.

The etiologies are broad; cardiovascular, lymphatic, hematologic, and chromosomal disorders are the most common identifiable underlying causes (Table 143.1). The etiology is unknown in approximately 10–20% of cases. However, improved understanding of the lymphatic system and its contribution to the development of nonimmune hydrops has led to increased identification of the underlying etiology. Lymphatic causes of nonimmune hydrops are congenital lymphovenous atresia, in which the thoracic duct outlet is not connected to the venous circulation, and complete absence of the thoracic duct or pulmonary lymphatic perfusion syndrome, in which the pulmonary lymphatic channels abnormally conduct to the pleural space resulting in chylothorax. Other mechanisms for the development of nonimmune hydrops are not well established (Fig. 143.2).

PRENATAL DIAGNOSIS AND TREATMENT

Hydrops fetalis is identified in utero by ultrasonographic findings of excess fluid. After ruling out immune-mediated hydrops (Rh alloimmunization), other diagnostic testing may include screening for hemoglobinopathies, testing for fetal-maternal hemorrhage (Kleihauer-Betke test), and testing for infection (i.e., TORCH infections, syphilis, and parvovirus B19). Fetal echocardiography should be performed to assess for structural heart defect or arrhythmia. Commonly diagnosed causes of nonimmune hydrops in fetuses greater than 24 weeks' gestation are cardiac disorders. Amniotic fluid can be obtained for fetal genetic testing to evaluate for chromosomal and specific gene abnormalities. In cases with fetal pleural effusions, a fluid sample may be collected via thoracentesis and tested for lymphocyte count to determine whether the underlying cause of hydrops is due to lymphatic dysfunction.

In utero treatment has been successful for fetal supraventricular tachycardia (SVT), twin-twin transfusion syndrome, nonimmune fetal anemias, large vascular masses, congenital diaphragmatic hernia, and other chest occupying lesions, such as congenital cystic adenomatoid malformation (CCAM) and pulmonary sequestration. In cases in which initial ultrasound is not useful in identifying a cause, repeat ultrasound or fetal magnetic resonance imaging (MRI) can be used to reassess fetal anatomy, monitor progression of hydrops, determine an underlying diagnosis, and direct fetal intervention. The finding of nutmeg lung on fetal MRI signifies abnormal pulmonary lymphatic flow that results in chylothorax. To treat fetal pleural effusions, in the absence of an infectious etiology, fetal thoracentesis and/or thoracoamniotic shunt placement can be performed.

Fig. 143.1 Hydrops fetalis. Longitudinal sonographic image of the fetus, with ascitic fluid outlining the liver *(large arrow)*. The *small arrow* shows pleural effusion above the diaphragm. *(From Wilkins I. Nonimmune hydrops. In Creasy RK, Resnick R, Iams JD, et al., eds.* Creasy & Resnik's Maternal-Fetal Medicine, *7th ed. Philadelphia: Elsevier; 2014: Fig. 37-2.)*

POSTNATAL DIAGNOSIS AND TREATMENT

Postnatal therapy includes a team approach to the delivery room management that often requires immediate endotracheal tube intubation for predicted respiratory failure secondary to pleural, peritoneal, or pericardial effusions, pulmonary hypoplasia, surfactant deficiency, pulmonary edema, or poor chest wall compliance due to soft tissue edema. Immediate transfusion of packed red blood cells (RBCs) may also be required in the delivery room in the presence of anemias. Drainage of large pleural, peritoneal, or pericardial effusions may aid in achieving effective mechanical ventilation and ensure successful resuscitation. High ventilatory pressures may be needed to overcome poor chest compliance but may result in pneumothoraces or pulmonary interstitial emphysema, especially in cases with pulmonary hypoplasia.

Once the infant is stabilized, additional intensive care includes fluid and electrolyte management. Maintenance fluids should be restricted as much as possible with the goal of resolving or improving the degree of hydrops. In cases with ongoing drainage of pleural or peritoneal fluid, fluid replacement may be necessary to replete serum sodium levels and maintain hemodynamic stability. If the fluid drained is secondary to a lymphatic disorder, albumin may need to be administered to maintain adequate serum levels.

Diagnostic testing should be performed if an underlying etiology of hydrops is unknown at the time of birth to direct additional therapies. Whole exome (or genome) sequencing and microarray duplication/deletion studies are recommended to establish a diagnosis. Analysis of fluid from the pericardial, pleural, or peritoneal space may confirm an underlying lymphatic disorder if there is a lymphocyte predominance. Hypoalbuminemia and the presence of soft tissue edema is also suggestive of a lymphatic disorder. Additional evaluation of the lymphatic system includes the use of T2 weighted MRI, dynamic contrast-enhanced magnetic resonance lymphangiogram (DCMRL), and direct or conventional lymphangiogram. Interventions for congenital lymphatic disorders include ethiodized oil injection to treat pulmonary lymphatic perfusion syndrome and lymphovenous anastomosis for lymphovenous atresia.

OUTCOMES

Mortality from nonimmune hydrops remains high at approximately 50% despite recent advances in diagnosis and treatment. Predictors of survival include gestational age at birth and degree of illness at the time of birth. Infants with parvovirus, isolated neonatal chylothorax, and SVT have the highest survival.

Table 143.1 Principal Diagnoses Associated with Nonimmune Hydrops Fetalis

CARDIOVASCULAR (21%)
STRUCTURAL
- Hypoplasias (left or right heart)
- AV canal defect
- Single ventricle
- Transposition of great arteries
- Septal defects (VSD/ASD)
- Tetralogy of Fallot
- Ebstein anomaly
- Ductus arteriosus closure
- Truncus arteriosus
- Valvular (stenosis/insufficiency)

ARRYTHMIAS
- Atrial (flutter/tachyarrhythmia)
- Wolff-Parkinson-White
- Supraventricular tachycardia
- Long QT interval
- Heart block

CARDIOMYOPATHY
- Tumors
- Neoplasias
- Myopathies
- Cardiosplenic syndromes
- Hereditary cardiomyopathies

INFECTION (6.7%)
- Cytomegalovirus
- Parvovirus B19
- Syphilis
- Herpes simplex
- Rubella
- Coxsackievirus
- Leptospirosis
- *Trypanosoma cruzi*

INBORN STORAGE DISEASE (1.1%)
- Gaucher disease
- GM1 gangliosidosis
- Sialidosis
- MPS IVA and VII
- Mucolipidosis type I+II
- Galactosialidosis
- Niemann-Pick type C

TTTS-PLACENTAL (5.6%)
Twin
- TTTS
- Acardiac twin

Placental
- Umbilical vein thrombosis
- Umbilical cord angiomyxoma
- True cord knot
- Chorionic vein thrombosis
- Rare placenta disorders

THORACIC/EXTRATHORACIC MASS/LYMPHATIC (12.4%)
Mass Effect
- Diaphragmatic hernia
- Congenital pulmonary adenomatoid malformation
- Intrathoracic mass
- Pulmonary sequestration
- Chylothorax
- Airway obstruction
- Pulmonary lymphangiectasia
- Bronchogenic cyst

Other
- Milroy syndrome
- Generalized lymphatic dysplasia
- Lymphedema-distichiasis syndrome

Skeletal Dysplasias
- Thanatophoric dysplasia
- Short rib polydactyly
- Hypophosphatasia
- Osteogenesis imperfecta chondrogenesis
- Campomelic dysplasia
- Lethal achondroplasia
- Nager syndrome

IDIOPATHIC (17.8%)
CHROMOSOMAL (13.4%)
TRISOMY
- 21
- 18
- 13

MONOSOMY
- 45, X
- 45, X (mosaic)

DUPLICATIONS
- 18 q +
- 11p

DELETIONS
- 13 q −
- 17 q −

TRIPLOIDY

HEMATOLOGIC (10.4%)
- Alpha-thalassemia
- Hereditary stomatocytosis
- Fetomaternal hemorrhage
- Glucose-6-phosphate deficiency
- Leukemia
- Pyruvate kinase deficiency
- Red blood cell aplasias
- Diamond-Blackfan syndrome

GASTROINTESTINAL (0.5%)
- Duodenal atresia
- Duodenal diverticulum
- Jejunoileal atresia
- Volvulus
- Imperforate anus
- Meconium peritonitis
- Intestinal malrotation
- Intestinal duplication
- Hepatic fibrosis
- Cholestasis
- Biliary atresia
- Hepatic vascular malformations
- Hepatitis
- Hepatic necrosis
- Liver tumor or cysts

SYNDROMIC/MISCELLANEOUS (8.1%)
- Noonan syndrome and other RASopathies
- Arthrogryposis
- Multiple pterygium syndrome
- Neu-Laxova syndrome
- Pena-Shokeir syndrome
- Myotonic dystrophy
- Saldino-Noonan syndrome
- Francois syndrome, type III
- Familial nuchal bleb
- Elejalde syndrome
- Thoracoabdominal syndrome

URINARY TRACT MALFORMATION (2.3%)
- Urethral stenosis
- Urethral atresia
- Posterior urethral valve
- Finnish type nephrosis
- Edwards (prune belly) syndrome

OTHER
- HLH
- IPEX
- Nemaline myopathy
- Multiple pterygium syndrome
- Hyper IgE syndrome

ASD, Atrial septal defect; AV, arteriovenous; HLH, hemophagocytic lymphohistiocytosis; IPEX, immune dysregulation polyendocrinopathy enteropathy X-linked, MPS, mucopolysaccharide; TTTS, twin-twin transfusion syndrome; VSD, ventricular septal defect.

Chapter 144

The Umbilicus

Eric C. Eichenwald

The umbilical cord typically consists of two umbilical arteries, the umbilical vein, and a gelatinous substance called Wharton jelly, all contained within a sheath derived from the amnion and coiled into a helical shape. The muscular umbilical arteries carry deoxygenated blood from the fetus to the placenta and are contiguous with the fetal internal iliac arteries. The umbilical vein carries oxygenated blood from the placenta back to the fetus, where it flows into the inferior vena cava by way of the ductus venosus. The placenta contains an estimated 20 mL/kg of blood; current recommendations are to delay clamping of the cord at delivery for 30-60 seconds in both term and preterm infants, to facilitate placental transfusion. At term, a normal umbilical cord is approximately 55 cm long. Abnormally short cords are associated with conditions causing decreased fetal movement, including fetal hypotonia, oligohydramnios, and uterine constraint, and lead to increased risk for complications during labor and delivery for both mother and infant. Long cords (>70 cm) increase the risk for true knots, wrapping around the fetus, and/or prolapse. Straight uncoiled cords are associated with anomalies, fetal distress, and intrauterine fetal demise.

When the cord is cut after birth, portions of these structures remain in the base but gradually become obliterated. The blood vessels are functionally closed but anatomically patent for 10-20 days. The umbilical arteries become the lateral umbilical ligaments; the umbilical vein, the ligamentum teres; and the ductus venosus, the ligamentum venosum. The umbilical cord stump usually sloughs within 2 weeks. Delayed separation of the cord, after more than 1 month, has been associated with neutrophil chemotactic defects and overwhelming bacterial infection (see Chapter 168).

A single umbilical artery is present in approximately 5-10/1,000 births; the frequency is higher (35-70/1,000) in twin births. It is estimated that 20–30% of infants with a single umbilical artery have other (and often multiple) congenital structural abnormalities. The presence of multiple anomalies is suggestive of an abnormal karyotype, including trisomies. Infants with an isolated single umbilical artery are not thought to be at increased risk of having a chromosomal anomaly, and no specific evaluation is indicated for these infants aside from a thorough physical examination.

The **omphalomesenteric duct (OMD)** is an embryonic connection between the developing midgut and the primitive yolk sac. It typically involutes at 8-9 weeks' gestation, but failure of this process can leave an abnormal connection between the umbilical cord and the gastrointestinal (GI) tract. The most common remnant of the OMD is a **Meckel diverticulum** (see Chapter 377), whereas abnormalities that would become symptomatic in the neonatal period include a **sinus** or **fistula** that would drain mucus or intestinal contents through the umbilicus. An umbilical **polyp** is one of the least common OMD remnants and represents exposed GI mucosa at the umbilical stump. The tissue of the polyp is bright red, firm, and has a mucoid secretion. Therapy for all OMD remnants is surgical excision of the anomaly.

A **persistent urachus** (urachal cyst, sinus, patent urachus, or diverticulum) is a result of failure of closure of the allantoic duct and may be associated with bladder outlet obstruction. Patency should be suspected if a clear, light-yellow, urine-like fluid is being discharged from the umbilicus. Symptoms include drainage, a mass or cyst, abdominal pain, local erythema, and infection. Urachal anomalies should be investigated by ultrasonography and a cystogram. Therapy for a persistent urachus is surgical excision of the anomaly and correction of any bladder outlet obstruction if present.

UMBILICAL HEMORRHAGE

Hemorrhage from the umbilical cord may be the result of trauma, inadequate ligation of the cord, or failure of normal thrombus formation. It may also indicate hemorrhagic disease of the newborn or other coagulopathies (especially factor XIII deficiency), septicemia, or local infection. The infant should be observed frequently during the first few days of life so that if hemorrhage does occur, it will be detected promptly.

UMBILICAL GRANULOMA

The umbilical cord stump usually dries and separates within 1-2 weeks after birth. The raw surface becomes covered by a thin layer of skin; scar tissue forms, and the wound is usually healed within 12-15 days. The presence of saprophytic organisms delays separation of the cord and increases the possibility of invasion by pathogenic organisms. Mild infection or incomplete epithelialization may result in a moist, granulating area at the base of the cord with a slight mucoid or mucopurulent discharge. Good results are usually obtained by cleansing with alcohol several times daily.

Persistence of granulation tissue at the base of the umbilicus is common. The tissue is soft, 3-10 mm in size, vascular and granular, colored dull red or pink, and may have a seropurulent discharge. Granulation tissue is treated by cauterization with silver nitrate, repeated at intervals of several days until the base is dry.

UMBILICAL INFECTIONS

The devitalized umbilical cord provides an ideal medium for bacterial growth and a potential portal of entry for microbes. The term **omphalitis** refers to infection of the umbilical cord stump, navel, or the surrounding abdominal wall. Omphalitis must be distinguished from local irritation from the umbilical cord clamp. Erythema that extends to the abdominal wall, particularly tracking superiorly is concerning. Most term infants with mild localized omphalitis appear well and are afebrile. However, ~10–15% are acutely ill and at risk for bacteremia, spreading cellulitis, necrotizing fasciitis, and extension into the portal vein and liver. **Necrotizing fasciitis** (which is often polymicrobial) is associated with a high mortality rate and is often associated wth neutropenia. Treatment of omphalitis includes prompt antibiotic therapy with agents effective against *Staphylococcus aureus* and *Escherichia coli*, such as an antistaphylococcal penicillin or vancomycin in combination with an aminoglycoside. If abscess formation or necrotizing fasciitis has occurred, surgical consultation for incision and drainage or debridement may be required.

In community and primary care settings in developing countries, topical application of chlorhexidine to the umbilical cord has been shown to reduce omphalitis and neonatal mortality. In hospital settings in developed countries, there is no convincing evidence that application of antiseptics (including triple dye, alcohol, or chlorhexidine) is superior to *dry cord care* in minimizing the risk of omphalitis for infants in these settings, although these treatments do reduce bacterial colonization.

UMBILICAL HERNIA

Often associated with **diastasis recti**, an umbilical hernia is caused by incomplete closure or weakness of the muscular umbilical ring. Predisposing factors include Black race and low birthweight. The hernia appears as a soft swelling covered by skin that protrudes during crying, coughing, or straining and can be reduced easily through the fibrous ring at the umbilicus. The hernia consists of omentum or portions of the small intestine. The size of the defect varies from <1 cm in diameter to as much as 5 cm (2 inches), but larger defects are rare. Most umbilical hernias that appear before age 6 months disappear spontaneously by 1 year. Even large hernias (5-6 cm in all dimensions) have been known to disappear spontaneously by 5-6 years. Strangulation of intestinal contents is *extremely rare*. Surgery is not advised unless the hernia persists to age 4-5 years, causes symptoms, becomes strangulated, or becomes progressively larger after age 1-2 years. Defects exceeding 2 cm are less likely to close spontaneously.

CONGENITAL OMPHALOCELE

An **omphalocele** is a herniation or protrusion of the abdominal contents into the base of the umbilical cord (Fig. 144.1). In contrast to the more common umbilical hernia, the sac is covered with peritoneum without overlying skin, and the insertion of the distal umbilical cord into the sac itself distinguishes this condition from other abdominal wall defects such as gastroschisis. The size of the sac that lies outside the abdominal cavity depends on its contents. Herniation of intestines into the cord occurs in approximately 1/5,000 births, and herniation of liver and intestines in 1/10,000 births. The abdominal cavity may be proportionately small because of the lack of space-occupying viscera. Treatment for an omphalocele consists of covering the sac with moist, sterile dressings, then initiating prompt surgical repair if the abdomen is able to accommodate the eviscerated organs. If the omphalocele is too large to allow immediate repair, continued dressings may temporize and encourage epithelialization of the sac. Occasionally, mesh or similar synthetic material may be used to cover the viscera if the sac has ruptured or if excessive mobilization of the tissues would be necessary to cover the mass and its intact sac.

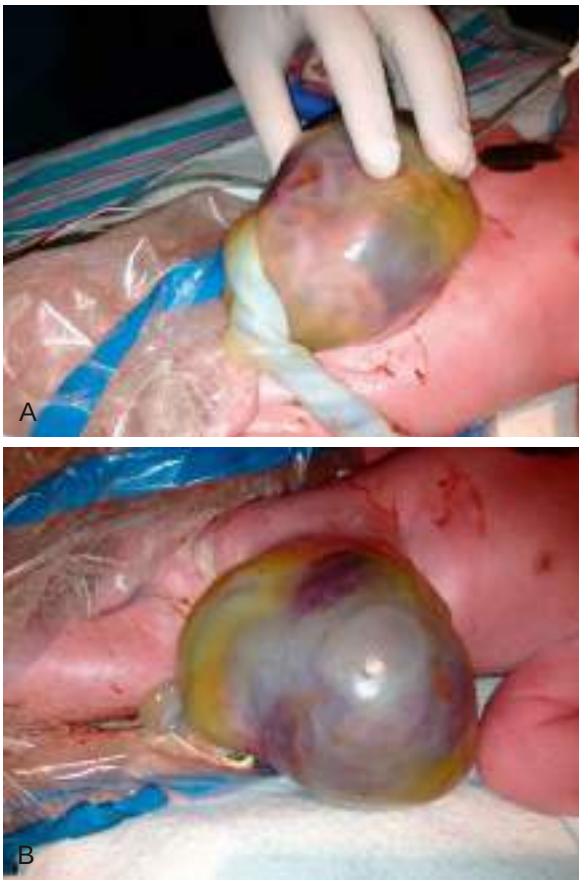

Fig. 144.1 A, Omphalocele with umbilical cord insertion into the sac and intestine visible. B, Omphalocele with sac containing liver. (*Courtesy Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.*)

Many infants with omphalocele (50–70%) have associated malformations, and about 30% have chromosomal abnormalities. The likelihood of an abnormal karyotype is increased when the liver is *intracorporeal* (not within the sac). Omphalocele can be part of well-defined syndromes, including **Beckwith-Wiedemann syndrome**, characterized by omphalocele, macrosomia, and hypoglycemia. The survival rate for affected infants is largely determined by the presence of associated malformations or chromosomal abnormalities. For patients with isolated omphalocele, the survival rate is >90%.

UMBILICAL TUMORS

Tumors of the umbilicus are rare and include angioma, enteroteratoma, dermoid cyst, myxosarcoma, and cysts of urachal or OMD remnants.

Chapter 145

Neonatal Abstinence Syndrome

Stephen W. Patrick

Neonatal abstinence syndrome (NAS) is a drug withdrawal syndrome that occurs among some substance-exposed infants shortly after birth. The syndrome most commonly occurs after in utero exposure to opioids and is also called neonatal opioid withdrawal syndrome (NOWS). Between 2000 and 2017, the rate of NAS in the United States increased sixfold reaching 7.2 per 1,000 hospital births, which mirrors the rise of other population-wide opioid-related complications including overdose deaths. The opioid overdose crisis in the United States was first driven by prescription opioids (e.g., oxycontin), then heroin, and more currently by illicitly produced fentanyl. For pregnant women opioid use disorder (OUD), or continued use of an opioid despite adverse consequences, often begins before pregnancy and is associated with myriad social risks including trauma and physical abuse. Treatment of OUD, especially with medications for OUD (MOUD), is effective in improving pregnancy outcomes. MOUD, including buprenorphine and methadone, has been shown to reduce risk of relapse, overdose death, HIV and hepatitis C virus (HCV), and preterm birth. **Methadone** is a full μ-opioid agonist, generally given once daily, and is administered through highly regulated opioid treatment programs. **Buprenorphine** is a partial μ-opioid agonist and a partial k-antagonist, can be prescribed in the outpatient setting, and is more widely available. Accessing treatment can be challenging for pregnant women, with studies showing they are nearly 20% less likely to be accepted for treatment than nonpregnant women. Notably, MOUD such as methadone and buprenorphine can cause NAS; however, this is generally thought of as a preferable outcome when compared to preterm birth or overdose.

The clinical signs of NAS are generally associated with neurologic (e.g., tremor), gastrointestinal (e.g., poor feeding), and autonomic signs (e.g., tachypnea) and can be documented using the NAS score (Fig. 145.1) as well as the Eat, Sleep, Console (ESC) assessment tool (Table 145.1).

NEONATAL ABSTINENCE SCORE

Date: _____ Weight: _____

System	Signs & Symptoms	Score	Time AM / PM	Comments
Central Nervous System Disturbances	Excessive High Pitched Cry	2

Table 145.1 Eat, Sleep, Console (ESC) Assessment Approach to Neonatal Opioid Withdrawl

EATS
Takes > 10 min to coordinate feeding with hunger cues
< 10 min for breastfeeds
< 10 mL of a feed
SLEEPS
< 1 hr after a feed
CONSOLES
Takes > 10 min to be consoled
Cannot stay consoled for 10 min
Nonpharmacologic interventions include rooming in, caregiver presence, skin to skin contact, holding/cuddling, safe swaddling (avoid face), feed on demand after hunger cues, breastfeeding, non-nutritive sucking, quiet low stimulation low-light environment, rhythmic motion, additional caregiver support, minimal disruptions in environment, cluster care to awake times, safe sleep, caregiver self-care and rest.

These parameters suggest withdrawl.

Data from Amin A, Frazie M, Thompson S, Patel A. Assessing the Eat, Sleep, Console model for neonatal abstinence syndrome management at a regional referral center. *J Perinatol.* 2023 Apr 25:1–7; Blount T, Painter A, Freeman E, et al. Eat, sleep, console approach or usual care for neonatal opioid withdrawal. *N Engl J Med.* 2023;388:2326–2336.

The timing of NAS onset can be related to several factors, including the last maternal use and half-life of the opioid. NAS signs can rarely begin within 24 hours of birth but more commonly occur within 48 hours after short-acting opioids, and 72-96 hours after exposure to long-acting or maintenance opioids (e.g., methadone). For these reasons, it is recommended to observe opioid-exposed infants for at least 3 days after birth for an infant exposed to short-acting opioids and 5 days for longer half-life opioids such as buprenorphine. Tremors, poor feeding, excessive crying, poor sleeping, and hyperirritability are the most prominent signs of NAS. Other signs include sneezing, yawning, hiccups, myoclonic jerks, skin breakdown and abrasions, vomiting, loose stools, nasal stuffiness, and seizures. Many prenatal and postnatal factors can influence the severity and duration of withdrawal. Polysubstance use, particularly with cigarettes, gabapentin, benzodiazepines, and selective serotonin reuptake inhibitors, has been associated with a higher risk or more severe NAS, whereas breastfeeding after delivery, rooming-in, and standardizing care processes (i.e., following protocols) have been associated with lower risk or less severe NAS (see Table 145.1 for nonpharmacologic interventions).

Identifying substance use as early as possible in pregnancy is critical to improving pregnancy outcomes. For that reason, it is recommended to perform universal screening for substance use using a standardized and validated tool such as the four Ps:

- **Parents:** Did any of your parents have problems with alcohol or other drug use?
- **Partner:** Does your partner have a problem with alcohol or drug use?
- **Past:** In the past, have you had difficulties in your life because of alcohol or other drugs, including prescription medications?
- **Present:** In the past month, have you drunk any alcohol or used other drugs?

Screening can be augmented with toxicology testing of the mother or infant; it is important to recognize that toxicology testing has limitations and for some substances may only capture a short window of exposure. Toxicology testing of pregnant women requires informed consent but is not needed for infants if done as part of routine care.

Testing urine of mothers or infants can capture recent exposures, whereas umbilical cord and meconium testing will capture a longer window of substance use. Toxicology testing may not be needed if women are in treatment and receive routine testing in pregnancy.

TREATMENT AND SETTING

Hospitals should have standardized protocols for the observation, scoring, and treatment of the opioid-exposed infant. The first line of treatment for all opioid-exposed infants is **nonpharmacologic support**, including rooming-in, breastfeeding, and tailoring the environment to not overstimulate the infant. Importantly, care for opioid-exposed infants and those diagnosed with NAS does not require admission to a neonatal intensive care unit (NICU); admission to a NICU may cause undue separation of the maternal–infant dyad as well as exacerbate clinical signs of withdrawal by placing the infant in a loud environment. Breastfeeding, in addition to its well-documented benefits, can also reduce NAS severity and can safely occur with maternal treatment using MOUD. Although there are no evidence-based guidelines, consensus guidelines suggest breastfeeding can be encouraged if there has been no relapse within 30 days of birth and should be encouraged if there has been no relapse within 90 days of birth. Untreated HIV is a contraindication to breastfeeding; however, breastfeeding is safe with HCV unless there are cracked or bleeding nipples.

The decision for pharmacologic treatment has been traditionally based on the nursing scoring assessment tool, and the most widely used tool is a modification of the Finnegan scoring tool (see Fig. 145.1). Other scoring tools include the Neonatal Narcotic Withdrawal Index, Neonatal Withdrawal Inventory, and MOTHER NAS Scale.

The **ESC model** is very useful and is an evidenced-based approach for improved outcomes and fewer pharmacologic interventions (Table 145.1). An inability to eat, sleep, or be consoled in at least two of the three parameters in the presence of nonpharmacologic interventions warrants pharmacologic therapy, usually with oral liquid morphine plus continued nonpharmacologic interventions. Other etiologies of poor eating, sleeping, and consolability must be evaluated. The main objectives when initiating pharmacologic treatment is to control clinical signs of withdrawal and to prevent adverse events (e.g., seizure). Excessive weight loss may be an indication for pharmacotherapy regardless of other clinical signs.

Pharmacologic treatment for NAS, when necessary, should be done with an opioid, and the most commonly used are morphine or methadone (Table 145.2). **Morphine** is a short-acting opioid given every 3 hours as a weight-based or clinical sign-based regimen. **Methadone** is a long-acting opioid that can generally be given twice a day after loading doses. **Buprenorphine** is an effective agent that may be superior to morphine; its use may be associated with a short duration of treatment and length of stay, as well as few adverse effects and less use of additional medications. Clinical trials have shown methadone and buprenorphine to decrease length of treatment when compared with morphine. Buprenorphine and some methadone formulations contain high ethanol levels, which may be deleterious to the infant and should be avoided. Closely adhering to NAS treatment protocols with guidelines on initiation and weaning have been shown to decrease both length of treatment and length of stay.

Adjuvant therapy is generally initiated in the unusual situation when the primary opioid is not effective in controlling the signs of NAS. The two medications used as adjuvant therapy are **phenobarbital** and **clonidine**. American Academy of Pediatrics (AAP) guidelines suggest clonidine be used as adjuvant therapy; phenobarbital should be avoided if possible as some studies suggest long-term use can be associated with developmental delay.

Long-term studies of opioid-exposed infants are lacking, and many are confounded by co-exposures (e.g., alcohol), maternal health (e.g., poor nutrition), or social risk (e.g., trauma), all of which could influence developmental outcomes. Still, infants should be closely monitored to optimize developmental trajectory. In many states a diagnosis of NAS qualifies for early intervention services, which are part of the Individuals with Disability and Education Act Part C, and infants should be referred to this service. Other supportive referrals should be

Table 145.2 Medications Used in Pharmacologic Treatment of Neonatal Abstinence Syndrome

DRUG	INITIAL DOSING	DOSING INCREASES	WEANING SCHEDULE	ADD ADJUVANT THERAPY
Morphine	0.05 mg/kg/dose q3h	Increase dose 10–20%	10% of stabilizing dose q24h	>1 mg/kg/day of morphine Unable to wean for 2 days
Methadone	0.1 mg/kg/dose q6h for 4 doses	Increase to q4h if unable to capture	0.7 mg/kg/dose q12h × 2 doses, then 0.05 mg/kg/dose q12h × 2 0.04 mg/kg/dose q12h × 2 0.03 mg/kg/dose q12h × 2 0.02 mg/kg/dose q12h × 2 0.01 mg/kg/dose q12h × 2 0.01 mg/kg/dose q24h × 1	Unable to wean for 2 days
Buprenorphine	4 µg/kg q8h	2 µg/kg until maximum of 15 µg/kg	3 µg/kg/dose q8h × 3 doses 2 µg/kg/dose q8h × 3 2 µg/kg/dose q8h × 2 2 µg/kg/dose q24h × 1	Unable to wean for 2 days
Phenobarbital	20 mg/kg	—	5 mg/kg daily	N/A
Clonidine	1.5 µg/kg/dose q3h	25% dose escalation q24h	10% every day	N/A

N/A, Not available; q24h, every 24 hours.

considered, including home visitation programs and Early Head Start. Further, in the discharge process clinicians should also assess other risk, including HIV and HCV exposure, which must be followed in the outpatient setting. Hospitals should standardize the discharge process for opioid-exposed infants to ensure connection to postdischarge services.

Chapter 146

Fetal Alcohol Spectrum Disorder

Susan A. Friedman and Hallam Hurt

Alcohol is a known teratogen that can cause irreversible central nervous system (CNS) damage. Injury can include reduced brain volume, particularly for the frontal lobe, and thinning of the corpus callosum. These injuries can lead to CNS dysfunction that can range from relatively mild to severe. Prenatal alcohol exposure (PAE) affects all stages of brain development from neurogenesis to myelination, through mechanisms that include disrupted cell-cell interactions, altered gene expression, and oxidative stress leading to abnormalities such as reduced brain volume in the frontal lobe, striatum and caudate nucleus, thalamus, and cerebellum; thinning of the corpus callosum; and abnormal functioning of the amygdala.

PAE can result in a spectrum of outcomes. The term fetal alcohol spectrum disorder (FASD) is the umbrella term that encompasses a group of conditions associated with PAE. The FASD group of disorders includes fetal alcohol syndrome (FAS), partial fetal alcohol syndrome (pFAS), alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defect (ARBD), and neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE).

EPIDEMIOLOGY

According to the CDC, approximately 1 in 7 pregnant women report consuming alcohol within the past 30 days. Approximately 20-30% report drinking at some point during the pregnancy, and more than 5% report binge drinking. consuming alcohol within the last 30 days, with ~20% reporting binge drinking. Because almost 50% of pregnancies in the United States are unplanned, unintentional PAE can occur before a woman knows she is pregnant.

PREVALENCE

FASDs are the most common causes of preventable developmental delay and intellectual disability. Prevalence rates vary across reports. The US Centers for Disease Control and Prevention (CDC) FAS Surveillance Network reported prevalence rate across several populations of 0.3 out of 1,000 children from 7 to 9 years of age. This prevalence rate is much lower than that obtained by active case ascertainment studies in the United States and Western Europe, which have estimated prevalence rates of 2–5%. Another study reported similar rates, 24-48 cases per 1,000 children (2.4–4.8%) for all FASDs, and 6-9 cases per 1,000 (0.6–0.9%) for FAS specifically. Studies that have examined PAE by anonymous meconium testing demonstrate 4.26 times greater identification of alcohol use during pregnancy compared with maternal self-report. Rates of FASDs have been reported to be higher in children living in poverty, in Indigenous populations, and in children living in foster care. The rate of FASDs for children in foster care has been found to be 10 to 15 times higher than that for children in the general population. FASDs often go undetected in these children, and as many as 86.5% of foster and adopted youth with FASDs go undiagnosed or are diagnosed incorrectly within the FASD spectrum. Children adopted internationally represent another high-risk group, particularly those adopted from Eastern Europe. Children adopted from orphanages and other children with a history of early trauma, such as those in foster care, may also exhibit symptoms of posttraumatic stress disorder (PTSD) and other neurobehavioral and developmental issues that can overlap with those of FASD, including those without physical features (ARND or ND-PAE). The impairments seen in children with an FASD may also include the negative impact of additional prenatal and postnatal risk factors.

DIAGNOSTIC SYSTEMS

The most widely used diagnostic guidelines are the Hoyme FASD diagnostic guidelines (revised 2016), the University of Washington 4-Digit Diagnostic Code (2004), the CDCFAS guidelines (revised

2004, only includes FAS), and the Canadian FASD guidelines (revised 2016).

These FASD diagnostic guidelines overlap but also have important distinctions. The Hoyme system uses more stringent alcohol exposure criteria than the 4-Digit Diagnostic Code. Both the Hoyme system (2016), and the 4-Digit Diagnostic Code system use the three diagnostic criteria of facial findings, growth restriction, and CNS abnormalities and both include a spectrum of disorders under the umbrella term of *fetal alcohol spectrum disorder* (FASD). However, they do differ in diagnostic tools, specific criteria used to define each category, and in diagnostic nomenclature. The result of these differences and others is that there may not be total agreement between the two in the diagnosis of a given patient. The CDC guidelines establish criteria only for FAS and require the three diagnostic criteria of facial findings, growth restriction, and CNS abnormalities, with or without documented PAE. In the updated Canadian guidelines, "fetal alcohol spectrum disorder" is considered a diagnostic term with two categories: FASD with sentinel facial features and FASD without sentinel facial features. These guidelines eliminate growth restriction as a required diagnostic criterion. They include an at-risk category for children with confirmed PAE who were too young to meet the criteria for neurodevelopmental deficits, or in whom assessment was incomplete. They also include a category for children with cardinal facial features without documentation or evidence of severe impairment in neurodevelopmental domains. There is no universal acceptance of one system. If less stringent criteria are used, the sensitivity increases, which may lead to overdiagnosis. Additional expert evaluation is then needed to confirm a diagnosis. In contrast, using more stringent criteria leads to greater specificity but may underdiagnose FASD.

Historical and Clinical Features

The historical and clinical features shared by all previously described diagnostic systems (although not required by all of the disorders) include five categories: (1) PAE, (2) three key facial features, (3) prenatal/postnatal growth restriction, (4) deficient brain growth and/or significant structural brain abnormalities, and (5) neurobehavioral impairment.

Prenatal Alcohol Exposure

A safe threshold or pattern of alcohol consumption during pregnancy has not been identified, and any PAE at any stage of gestation is believed to present a risk to a developing fetus. Significant alcohol exposure has been carefully defined in the 2016 updated Hoyme guidelines as follows.

One or more of the following exposures, beginning 3 months before pregnancy and continuing until delivery, with a standard drink defined as 1.5 oz of hard liquor, 5 oz of wine, or 12 oz of beer or wine cooler:

- ≥6 drinks/week for ≥2 weeks during pregnancy
- ≥3 drinks per occasion on ≥2 occasions
- Documented alcohol-related social or legal problems before or during pregnancy or a history of treatment for an alcohol-related condition
- Documentation of intoxication of blood, breath, or urine alcohol testing
- Positive testing with an established biomarker of alcohol exposure during pregnancy or at birth
- Positive finding on a validated screening tool for drinking during pregnancy

Information can be obtained from a variety of sources in addition to the birth mother, including family members, foster or adoptive parents, social service agencies who observed maternal alcohol consumption during pregnancy, or medical records that document PAE, alcohol treatment, or social, legal, or medical problems related to drinking during pregnancy. Binge drinking (4 or more drinks per occasion) has been shown to be the most harmful to fetal development. PAE in the first trimester leads to the classic facial dysmorphia associated with FAS and other structural defects. PAE can have other deleterious effects (e.g., spontaneous abortion, growth defect, CNS effects) on the fetus throughout the pregnancy.

Several well-validated screens are used to identify alcohol use in pregnant and nonpregnant women of childbearing years, including the assessments of Tolerance, Annoyance, Cut Down, Eye-Opener (T-ACE), Cut Back, Annoyed, Guilty, Eye-Opener (CAGE); Car; Relax; Alone; Forget; Friends; Trouble (CRAFFT); Alcohol Use Disorders Identification Test (Audit-C); and Tolerance, Worried, Eye-Opener, Amnesia, Kut Down (TWEAK). There are, however, no well-validated screens designed to ask about past consumption of alcohol. Pediatricians can ask the following two questions to determine the likelihood of significant PAE: "In the 3 months before you knew you were pregnant, how many times did you have 4 or more alcohol drinks in a day?" and "During your pregnancy, how many times did you have any alcohol?" If a positive response is given to either question, the clinician can follow up to determine the level of PAE by asking the following: (1) "During your pregnancy, on average, how many days per week did you have any alcohol?"; (2) "During your pregnancy, on a typical day when you had an alcoholic beverage, how many drinks did you have?"; and (3) "During your pregnancy, what was the maximum number of drinks that you had in a day?"

Dysmorphologic Facial Features

The three key, facial dysmorphologic features include short palpebral fissures, a thin vermilion border of the upper lip, and a smooth philtrum (Fig. 146.1). Measurement of the **palpebral fissure length (PFL)** is shown in Figure 146.2. There are several different PFL charts that can be used to plot this measurement. That of Hall is included here (Fig. 146.3), with additional charts listed under Additional Resources for Healthcare Providers. In addition, different diagnostic systems have different cutoffs to define the criteria. Evaluation of the philtrum and upper lip utilizes the Lip-Philtrum

Fig. 146.1 Examples of facial features of FAS in children of different ethnicities. **A,** White. **B,** Native American. **C,** Black. **D,** Asian. (*Copyright 2021 Susan (Astley) Hemingway PhD, University of Washington.*)

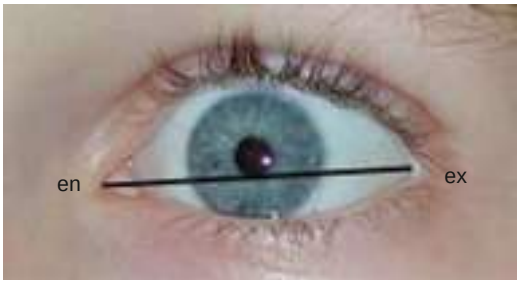

Fig. 146.2 The palpebral fissure length is defined by the distance between the endocanthion *(en)* and exocanthion *(ex)* landmarks. (*Copyright 2021 Susan (Astley) Hemingway PhD, University of Washington.*)

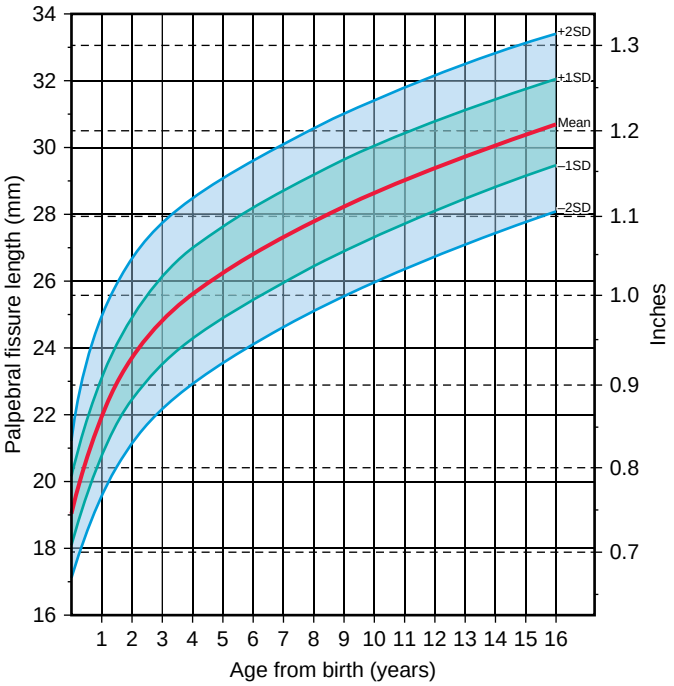

Fig. 146.3 Palpebral fissure measurements. (*From Hall JG, Froster-Iskenius UG, Allanson J, eds. Handbook of Normal Physical Measurements. Oxford: Oxford University Press; 1989: p. 150.*)

Guide developed at the University of Washington (Fig. 146.4), which can be obtained on request in digital format or as a laminated card from the University of Washington. Although this guide includes norms for White and Black children, additional work is needed on establishing norms for the three facial features across a wider range of racial groups.

Additional minor anomalies may also occur in association with PAE but are not included in the diagnostic criteria: mid-face hypoplasia, epicanthal folds, ptosis, strabismus, altered palmar crease ("hockey stick" and clinodactyly of the fifth finger [Fig. 146.5], "railroad track ears" [Fig. 146.6], hypoplastic nails, limited elbow supination, camptodactyly, hypertrichosis).

Prenatal/Postnatal Growth Deficiency

This is defined as ≤10th percentile for age (Hoyme and CDC) or ≤3rd percentile (4-Digit Diagnostic Code) for *either* height or weight. The systems also vary in the timing of the growth problems (prenatal/at birth, or at any point in life).

Deficient Brain Growth and Significant Structural Brain Abnormalities

Deficient brain growth is defined as an occipitofrontal head circumference (OFC) <10% for age, abnormal morphogenesis, or abnormal neurophysiology. The criteria additionally state that if the child has weight and height <10th percentile, then the OFC should be at or below the 3rd percentile. Structural brain abnormalities seen on brain imaging may include abnormalities of the corpus callosum, the cerebellum, or basal ganglia.

Neurobehavioral/Neurodevelopmental Impairment

These criteria can include abnormal findings on neurologic exam or seizures, and/or functional neurobehavioral or neurodevelopmental abnormalities. There is tremendous variability in the presentation of the neurobehavioral and neurocognitive features of children with FASD due to the timing and amount of PAE and unique characteristics of the birth mother and the child. The assessment of neurobehavioral impairment is also different for children under 3 years of age than for children 3 years or older.

The degree of developmental impairment can range from relatively mild delays to severe intellectual disability, although approximately 75% of individuals with an FASD *do not* have intellectual disability. In *infants*, the symptoms can be nonspecific and may include irritability, poor feeding, sleep difficulties, a tendency to become easily overstimulated, or difficulty forming attachments with caregivers. *Young children* may demonstrate developmental delays, inattention, impulsivity, internalizing and externalizing problems, social impairments and difficulty with peers, and behavioral difficulties such as mood lability, frequent tantrums, or aggression. The neurocognitive profile of children with an FASD that emerges at *elementary or middle school age* includes challenges with processing speed, memory, visual-spatial reasoning, math, auditory comprehension, use of pragmatic language, and executive functioning skills. In *adolescents*, difficulties with abstract reasoning, time and money management, and social and adaptive skills may become more pronounced.

The most common comorbid mental health condition seen in children with an FASD is attention-deficit/hyperactivity disorder (ADHD; see Chapter 50), which occurs in >50% of children. Individuals with FASD may also present with problems of self-regulation, impulse control, and adaptive functioning. Additional mental health disorders typically seen in children and adolescents include oppositional defiant and conduct disorder, anxiety disorder, adjustment disorder, sleep disorder, mood disorders (e.g., depression, bipolar disorder), and disinhibited social engagement disorder. FASD may increase the severity or complexity of these conditions.

DIAGNOSTIC CRITERIA

Five diagnoses included under the FASD umbrella include the following:

1. Fetal alcohol syndrome (FAS)
2. Partial fetal alcohol syndrome (pFAS)
3. Alcohol related neurodevelopmental disorder (ARND)
4. Neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE)
5. Alcohol related birth defects (ARBD)

The previously described clinical features with or without a history PAE are used to define the disorders within the FASD spectrum (Tables 146.1-146.5). As noted earlier, the criteria do vary somewhat depending upon which diagnostic system is used.

DIFFERENTIAL DIAGNOSIS

It is important to consider other causes of the facial features of FAS and pFAS, as each of these can be seen in certain genetic and teratogenic exposure conditions. Genetic conditions can include Williams syndrome, Dubowitz syndrome, Noonan syndrome, 22q11.2 deletion (velocardiofacial syndrome), Cornelia de Lange syndrome, chromosome 15q duplication syndrome, and others. Teratogenic exposure conditions include fetal valproate syndrome, fetal hydantoin syndrome, maternal phenylketonuria

Fig. 146.4 University of Washington Lip-Philtrum Guides 1 (A) and 2 (B) are used to rank upper lip thinness and philtrum smoothness. The philtrum is the vertical groove between the nose and upper lip. The guides reflect the full range of lip thickness and philtrum depth with Rank 3 representing the population mean. Ranks 4 and 5 reflect the thin lip and smooth philtrum that characterize the FAS facial phenotype. Guide 1 is used for Whites and all other races with lips like Whites. Guide 2 is used for Blacks and all other races with lips like Blacks. Free digital images of these guides for use on smartphones are available from astley@uw.edu. (*Copyright 2021 Susan (Astley) Hemingway PhD, University of Washington.*)

(PKU) effects, toluene embryopathy, and others. Therefore a genetics evaluation may be warranted, especially when there is unconfirmed PAE.

The neurobehavioral issues associated with FASD can be difficult to distinguish from those of other behavioral health disorders, such as autism spectrum disorder, ADHD, intellectual disability, reactive attachment disorder, PTSD, exposure to other maternal substance use during pregnancy, and others. This is particularly the case when the FASD facial features are not present. Children who experience "adverse childhood experiences" (ACEs), such as neglect, abuse, poverty, and parental substance abuse, can have similar findings of hyperactivity, poor impulse control, emotional dysregulation, deficits in executive function, and memory weaknesses as children with FASD. Furthermore, these disorders are not mutually exclusive and more than one underlying disorder can result in the neurobehavioral issues found.

OUTCOMES

Children with an FASD are at higher risk for victimization and bullying, often due to poor social judgment. Children and adolescents who are not identified early and treated aggressively are significantly more likely to have secondary disabilities, including encounters with juvenile justice and incarceration, substance abuse problems, severe mental health problems, sexual promiscuity and other inappropriate sexual behaviors, high rates of school failure, dropout and under- or unemployment, health problems, and premature death. Children and adolescents with an FASD have a 95% lifetime likelihood of having a mental health diagnosis and are at higher risk for suicide. Although an FASD cannot be cured, the long-term negative effects of the brain injury caused by PAE can be reduced through aggressive, sustained intervention initiated early. Factors associated with a better outcome include early diagnosis (under age 6 years), a stable and nurturing home, lack of exposure to violence, full assessment for disabilities and adequate provision of appropriate education, therapies, and social services. Prevention of FASD and early identification and interventions for children with an FASD is essential and has become an important goal of the CDC and other organizations.

Fig. 146.5 Characteristic hand findings that can be seen in a child with an FASD: curved fifth finger (clinodactyly) and upper palmar crease that widens after the bend and ends between the second and third fingers ("hockey stick" crease). (*Courtesy Darryl Leja, NHGRI, National Institutes of Health.*)

Fig. 146.6 Ear findings that can be seen in a child with an FASD: "railroad track" appearance of ear creases. (*Courtesy Darryl Leja, NHGRI, National Institutes of Health.*)

Table 146.1 Diagnostic Criteria for Fetal Alcohol Syndrome

ALL of the following, *with or without* documented prenatal alcohol exposure:

Facial features (Hoyme system requires two or more, 4-Digit Diagnostic Code requires all three):
- Palpebral fissures ≤10th percentile (Hoyme system) or ≤3rd percentile (4-Digit code)
- Thin upper lip (ranking of 4 or 5 on racially normed Lip-Philtrum Guide*)
- Smooth philtrum (ranking of 4 or 5 on racially normed Lip-Philtrum Guide*)

Prenatal and/or postnatal growth deficiency:
- Height and/or weight ≤10% for age and sex at any point of time (prenatal or postnatal)
- Adjust for gestational age if preterm. (4-Digit Diagnostic Code puts emphasis on short stature)

Deficient brain growth, abnormal brain formation or neurophysiology: one or more of following:
- Head circumference ≤10th % (Hoyme system) or ≤3rd percentile (4-Digit Diagnostic Code)
- Structural brain abnormalities
- Recurrent nonfebrile seizures with other causes excluded (Hoyme system)

Neurobehavioral impairment:
- For children <3 y/o: Developmental delay ≥1.5 SD below the mean
- For children 3 y/o or older (either of the following):
  - Cognitive impairment: Scores ≥1.5 SD below mean (Hoyme) or ≥2 SD below mean (4-Digit Diagnostic Code) either for global abilities or for at least one neurobehavioral domain (executive function, specific learning impairment, memory impairment, or visual-spatial impairment). The Hoyme system defines impairment domain as normal or abnormal. The 4-Digit Diagnostic Code has three domains defined: normal, moderate, severe.
  - Behavioral impairment without cognitive impairment: ≥1.5SD below mean in self-regulation (mood or behavioral regulation), attention deficit, or impulse control.

*The Hoyme system and the 4-Digit Diagnostic Code have different Lip-Philtrum Guides.
SD, Standard deviation.

INTERVENTIONS AND TREATMENTS

Given the heterogeneity of presenting problems associated with the FASDs, interventions need to be tailored to address each individual child's or adolescent's profile of strengths and difficulties. Studies support that the most successful interventions begin early and continue across the life span, include a preventive focus, are intensive and individualized, address multiple domains of functioning, include parent education and training, and are coordinated across systems of care.

Behavioral issues seen in children with FASD can be difficult for parents to manage and can cause significant stress within the home. These children often have impaired cause-and-effect understanding and therefore may not respond to traditional behavior modification strategies. Pediatricians can help support families by providing parenting tips suggested by the CDC, such as providing a structured environment and stable routines, using simple concrete language and lots of repetition, viewing the difficult behaviors as brain based rather than willful misbehavior, focusing on strengths, and providing an abundance of positive reinforcement. Specific programs include *Families Moving Forward* and *Parents and Children Together* teaching parents strategies designed to improve self-regulation and executive function, and decreasing child behavior problems. Children with FASD often have significant difficulties with social functioning, such as interpreting social cues and communicating in social settings. Programs such as *Children's Friendship Training* provides group-based, parent-assisted intervention that teaches social skills, which have been shown to improve standardized rating of social skills. Programs such as *Good Buddies* provide classes that address issues related to impaired social skills. Children with FASD may have decreased safety awareness, poor judgement, and impulsivity, which can place them at increased risk for unintentional injuries. A video-based intervention, *Fire and Street Safety,* was developed to address this. Children who participated showed significant improvement in safety-related knowledge and appropriate behavioral responses following the training and were also able to apply this training to real-world situations.

Young children with FASD are generally eligible for early intervention therapies (occupational therapy, physical therapy, speech therapy, and developmental instruction) and should be referred for these services as needed. Older children with an FASD often have difficulties with verbal and spatial learning, executive functioning, adaptive skills, social skills and peer relations, and mental health, which can interfere with academic performance. High rates of school failure and disruption are reported for this population. Difficulties with memory often require simplification of instructions, repetition, and patience. A home and school environment that is structured and predictable can also help to address this issue. To enhance generalizability of skills and to ensure they are encoded into memory, children with an FASD require consistent and predictable interventions, simplified directions, repeated instructions, and reduced distractions in the classroom. Classroom intervention programs such as *Cognitive Control Therapy* have been found to result in significant improvements in classroom behavior and academic achievement. Programs have also been developed that

Table 146.2 Diagnostic Criteria for Partial Fetal Alcohol Syndrome

- WITH documented prenatal alcohol exposure (requires A and B):
  - A. Facial features (at least two of three)
  - B. Neurobehavioral impairment (same as for FAS), i.e., leaves out brain abnormalities and growth deficiency
- WITHOUT documented prenatal alcohol exposure (requires A, B, and C):
  - A. Facial features (at least two of three)
  - B. Growth deficiency OR deficient brain growth/structural brain abnormalities/recurrent seizures (at least one of these)
  - C. Neurobehavioral impairment (same as for FAS), i.e., same as FAS except it is EITHER growth deficiency OR brain growth/structural brain abnormalities/recurrent seizures (does not require both)

Note that the diagnosis of FAS and pFAS are the only FASDs that can be diagnosed in the absence of a confirmed maternal history of PAE.

FAS, Fetal alcohol syndrome; FASD, fetal alcohol spectrum disorder; pFAS, partial fetal alcohol syndrome.

Table 146.3 Diagnostic Criteria for Alcohol-Related Neurodevelopmental Disorder

Requires A *and* B:

Note: *Cannot* be diagnosed definitively in children <3 yr old

A. Documented prenatal alcohol exposure

B. Neurobehavioral impairment:
- WITH cognitive impairment: Global delay OR deficit in at least TWO neurobehavioral domains (executive function, specific learning impairment, memory impairment, visual-spatial impairment)
- WITHOUT cognitive impairment: Behavioral deficit in at least TWO domains (behavioral regulation, attention, impulse control)

Table 146.4 Diagnostic Criteria for Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure

ND-PAE is a mental health disorder (rather than a medical disorder) included in the DSM-5 (2013) as a "new clarifying term" that encompasses the range of developmental disabilities associated with PAE that affect function and are not due to other conditions. This diagnosis requires:
- ≥1 deficit in neurocognition
- ≥2 deficits in adaptive functioning (at least one in communication or social communication and interaction)
- ≥1 deficit in self-regulation
- History of maternal consumption of more than 13 alcoholic drinks in any 30-day period of the pregnancy or more than 2 alcoholic drinks in one sitting
- Onset of the disorder in childhood
- The findings cause clinically significant distress or impairment in important areas of functioning and are not better explained by other causes (medication, medical conditions, genetic disorders, or environmental neglect)

Although the diagnosis of ND-PAE overlaps with ARND, ND-PAE aims to describe the *behavioral and mental health effects* on an individual with PAE. Unlike ARND, a diagnosis of ND-PAE can be given with or without the physical characteristics of FAS (ARND does not include physical characteristics) and the diagnosis of ND-PAE can be given in addition to FAS or pFAS.

ARND, Alcohol-related neurodevelopmental disorder; DSM, *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*; FAS, fetal alcohol syndrome; ND-PAE, neurobehavioral disorder associated with prenatal alcohol exposure; pFAS, partial fetal alcohol syndrome.

address specific areas of learning, such as *Language and Literacy Training Math Interactive Learning Experience*. A cognitive-based intervention, the *Alert Program* has been adapted to address self-regulation and executive function difficulties in children with FAS or ARND living in foster care or adoptive homes. A video game, *GoFar*, was developed by to address issues of self-regulation. An intervention that uses rehearsal training interventions has been shown to result in improvement in working memory. Children with FASD have been found to show deficits in adaptive functioning more significant than expected based on their cognitive testing. Occupational therapy to address this issue can help to decrease the significant level of supervision and support required of parents and caregivers.

Table 146.5 Alcohol-Related Birth Defects

This diagnosis refers to a pattern of structural birth defects and other congenital abnormalities that can be characteristic of FASD.

Requires both A *and* B

A. Documented prenatal alcohol exposure

B. One or more specific major malformations found to be the result of prenatal alcohol exposure:
- Cardiac: ASD, VSD, aberrant great vessels, conotruncal heart defects
- Skeletal: radioulnar synostosis, vertebral segmentation defects, large joint contractures, scoliosis
- Renal: kidney/ureteral malformations
- Eyes: strabismus, ptosis, retinal vascular abnormalities, optic nerve hypoplasia
- Ears: conductive or neurosensory hearing loss

ASD, Atrial septal defect; FASD, fetal alcohol spectrum disorder; VSD, ventricular septal defect.

There are no medications that are approved specifically for FASDs, but some medications may be used for symptom management. These can include stimulants (for hyperactivity, inattention, and poor impulse control), antidepressants, neuroleptics, and antianxiety drugs. Children with an FASD are often treated with a higher number of drugs and at higher doses, likely because of atypical or less favorable responses. Such atypical responses may require an adjustment in medication or discontinuation. Stimulant medication use in patients with FASD is controversial but is often considered, since there is a high prevalence of ADHD-like symptoms in this population. Stimulants can lead to some improvement in hyperactivity but may be less helpful for impulsivity and attention, and the rate of efficacy in general is not as high as in idiopathic ADHD. A diagnosis in the FASD spectrum should, in fact, be considered in a child with ADHD who has an atypical response to such medications. The efficacy of nonstimulant medications used for ADHD, such as alpha-2 agonists is being studied and may be shown to be helpful. Studies are also underway for use of choline supplementation and treatment with atomoxetine (a selective norepinephrine reuptake inhibitor). Data regarding the use of SSRI (selective serotonin reuptake inhibitors) medications, antipsychotics, and mood stabilizers are limited in terms of efficacy and safety.

THE PEDIATRICIAN/PRIMARY CARE PROVIDER'S ROLE

Pediatricians and other primary care providers need to document findings related to PAE and refer the child for a full evaluation. Indications for referral for further evaluation for FASD include confirmed history of significant PAE, concern raised by the caregiver about the possibility of FASD, all three facial features present, one or more facial features plus growth deficits, and one or more facial features along with one or more CNS abnormalities ± growth deficits. Evaluation for an FASD is best done by a multidisciplinary team that can provide a medical, genetic, and neuropsychologic assessment. This team might include a developmental behavioral pediatrician, psychologist/psychiatrist, geneticist, social worker, speech therapist, occupational therapist, physical therapist, and educational therapist/special education teacher. Evaluations by audiology and ophthalmology should be included if not already completed.

Once a diagnosis of an FASD is made, the pediatrician's/primary care providers role is important in establishing a medical home for the child that provides coordinated care between medical and mental health professionals, therapists, and educators who can help and support the child and family. The American Academy of Pediatrics (AAP) has developed an FASD toolkit (https://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/fetal-alcohol-spectrum-disorders-toolkit/Pages/default.aspx) that includes a "Flow Diagram for Medical Home Evaluation of Fetal Alcohol Spectrum Disorders" to assist primary care providers in identifying children with an FASD and managing their challenges in an effort to reduce the lifelong adverse consequences.

Chapter 147

Infants of Diabetic Mothers

Kesi C. Yang

Diabetes (type 1, type 2, or gestational) in pregnancy increases the risk of complications and adverse outcomes in the mother and the baby. Complications related to diabetes are milder in gestational vs pregestational (preexisting type 1 or type 2) diabetes. Pregnancy outcomes are correlated with onset, duration, and severity of maternal hyperglycemia. Preconception planning and tight glycemic control (hemoglobin A_{1c} [HbA_{1c}] <6.5%) is crucial in pregestational diabetes to achieve the best outcomes for the mother and the baby. The risk of **diabetic embryopathy** (neural tube defects, cardiac defects, caudal regression syndrome) and spontaneous abortions is highest in those with pregestational diabetes who have poor control (HbA_{1c} >7%) in the first trimester. The risk of congenital malformations in **gestational diabetes** is only slightly increased compared to the general population, because the duration of diabetes is less and hyperglycemia occurs later in gestation (typically >25 weeks).

Mothers with pregestational and gestational diabetes have a high incidence of complications during the pregnancy. Polyhydramnios, preeclampsia, preterm labor (induced and spontaneous), and chronic hypertension occur more frequently in mothers with diabetes. Accelerated fetal growth is also common, and 36–45% of **infants of diabetic mothers (IDMs)** are born large for gestational age (LGA). Restricted fetal growth is seen in mothers with pregestational diabetes and vascular disease, but it is less common. Fetal mortality rate is greater in both pregestational and gestational diabetic mothers than in nondiabetic mothers, but the rates have dropped precipitously over the years. Fetal loss throughout pregnancy is associated with poorly controlled maternal diabetes, especially **diabetic ketoacidosis**. The neonatal mortality rate of IDMs is >5 times that of infants of nondiabetic mothers and is higher at all gestational ages and in every birthweight for gestational age category. The rate is higher in women with pregestational diabetes, smoking, obesity, hypertension, and poor prenatal care.

PATHOPHYSIOLOGY

The probable pathogenic sequence is that maternal hyperglycemia causes fetal hyperglycemia, and the fetal pancreatic response leads to fetal hyperinsulinemia, or hyperinsulinism. It is important to recognize that while maternal glucose crosses the placenta, maternal and exogenous insulin does not. Fetal hyperinsulinemia and hyperglycemia then cause increased hepatic glucose uptake and glycogen synthesis, accelerated lipogenesis, and augmented protein synthesis (Fig. 147.1). Related pathologic findings are hypertrophy and hyperplasia of the pancreatic β cells, increased weight of the placenta and infant organs (except the brain), myocardial hypertrophy, increased amount of cytoplasm in liver cells, and extramedullary hematopoiesis. Hyperinsulinism and hyperglycemia produce fetal acidosis, which may result in an increased rate of stillbirth. Separation of the placenta at birth suddenly interrupts glucose infusion into the neonate without a proportional effect on hyperinsulinism, leading to hypoglycemia during the first few hours after birth. The risk of rebound hypoglycemia can be diminished by tight blood glucose control during labor and delivery.

Hyperinsulinemia has been documented in infants of mothers with pregestational and gestational diabetes. The infants of mothers with *pregestational* diabetes have significantly higher fasting plasma insulin levels than normal newborns, despite similar glucose levels, and respond to glucose with an abnormally prompt elevation in plasma insulin. After arginine administration, they also have an enhanced insulin response and increased disappearance rates of glucose compared with normal infants. In contrast, fasting glucose production and utilization rates are diminished in infants of mothers with *gestational* diabetes. Although hyperinsulinism is probably the main cause of hypoglycemia, the diminished epinephrine and glucagon responses that occur may be contributing factors. Infants of mothers with pregestational and gestational diabetes are at risk for neonatal hypoglycemia in the first hours of life, with an increased risk in both large- and small-for-gestational-age infants. Aggressive screening and treatment is recommended as outlined later.

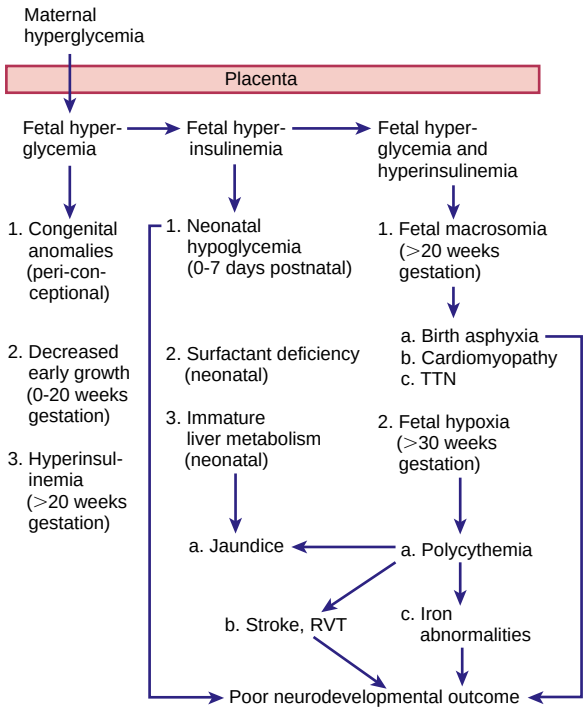

Fig. 147.1 The fetal and neonatal events attributable to fetal hyperglycemia *(column 1)*, fetal hyperinsulinemia *(column 2)*, or both in synergy *(column 3)*. Time of risk is denoted in parentheses. RVT, Renal vein thrombosis; TTN, transient tachypnea of the newborn. (*From Nold JL, Georgieff MK. Infants of diabetic mothers. Pediatr Clin North Am. 2004;51:619–637.*)

CLINICAL MANIFESTATIONS

Infants of mothers with pregestational diabetes and those of mothers with gestational diabetes often bear a surprising resemblance to each other (Fig. 147.2). They tend to be macrosomic as a result of increased body fat and enlarged viscera, with puffy, plethoric facies resembling those of patients who have been receiving corticosteroids. These infants may also be of normal birthweight if diabetes is well controlled or low birthweight if they are delivered before term or if their mothers have associated diabetic vascular disease. Infants that are macrosomic or LGA are at high risk of birth trauma (brachial plexus injury) and birth asphyxia because of not only their large size but also their decreased ability to tolerate stress, especially if they have cardiomyopathy and other effects of fetal hyperinsulinemia (Table 147.1).

Hypoglycemia develops in approximately 25–50% of infants of mothers with pregestational diabetes and 15–25% of infants of mothers with gestational diabetes, but only a small percentage of these infants become symptomatic. The probability that hypoglycemia will develop in such infants increases with higher cord or maternal fasting blood glucose levels. The nadir in an infant's blood glucose concentration is usually reached between 1 and 3 hours of age. Hypoglycemia can persist for 72 hours and in rare cases last up to 7 days. Frequent feedings can be used to treat the hypoglycemia, but some infants require intravenous (IV) dextrose.

Fig. 147.2 Macrosomic, plethoric infant of a mother with gestational diabetes. The baby was born at 38 weeks of gestation but weighed 9 lb, 11 oz (4,408 g). Mild respiratory distress was the only symptom other than appearance.

Table 147.1 Morbidity in Infants of Diabetic Mothers

Congenital anomalies
Heart failure and septal hypertrophy of heart
Surfactant deficiency, respiratory distress syndrome, transient tachypnea of the newborn, persistent pulmonary hypertension
Hyperbilirubinemia
Hypoglycemia, hypocalcemia, hypomagnesemia
Macrosomia, nerve injury related to birth trauma
Renal vein thrombosis
Small left colon
Unexplained intrauterine demise
Polycythemia
Visceromegaly
Predisposition to later-life obesity, insulin resistance, and diabetes

From Devaskar SU, Garg M. Disorders of carbohydrate metabolism in the neonate. In: Martin RJ, Fanaroff AA, Walsh MC, eds. *Fanaroff & Martin's Neonatal-Perinatal Medicine*, 10th ed. Philadelphia: Elsevier; 2015: Box 95-3.

The infants tend to be jittery, tremulous, and hyperexcitable during the first 3 days after birth, although hypotonia, lethargy, and poor feeding may also occur. Early appearance of these signs is more likely to be related to hypoglycemia but can also be caused by hypocalcemia and hypomagnesemia, which also occur in the first 24-72 hours of life due to delayed response of the parathormone system. Perinatal asphyxia is associated with increased irritability and also increases the risk of hypoglycemia, hypomagnesemia, and hypocalcemia.

Tachypnea develops in many IDMs during the first 2 days after birth and may be a manifestation of hypoglycemia, hypothermia, polycythemia, cardiac failure, transient tachypnea, or cerebral edema from birth trauma or asphyxia. IDMs have a higher incidence of **respiratory distress syndrome** (RDS) than do infants of nondiabetic mothers born at comparable gestational age. The greater incidence is likely related to an inhibitory effect of insulin on surfactant protein expression. **Polycythemia** often occurs with RDS as they are both a result of fetal hyperinsulinism.

Cardiomegaly is common, and heart failure occurs in 5–10% of IDMs. Interventricular septal hypertrophy may occur and may manifest as **transient idiopathic hypertrophic subaortic stenosis**. This is thought to result from chronic hyperglycemia and chronic hyperinsulinism leading to glycogen loading in the heart. Inotropic agents worsen the obstruction and are contraindicated. β-Adrenergic blockers have been shown to relieve the obstruction, but ultimately the condition resolves spontaneously over time.

Fig. 147.3 Caudal dysplasia sequence. Newborn male infant with a normal upper body and a short lower segment. (*Modified from Jones KL, Jones MC, Del Campo M, eds. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier; 2022: Fig. 1, p. 897.*)

Acute neurologic abnormalities (lethargy, irritability, poor feeding) can be seen immediately after birth. The symptoms will resolve with treatment of the underlying cause but may persist for weeks if caused by birth asphyxia. Neurologic development and ossification centers tend to be immature and to correlate with brain size (which is not increased) and gestational age rather than total body weight in infants of mothers with gestational and pregestational diabetes. In addition, IDMs have an increased incidence of hyperbilirubinemia, polycythemia, iron deficiency, and renal vein thrombosis. Renal vein thrombosis should be suspected in the infant with a flank mass, hematuria, and thrombocytopenia.

There is a fourfold increase in **congenital anomalies** in infants of mothers with pregestational diabetes, and the risk varies with HbA_{1c} during the first trimester when organogenesis occurs. The recommended goal for periconceptual HbA_{1c} is <6.5%. Although the risk of congenital malformations increases with increasing HbA_{1c} levels, there may still be an increased risk in the therapeutic goal range. Congenital anomalies of the central nervous system and cardiovascular system are most common, including failure of neural tube closure (encephalocele, meningomyelocele, and anencephaly), transposition of great vessels, ventricular septal defect (VSD), atrial septal defect (ASD), hypoplastic left heart, aortic stenosis, and coarctation of the aorta. Other less common anomalies include caudal regression syndrome (Fig. 147.3), intestinal atresia, renal agenesis, hydronephrosis, and cystic kidneys. **Small left colon syndrome** is a rare anomaly that develops in the second and third trimester because of rapid fluctuations in maternal and therefore fetal glucose, leading to impaired intestinal motility and subsequent intestinal growth. Prenatal ultrasound and a thorough newborn physical examination will identify most of these anomalies. High clinical

suspicion and a good prenatal history will help identify needed screening for subtle anomalies.

TREATMENT

Preventive treatment of IDMs should be initiated before birth by means of preconception and frequent prenatal evaluations of all women with preexisting diabetes and pregnant women with gestational diabetes. This involves evaluation of fetal maturity, biophysical profile with nonstress testing (NST), Doppler velocimetry, and planning of the delivery of IDMs in hospitals where expert obstetric and pediatric care is continuously available. Preconception glucose control reduces the risk of anomalies and other adverse outcomes in women with pregestational diabetes, and glucose control during labor reduces the incidence of neonatal hypoglycemia. Women with type 1 diabetes who have tight glucose control during pregnancy (average daily glucose levels <95 mg/dL and $HgbA_{1c}$ <6.5%, if safely achievable without hypoglycemia) deliver infants with birthweight and anthropomorphic features similar to those of infants of nondiabetic mothers. Treatment of gestational diabetes (diet, glucose monitoring, insulin, and oral antihyperglycemic treatment with metformin or glyburide as needed) decreases the rate of serious perinatal outcomes (death, shoulder dystocia, bone fracture, or nerve palsy). Continuous glucose monitoring has been increasingly used in pregnancy to achieve these purposes. In these mothers, the incidence of macrosomia and neonatal hypoglycemia is similar to that in mothers with insulin-treated gestational diabetes.

Regardless of size, IDMs should initially receive close observation and care. All infants should initiate feedings within 1 hour after birth. A screening glucose test should be performed no sooner than 30 minutes of life but no later than 2 hours and should be performed immediately in symptomatic infants. Defining precise glucose thresholds in neonates remains a challenge. The American Academy of Pediatrics (AAP) and the Pediatric Endocrine Society (PES) have both published guidelines based on observational data and expert opinion. These guidelines are adapted within individual institutions, with one example included in Figure 147.4. The AAP recommends maintaining a blood glucose level greater than 40 mg/dL (2.2 mmol/L) in the first 4 hours of life and greater than 45 mg/dL in the first 4 to 24 of life (2.5 mmol/L). In comparison, the PES recommends maintain a threshold of greater than 50 mg/dL (2.8 mmol/L) in the first 48 hours.

Feeding is the initial treatment for *asymptomatic* hypoglycemia. Oral or gavage feeding with breast milk or formula per maternal preference can be given. **Dextrose gel** has been shown to be a safe and

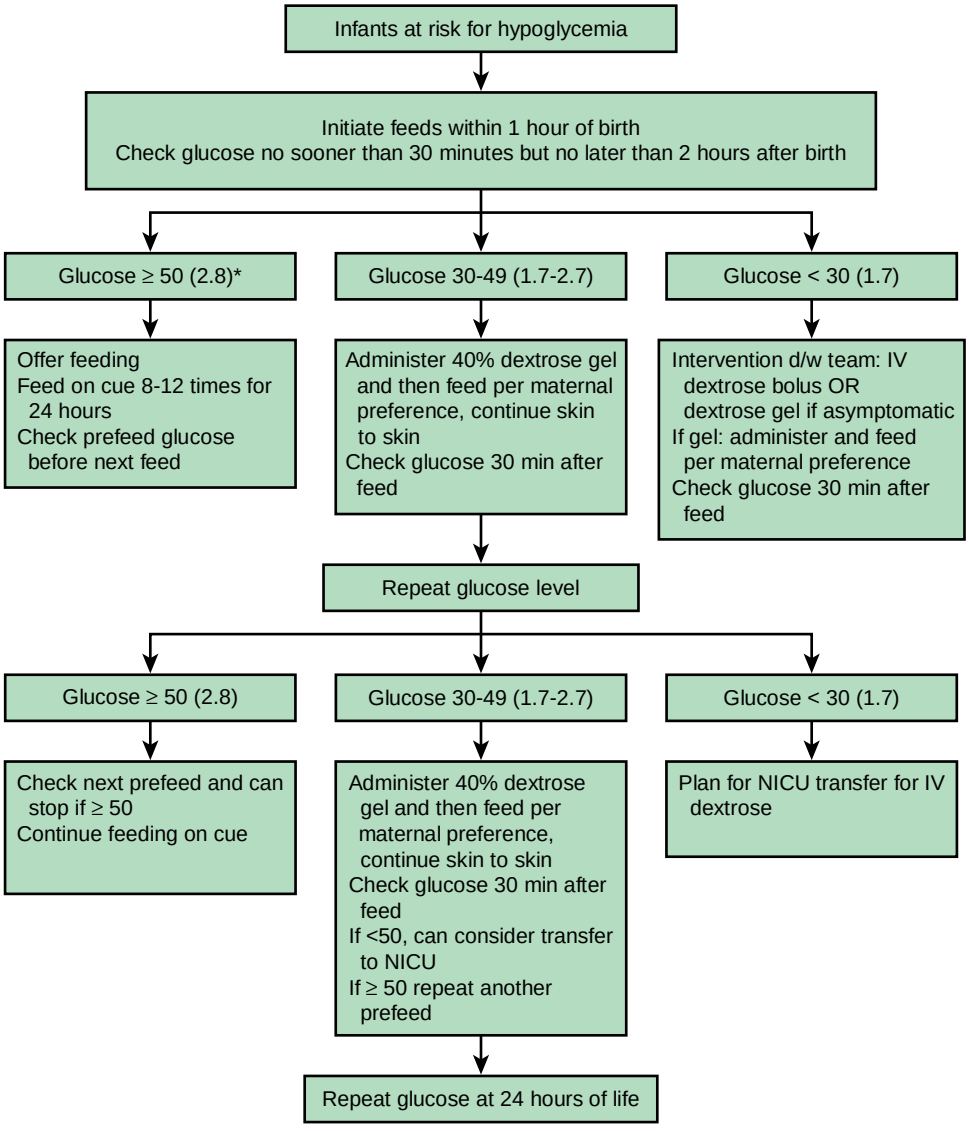

Fig. 147.4 Neonatal hypoglycemia algorithm at the Hospital of the University of Pennsylvania. This was derived from institutional consensus and meant to serve as a sample management protocol as there is no defined threshold for neonatal hypoglycemia in the first day of life. IV, Intravenous; NICU, neonatal intensive care unit. *Units are mg/dL (mmol/L).

effective adjunct to feeding and should be administered if available. Infants with *persistent* (and unresponsive to oral therapy) hypoglycemia should be treated with IV glucose (bolus followed by continuous infusion), especially if symptomatic. If question arises about an infant's ability to tolerate oral feeding, a continuous peripheral IV infusion at a rate of 4-8 mg/kg/min should be given. Neurologic symptoms of hypoglycemia *must* be treated with IV glucose. Bolus injections of hypertonic (25%) glucose should be avoided because they may cause further hyperinsulinemia and potentially produce rebound hypoglycemia (see Chapter 113). For treatment of hypocalcemia and hypermagnesemia, see Chapters 121.4 and 121.5; for RDS treatment, see Chapter 126; and for treatment of polycythemia, see Chapter 141.

PROGNOSIS

The subsequent incidence of diabetes mellitus in IDMs is higher than that in the general population because of genetic susceptibility in all types of diabetes. Infants of mothers with either pregestational diabetes or gestational diabetes are at risk for obesity and impaired glucose metabolism in later life as a result of intrauterine exposure to hyperglycemia. Disagreement persists about whether IDMs have a slightly increased risk of impaired intellectual development because of the many confounding factors (e.g., parental education, maternal age, neonatal complications). In general, the outcomes have improved over the last several decades due to increased awareness, screening, and improved prenatal care for pregnant women with diabetes.

Chapter 148

Epidemiology of Infections

Dustin D. Flannery

Neonatal infections are often classified by their timing relative to birth and include congenital, perinatal, early-onset, and late-onset disease. This categorization is clinically useful because infectious mechanisms, etiologies, and outcomes are fairly distinct for each, although there is some overlap between the different types. **Congenital infection** denotes infection acquired in utero. Such infections are often associated with injury to developing organs, depending on the timing of infection during gestation (see Chapter 149). **Perinatal infection** indicates acquisition around the time of delivery. Perinatally acquired organisms include both bacteria and viruses, some of which are the same as those causing congenital infection, but often manifest with different features. **Early-onset infection** occurs in the first 3 days after birth and is generally the consequence of infection caused by organisms acquired during the perinatal period. **Late-onset infection** occurs after 3 days and is caused by organisms that are typically acquired in the postnatal period. Notably, some studies categorize early-onset and late-onset infections as within the first 7 days of age and after 7 days, respectively, particularly for infants not continuously admitted to the hospital from birth, who are exposed to pathogens in the community.

Neonates are prone to infection for multiple reasons, namely because of their lack of fully responsive innate immunity (Fig. 148.1). Attenuated immune responses often result in minimal or nonspecific clinical manifestations, and effective treatment requires attention to subtle signs of infection and known risk factors. Compared with older infants, neonates are often treated empirically with systemic antimicrobials while awaiting results of laboratory investigations. Preterm infants are particularly susceptible to infection because of their decreased innate immune and barrier defenses, need for invasive medical devices such as central venous catheters, and prolonged hospitalizations. The term "neonatal sepsis" typically refers to culture-confirmed infection of the blood, cerebrospinal fluid, and/or urine, though definitions vary across studies.

INCIDENCE

Despite advances in maternal and neonatal care, infections remain a frequent and important cause of neonatal and infant morbidity and mortality. Neonatal infections are more common in areas with limited access to healthcare than in areas with a well-established healthcare infrastructure. Estimated incidence rates vary based on the case definition, geographical region, and the population studied. The overall global incidence of neonatal sepsis and other severe infections remains unknown given the lack of data from many countries, though the disease is common and often fatal. The global incidence is estimated at 2,824 cases per 100,000 live births; ~18% are fatal. For congenital infections, the incidence varies greatly depending on the specific infectious etiology and geographic region, though low- and middle-income countries have the greatest burden of disease.

The overall incidence of early-onset infection in the United States is approximately 1 per 1,000 live births and is dramatically higher among infants born preterm. The incidence varies significantly by gestational age (GA) and is highest among infants with a GA of 22 to 28 weeks (18.5 cases per 1,000 births). A 2021 report of over 84,000 very preterm infants at centers in the United States estimated the incidence of early-onset infection at 13.5 per 1,000 births; the incidence again varied substantially by GA (Table 148.1) and was highest for infants born <24 weeks (45.4 per 1,000 births). Similar to early-onset infection, late-onset infection incidence is inversely related to the degree of prematurity with significant variation across centers and geography. Among hospitalized newborns, 0.6–14% develop late-onset infection, with up to 40% of very preterm infants suffering from at least one episode.

MICROBIOLOGY

Infection microbiology is critically important to inform preventative strategies, as well as empiric and targeted antimicrobial therapies. A number of bacterial and nonbacterial pathogens can infect fetuses and newborns. Although there is overlap, pathogen types may be distinguished by timing of infection (Table 148.2).

The TORCH pneumonic, although not all-encompassing, is used to describe common causes of most often congenital or perinatal but also postnatal infection (see Table 148.2): toxoplasmosis, *Treponema pallidum* (syphilis), rubella, cytomegalovirus (CMV), herpes simplex virus (HSV), hepatitis B virus (HBV), hepatitis C virus (HCV), HIV, and other pathogens including parvovirus B19, varicella, and tuberculosis (TB). For pathogens causing congenital (prenatal), perinatal, and postnatal infection, modes of transfer include transplacental infection, exposure during labor and delivery through an infected or colonized birth canal, or from contact with an infected caretaker and/or infected breast milk (see Chapter 149). Some viral infections (e.g., CMV) can be substantial causes of disease whether acquired during gestation or acquired postpartum, whereas others (e.g., respiratory syncytial virus) are typically acquired only in the postnatal period (Fig. 148.2).

The two most common bacterial causes of **early-onset infection** are group B *Streptococcus* (GBS) and *Escherichia coli*; GBS is most common among term infants, whereas *E. coli* is the predominant pathogen among preterm infants. Approximately 30% of early-onset infections are caused by organisms other than GBS or *E. coli* (see Table 148.2). Coagulase-negative staphylococci (CONS) are the predominant cause of **late-onset infection** in hospitalized neonates, often accounting for 50–80%. Other common causes (see Table 148.2) include *Staphylococcus aureus*, gram-negative bacilli (*E. coli, Klebsiella* spp., *Enterobacter* spp., *Pseudomonas* spp.), and fungi (*Candida* spp.). In Asia and Africa additional pathogens cause early-onset sepsis (*Acinetobacter* spp., *Klebsiella pneumoniae*); these pathogens are often resistant to first-line antibiotics.

Microorganisms causing pneumonia acquired during labor and delivery include GBS, gram-negative enteric aerobes, *Listeria monocytogenes,*

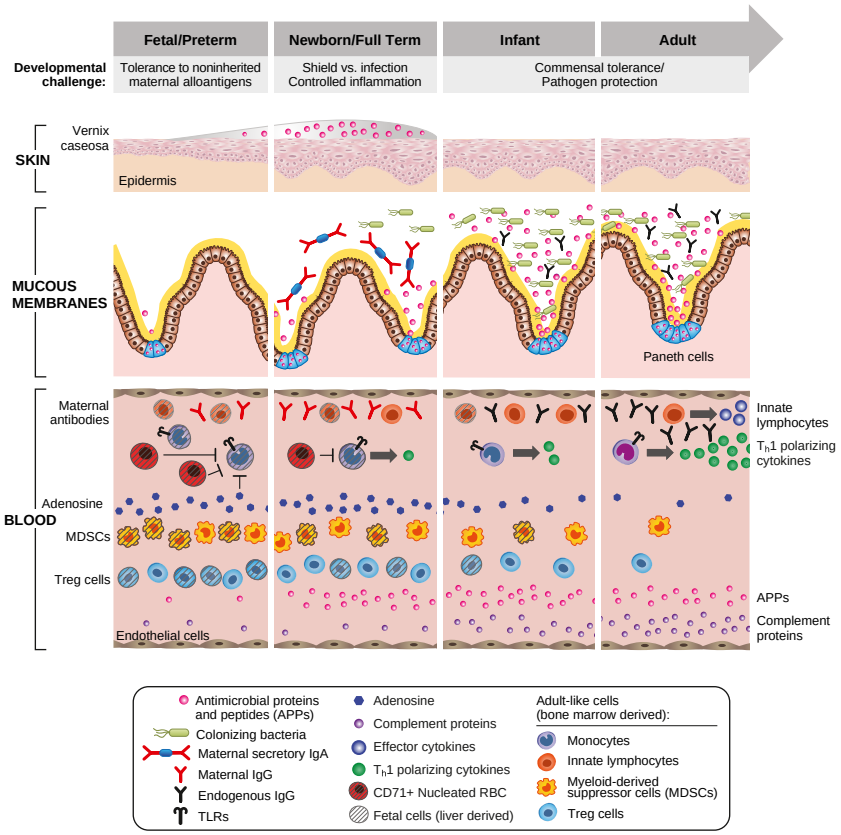

Fig. 148.1 Ontogeny of skin, soluble, and cellular innate defense systems. Host-protective barrier functions include physical, chemical, and functional components of the skin and mucous membrane epithelia of the fetus, neonate (birth to 28 days of age), and infant (1 month to 1 year of age). Skin: while physical and chemical barriers are impaired in early in life, especially in the preterm newborn, the vernix caseosa and skin epithelia of full-term newborns robustly express antimicrobial proteins and peptides (APPs). Mucous membranes: in parallel with and induced by an increasingly complex microbiota, the newborn intestinal mucosal epithelium rapidly changes structurally, with an increase in the population of crypts and crypt-based Paneth cells, as well as functionally with increasing APP expression. Blood: the composition of neonatal blood is distinct, with relatively low concentrations of complement components and APPs and high concentrations of the immunosuppressive purine metabolite adenosine. Plasma also contains maternal antibodies that are transferred beginning midgestation and supplemented by postnatal factors derived from breast milk. Innate immunity is detectable from the end of the first month of gestation, with changes driven largely by the increasing exposure to environmental microbes. Neonatal antigen-presenting cells such as blood monocytes express pattern recognition receptors (e.g., toll-like receptors [TLRs]) with distinct functional responses, including limited Th1-polarizing cytokine production, to most stimuli. Adaptive immunity develops from 4 weeks of gestation onward, with changes driven by an evolving chimerism reflecting fetal (liver-derived, *shaded cells*) regulatory T (Treg)-cell–rich lymphocytes, and more adultlike (bone marrow derived, *unshaded cells*) lymphocytes with distinct, epigenetically encoded functional programs. Ig, Immunoglobulin; RBC, red blood cell. *(Modified from Kollmann TR, Kampmann B, Mazmanian SK, et al. Protecting the newborn and young infant from infectious diseases: lessons from immune ontogeny. Immunity. 2007;46:350–363.)*

Table 148.1 Incidence of Early-Onset Infection Among Very Preterm Infants

CATEGORY	INCIDENCE RATE PER 1,000 BIRTHS (99% CI)
Overall	13.5 (12.5-14.6)
Gestational age, completed weeks	
≤23	45.4 (38.3-53.7)
24-25	26.0 (22.6-29.9)
26-27	15.5 (13.2-18.2)
28-29	10.1 (8.5-11.9)

Adapted from Flannery DD, Edwards EM, Puopolo KM, et al. Early-onset sepsis among very preterm infants. *Pediatrics.* 2021;148(4):e2021052456.

Mycoplasma, Chlamydia trachomatis, CMV, HSV, and *Candida* spp. (Table 148.3). The most common bacterial causes of neonatal meningitis are GBS, *E. coli, L. monocytogenes, Streptococcus pneumoniae,* other streptococci, *Haemophilus influenzae,* both coagulase-positive and coagulase-negative staphylococci, and other gram-negative bacilli. *Treponema pallidum* and TB infection involving the central nervous system (CNS) may also result in meningitis.

PATHOGENESIS

Early-Onset Infections

In most cases, the fetus or neonate is not exposed to potentially pathogenic bacteria until the membranes rupture and the infant passes through the birth canal and/or enters the extrauterine environment. The human birth canal is colonized with aerobic and anaerobic organisms that may result in ascending amniotic infection and/or

Table 148.2 Most Common Pathogens Causing Neonatal Infections, Grouped by Timing of Infection

CONGENITAL/PERINATAL
- Toxoplasmosis

LATE-ONSET
- Coagulase-negative staphylococci
- *Staphylococcus aureus*
- *Escherichia coli*
- *Candida* species
- *Enterococcus* species
- *Group B Streptococcus*
- *Klebsiella* species
- *Enterobacter* species
- *Pseudomonas* species
- Respiratory syncytial virus
- Herpes simplex virus
- Enteroviruses
- *Listeria monocytogenes*

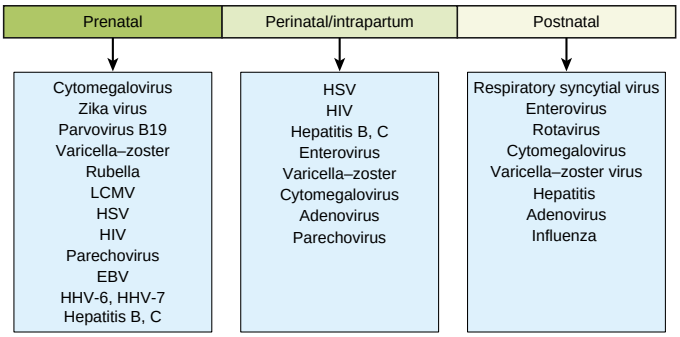

Fig. 148.2 Relative importance of neonatal viral infections related to the timing of acquisition of infection. Viruses are listed in declining order of importance relative to prenatal, perinatal (intrapartum), and postnatal timing of typical infection. Some neonatal virus infections (e.g., cytomegalovirus) can be substantial causes of disease whether acquired during gestation or acquired postpartum, whereas others (e.g., respiratory syncytial virus) are typically acquired in the postnatal period. EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus. *(From Schleiss MR, Marsh KJ. Viral infections of the fetus and newborn. In: Gleason CA, Juul SE, eds. Avery's Diseases of the Newborn. 10th ed. Philadelphia: Elsevier; 2018: Fig. 37.1.)*

colonization of the neonate at birth. Vertical transmission of agents that infect the amniotic fluid and vaginal canal, and contamination from the gastrointestinal tract, may occur in utero or, more often, during labor and delivery (Fig. 148.3).

Chorioamnionitis results from microbial invasion of amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane. Amniotic infection may also occur with apparently intact membranes or with a relatively brief duration of membrane rupture. The term *chorioamnionitis* refers to the clinical syndrome of intrauterine infection, which includes maternal fever, with or without local or systemic signs of chorioamnionitis (uterine tenderness, foul-smelling vaginal discharge/amniotic fluid, maternal leukocytosis, maternal and/or fetal tachycardia). Chorioamnionitis may also be asymptomatic, diagnosed only by amniotic fluid analysis or pathologic examination of the placenta. The rate of histologic chorioamnionitis is inversely related to GA at birth (Fig. 148.4) and directly related to duration of membrane

Table 148.3 Etiologic Agents of Neonatal Pneumonia According to Timing of Acquisition

rupture. Chorioamnionitis increases the risk of neonatal sepsis; however, most infants exposed to chorioamnionitis do not develop sepsis.

Chorioamnionitis was thought to result from infection of the amniotic fluid but is now better defined by the term *intrauterine inflammation* or *infection* at birth *(Triple I)*. This is defined by fetal tachycardia, maternal leukocytosis (>15,000 cells in the absence of corticosteroids), purulent fluid from the cervical os, biochemical or microbiologic amniotic fluid changes consistent with infection, and fever (≥39.0°C) (see Chapter 149.2).

Bacterial colonization does not always result in fetal or neonatal disease. Factors influencing which colonized infant will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies (Fig. 148.5). Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (apnea, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.

Resuscitation at birth, particularly if it involves endotracheal intubation, insertion of an umbilical vessel catheter, or both, is associated with an increased risk of bacterial infection. Explanations include the presence of infection at the time of birth or acquisition of infection during the invasive procedures associated with resuscitation.

Late-Onset Infections

After birth, neonates are exposed to infectious agents in the hospital or in the community (including family and caretakers). Postnatal infections may be transmitted by direct contact with hospital personnel, the mother, or other caretakers; from breast milk (e.g., HIV, CMV); or from inanimate sources such as contaminated equipment or surfaces. The most common source of postnatal infections in hospitalized newborns is *hand contamination* of healthcare personnel, underscoring the importance of hand hygiene. Contaminated milk, especially powdered formula *(Cronobacter sakazakii, Salmonella)*, equipment, other objects, or the environment are rare sources of neonatal infections but should be suspected during outbreaks of single organism disease.

Most cases of meningitis result from hematogenous dissemination. Less often, meningitis results from contiguous spread as a result of contamination of open neural tube defects, congenital sinus tracts, or penetrating wounds from fetal scalp sampling or internal fetal electrocardiographic monitors. Cerebral abscess formation, ventriculitis, septic infarcts, hydrocephalus, and subdural effusions are complications of meningitis that occur more often in newborn infants than in older children. Metabolic factors, including hypoxia, acidosis, hypothermia, and inherited metabolic disorders (e.g., galactosemia), are likely to contribute to risk for and severity of neonatal infection.

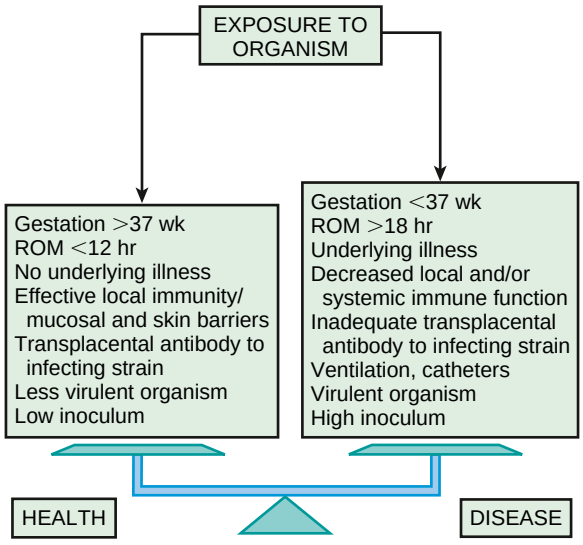

Fig. 148.5 Factors influencing the balance between health and disease in neonates exposed to a potential pathogen. ROM, Rupture of membranes. *(Adapted from Baker CJ. Group B streptococcal infections. Clin Perinatol 1997;24:59–70.)*

Infection in Premature Infants

The most important neonatal factors predisposing to infection are prematurity and low birthweight. Premature infants have a 3- to 10-fold higher incidence of infection than full-term normal birthweight infants. Possible explanations include the following: (1) maternal genital tract infection is considered to be an important cause of preterm labor, with an increased risk of vertical transmission to the newborn; (2) the frequency of intraamniotic infection is inversely related to GA (see Figs. 148.1 and 148.5); (3) premature infants have documented immune dysfunction; and (4) premature infants often require prolonged intravenous access, endotracheal intubation, or other invasive procedures that provide a portal of entry or impair barrier and clearance mechanisms, putting them at continued risk for hospital-acquired infections.

CLINICAL MANIFESTATIONS

The maternal history and circumstances of delivery provide important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired), and obstetric risk factors (prematurity, prolonged ruptured membranes, maternal chorioamnionitis). Signs and symptoms in the neonate are often subtle and nonspecific. Temperature instability, tachypnea, lethargy, apnea, and poor feeding are common initial signs and should raise suspicion for systemic or focal infection (Table 148.4).

Bacterial Sepsis

Neonates with bacterial sepsis may have either nonspecific manifestations or focal signs of infection (see Table 148.4), including temperature instability, hypotension, poor perfusion with pallor and mottled skin, metabolic acidosis, tachycardia or bradycardia, apnea, respiratory distress, grunting, cyanosis, irritability, lethargy, seizures, feeding intolerance, abdominal distention, jaundice, petechiae, purpura, and bleeding. Table 148.5 lists World Health Organization *international criteria* for sepsis. The initial manifestation may involve only limited symptomatology and only one system, such as apnea alone or tachypnea with retractions, or tachycardia, or the infant may present with an acute catastrophic manifestation

Table 148.4 Initial Signs and Symptoms of Infection in Newborn Infants

GENERAL	**CARDIOVASCULAR**
Fever, temperature instability	Pallor; mottling; cold, clammy skin
Hypothermia	Tachycardia
"Not doing well"	Hypotension
Poor feeding	Bradycardia
Edema	
GASTROINTESTINAL	**CENTRAL NERVOUS**
Abdominal distention	Irritability, lethargy
Vomiting	Tremors, seizures
Diarrhea	Hyporeflexia, hypotonia
Hepatomegaly	Abnormal Moro reflex
	Irregular respirations
RESPIRATORY	Full fontanel
Apnea, dyspnea	High-pitched cry
Tachypnea, retractions	
Flaring, grunting	**HEMATOLOGIC**
Cyanosis	Jaundice
	Splenomegaly
RENAL SYSTEM	Pallor
Oliguria	Petechiae, purpura
	Bleeding

Table 148.5 Clinical Criteria for the Diagnosis of Sepsis in the International Setting: IMCI and WHO Criteria for Severe Infections in Children

- *Neurologic:* Convulsions, drowsy or unconscious, decreased activity, bulging fontanel
- *Respiratory*: Respiratory rate >60 breaths/min, grunting, severe chest indrawing, central cyanosis
- *Cardiac*: Poor perfusion, rapid and weak pulse
- *Gastrointestinal*: Jaundice, poor feeding, abdominal distention
- *Dermatologic*: Skin pustules, periumbilical erythema or purulence
- *Musculoskeletal*: Edema or erythema overlying bones or joints
- Other: Temperature >37.7°C (99.9°F; or feels hot) or <35.5°C (95.9°F; or feels cold)

IMCI, Integrated Management of Childhood Illness; WHO, World Health Organization. Adapted from WHO. *Pocket Book Of Hospital Care for Children: Guidelines for the Management of Common Childhood Illnesses.* 2nd ed. Geneva: WHO. 2013. p 45–69. http://www.who.int/maternal_child_adolescent/documents/child_hospital_care/en/.

with multiorgan dysfunction and shock. Infants should be reevaluated over time to determine whether the symptoms have progressed from mild to severe. Later complications of sepsis include respiratory failure, pulmonary hypertension, cardiac failure, shock, renal failure, liver dysfunction, cerebral edema or thrombosis, adrenal hemorrhage and/or insufficiency, bone marrow dysfunction (neutropenia, thrombocytopenia, anemia), and disseminated intravascular coagulopathy (DIC).

A variety of noninfectious conditions can occur together with neonatal infection or can make the diagnosis of infection more difficult. Respiratory distress syndrome (RDS) secondary to surfactant deficiency can mimic and/or coexist with bacterial pneumonia in premature infants. Because bacterial sepsis can be rapidly progressive, the physician must be alert to the signs and symptoms of possible infection and must initiate diagnostic evaluation and empirical therapy in a timely manner for infants at risk. The differential diagnosis of many of the signs and symptoms that suggest infection is extensive; noninfectious disorders must also be considered (Table 148.6).

Systemic Inflammatory Response Syndrome

The clinical manifestations of infection depend on the virulence of the infecting organism and the body's inflammatory response. The term *systemic inflammatory response syndrome* (SIRS) is most frequently used to describe this unique process of infection and the subsequent systemic response (see Chapter 85). In addition to infection, SIRS may result from trauma, hemorrhagic shock, other causes of ischemia and inflammation, necrotizing enterocolitis, and pancreatitis.

Patients with SIRS have a spectrum of clinical symptoms that represent progressive stages of the pathologic process. In adults, SIRS is defined by the presence of two or more of the following: (1) fever or hypothermia, (2) tachycardia, (3) tachypnea, and (4) abnormal white blood cell (WBC) count or an increase in immature forms. In neonates and pediatric patients, SIRS manifests as temperature instability, respiratory dysfunction (altered gas exchange, hypoxemia, acute RDS), cardiac dysfunction (tachycardia, delayed capillary refill, hypotension), and perfusion abnormalities (oliguria, metabolic acidosis) (Table 148.7). Increased vascular permeability results in capillary leak into peripheral tissues and the lungs, with resultant peripheral and pulmonary edema. DIC results in the more severely affected cases. The cascade of escalating tissue injury may lead to multisystem organ failure and death.

There are neonates who appear to have sepsis or SIRS but no bacterial or viral pathogen has been recovered. Culture negative sepsis may be due to a hard-to-culture bacteria (anaerobes) or virus, as well as noninfectious inflammatory conditions. In addition, an undetected localized source with transient bacteremia (osteomyelitis), prior antibiotic treatment, and poor culture technique (too small blood sample for culture may miss bacteremia) may be responsible.

Table 148.6 Serious Systemic Illness in Newborns: Differential Diagnosis of Neonatal Sepsis

CARDIAC
Congenital: hypoplastic left heart syndrome, other structural disease, persistent pulmonary hypertension of the newborn (PPHN)
Acquired: myocarditis, hypovolemic or cardiogenic shock, PPHN

GASTROINTESTINAL
Necrotizing enterocolitis
Spontaneous gastrointestinal perforation
Midgut volvulus
Hepatic failure (inborn errors of metabolism, neonatal iron storage disease)

HEMATOLOGIC
Neonatal purpura fulminans
Immune-mediated thrombocytopenia
Immune-mediated neutropenia
Severe anemia
Malignancies (congenital leukemia)
Langerhans cell histiocytosis
Hereditary clotting disorders
Familial hemophagocytic lymphohistiocytosis

METABOLIC
Hypoglycemia
Adrenal disorders: adrenal hemorrhage, adrenal insufficiency, congenital adrenal hyperplasia
Inborn errors of metabolism: organic acidurias, lactic acidoses, urea cycle disorders, galactosemia

NEUROLOGIC
Intracranial hemorrhage: spontaneous, caused by child abuse
Hypoxic-ischemic encephalopathy
Neonatal seizures
Infant botulism

RESPIRATORY
Respiratory distress syndrome
Aspiration pneumonia: amniotic fluid, meconium, or gastric contents
Lung hypoplasia
Tracheoesophageal fistula
Transient tachypnea of the newborn

Table 148.7 Definitions of Systemic Inflammatory Respiratory Response Syndrome (SIRS) and Sepsis in Pediatric Patients

SIRS: The systemic inflammatory response to a variety of clinical insults, manifested by two or more of the following conditions:
Temperature instability <35°C (95°F) or >38.5°C (101.3°F)
Respiratory dysfunction:
  Tachypnea >2 SD above the mean for age
  Hypoxemia (Pa_{O_2} <70 mm Hg on room air)
Cardiac dysfunction:
  Tachycardia >2 SD above the mean for age
  Delayed capillary refill >3 sec
  Hypotension >2 SD below the mean for age
Perfusion abnormalities:
  Oliguria (urine output <0.5 mL/kg/hr)
  Lactic acidosis (elevated plasma lactate and/or arterial pH <7.25)
  Altered mental status
Sepsis: The systemic inflammatory response to an infectious process

SD, Standard deviation.
From Adams-Chapman I, Stoll BJ. Systemic inflammatory response syndrome. *Semin Pediatr Infect Dis.* 2001;12:5–16.

Temperature Instability

Fever or hypothermia may be the only initial manifestation of serious infection in newborns. However, only approximately 50% of infected newborn infants have a temperature >37.8°C (see Chapter 220). Fever in newborn infants does not always signify infection; it may be caused

by increased ambient temperature, isolette or radiant warmer malfunction, dehydration, CNS disorders, hyperthyroidism, familial dysautonomia, or ectodermal dysplasia. A single temperature elevation is infrequently associated with infection; sustained fever is more likely to be caused by infection. Most febrile infected infants have additional signs compatible with infection, although a focus of infection is not always apparent. Acute febrile illnesses occurring later in the neonatal period may be caused by urinary tract infection, meningitis, pneumonia, osteomyelitis, or gastroenteritis and viral infections (enteroviruses, others) in addition to sepsis, thus underscoring the importance of a diagnostic evaluation that includes blood culture, urine culture, lumbar puncture (LP), and other studies as indicated. Numerous pathogens may cause these late infections (see Table 148.2), including HSV, enteroviruses, respiratory syncytial virus, and bacterial organisms. In premature infants, hypothermia or temperature instability requiring increasing ambient (isolette, warmer) temperatures is more likely to accompany infection.

Respiratory and Cardiovascular Symptoms

Early signs and symptoms of pneumonia may be nonspecific, including poor feeding, lethargy, irritability, cyanosis, temperature instability, and the overall impression that the infant is not well. Respiratory symptoms of increasing severity include grunting, tachypnea, retractions, nasal flaring, cyanosis, apnea, and progressive respiratory failure. If the infant is premature, signs of progressive respiratory distress may be *superimposed* on RDS or bronchopulmonary dysplasia (BPD). For mechanically ventilated infants, the need to increase ventilator support may indicate infection. Although a common finding in neonatal sepsis, tachycardia is nonspecific. Bradycardia may also occur. Poor perfusion and hypotension are more sensitive indicators of sepsis but tend to be late findings. In a prospective national surveillance study, 40% of neonates with sepsis required volume expansion, and 29% required vasopressor support.

Signs of pneumonia on physical examination, such as dullness to percussion, change in breath sounds, and the presence of rales or rhonchi, are very difficult to appreciate in a neonate. Radiographs of the chest may reveal new infiltrates or an effusion, but if the neonate has underlying RDS or BPD, it is very difficult to determine whether the radiographic changes represent a new process or worsening of the underlying disease.

The progression of neonatal pneumonia can be variable. Fulminant infection is most frequently associated with pyogenic organisms such as GBS (see Chapter 230). Onset may occur during the first hours or days of life, with the infant often manifesting rapidly progressive circulatory collapse and respiratory failure. With early-onset pneumonia in premature infants, the clinical course and chest radiographs may be indistinguishable from those with severe RDS, particularly for GBS pneumonia.

In contrast to the rapid progression of pneumonia caused by pyogenic organisms, an indolent course may be seen in nonbacterial infection. The onset can be preceded by upper respiratory tract symptoms or conjunctivitis. The infant may demonstrate a nonproductive cough, and the degree of respiratory compromise is variable. Fever is usually absent or low grade, and radiographic examination of the chest shows focal or diffuse interstitial pneumonitis or hyperinflation. Infection can be caused by *C. trachomatis,* CMV, *Ureaplasma urealyticum,* and other respiratory viruses. Rhinovirus has been reported to cause severe respiratory compromise in infants, particularly those who are preterm.

Conjunctivitis

Conjunctival infection is relatively common and may be caused by a variety of organisms. The presentation includes periorbital swelling, conjunctival injection, and purulent conjunctival drainage. *C. trachomatis* and *Neisseria gonorrhoeae* are common causes; other gram-positive and gram-negative organisms are occasionally involved. *Pseudomonas aeruginosa* is an important pathogen in hospitalized preterm infants and may be a precursor to invasive disease. Viral infections (e.g., HSV, adenovirus) are occasionally seen. Recognition of HSV infection is important to prevent corneal injury and dissemination to systemic sites.

Skin and Soft Tissue Infection

Cutaneous manifestations of infection include omphalitis, cellulitis, mastitis, and subcutaneous abscesses. Pustules likely indicate the presence of staphylococcal infection but must be distinguished from the vesicular rash of HSV infection. Staphylococcal pustulosis results in larger, pus-filled lesions often scattered around the umbilicus, whereas HSV infection often appears as tiny vesicles in crops, often on the scalp. The presence of small, salmon-pink papules suggests *L. monocytogenes* infection. Mucocutaneous lesions suggest *Candida* spp. (see Chapter 280.1). Petechiae and purpura may be the result of systemic viral or bacterial infection. Neonatal **mastitis** is caused by *S. aureus* and in an otherwise well appearing afebrile neonate is a localized infection.

Omphalitis

Omphalitis is a neonatal infection resulting from unhygienic care of the umbilical cord, which continues to be a problem, particularly in developing countries. The umbilical stump is colonized by bacteria from the maternal genital tract and the environment (see Chapter 144). The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, and the liver. Abdominal wall cellulitis or necrotizing fasciitis, with associated sepsis and a high mortality rate, may develop in infants with omphalitis. Prompt diagnosis and treatment are necessary to avoid serious complications. *S. aureus* and gram-negative organisms are common involved pathogens.

Tetanus

Neonatal tetanus remains a serious infection in resource-limited countries (see Chapter 257). It results from unclean delivery and unhygienic management of the umbilical cord in an infant born to a mother who has not been immunized against tetanus. The surveillance case definition of neonatal tetanus requires the ability of a newborn to suck at birth and for the first few days of life, followed by an inability to suck. Neonatal tetanus typically occurs in infants 5-7 days after birth (range: 3-24 days) and is complicated by difficulty swallowing, spasms, stiffness, seizures, and death. Bronchopneumonia, presumably resulting from aspiration, is another complication and cause of death. Neonatal tetanus can be prevented by immunizing mothers before or during pregnancy and by ensuring a clean delivery, sterile cutting of the umbilical cord, and proper cord care after birth.

LABORATORY FINDINGS

Maternal history and infant signs should guide diagnostic evaluation (Table 148.8). Additionally, signs of systemic infection in newborn infants may be unrevealing, so laboratory investigation plays a particularly important role in diagnosis. Cultures and cell counts are obtained from blood and urine. Cerebrospinal fluid (CSF) should be sent for Gram stain, routine culture, cell count with differential, and protein/glucose concentrations. Surface swabs, blood, and CSF are often obtained for HSV testing. Except for culture and directed pathogen testing, no single laboratory test is completely reliable for diagnosis of invasive infection in the newborn. CBC may demonstrate elevated or decreased WBC count, often with a shift toward more immature forms. Thrombocytopenia can be seen in systemic bacterial, fungal, or viral infection. Hyponatremia, acidosis, and other electrolyte abnormalities can be seen. Hyperbilirubinemia is nonspecific but may be an indication of systemic infection, particularly of the urine tract. Elevated serum transaminases may be a clue to systemic HSV, enterovirus, or other viral infection.

Various **serum biomarkers** have been investigated for their ability to identify infants with serious bacterial infection (SBI). An immature-to-total phagocyte count (I/T ratio) (≥0.2) has the best sensitivity of the neutrophil indices for predicting neonatal sepsis. After the newborn period, serum C-reactive protein (CRP), procalcitonin, and ferritin have demonstrated reasonable sensitivity and specificity for SBI.

Table 148.8 Evaluation of a Newborn for Infection or Sepsis

HISTORY (SPECIFIC RISK FACTORS)
Maternal infection during gestation or at parturition (type and duration of antimicrobial therapy):
Urinary tract infection
Chorioamnionitis
Maternal colonization with group B *Streptococci*, *Neisseria gonorrhoeae*, herpes simplex
Low gestational age/birthweight
Multiple birth
Duration of membrane rupture
Complicated delivery
Fetal tachycardia (distress)
Age at onset (in utero, birth, early postnatal, late)
Location at onset (hospital, community)
Medical intervention:
Vascular access
Endotracheal intubation
Parenteral nutrition
Surgery
EVIDENCE OF OTHER DISEASES*
Congenital malformations (heart disease, neural tube defect)
Respiratory tract disease (respiratory distress syndrome, aspiration)
Necrotizing enterocolitis
Metabolic disease (e.g., galactosemia)
EVIDENCE OF FOCAL OR SYSTEMIC DISEASE
General appearance, neurologic status
Abnormal vital signs
Organ system disease
Feeding, stools, urine output, extremity movement
LABORATORY STUDIES
Evidence of Infection
Culture from a normally sterile site (blood, CSF, other)
Demonstration of a microorganism in tissue or fluid
Molecular detection (blood, urine, CSF) by specific PCR and/or 16S ribosomal DNA
Maternal or neonatal serology (syphilis, toxoplasmosis)
Evidence of Inflammation
Leukocytosis, increased immature/total neutrophil count ratio
Acute-phase reactants: C-reactive protein, erythrocyte sedimentation rate, procalcitonin, ferritin
Cytokines: interleukin-6, interleukin-B, tumor necrosis factor
Pleocytosis in CSF or synovial or pleural fluid
Disseminated intravascular coagulation: fibrin degradation products, D-dimer
Evidence of Multiorgan System Disease
Metabolic acidosis: pH, P_{CO_2}
Pulmonary function: P_{O_2}, P_{CO_2}
Renal function: blood urea nitrogen, creatinine
Hepatic injury/function: bilirubin, alanine transaminase, aspartate transaminase, ammonia, prothrombin time, partial thromboplastin time
Bone marrow function: neutropenia, anemia, thrombocytopenia

*Diseases that increase the risk of infection or may overlap with signs of sepsis.
CSF, Cerebrospinal fluid; PCR, polymerase chain reaction.

CRP may be monitored serially in newborn infants to assess response to therapy. Their value in the initial diagnosis of sepsis in the newborn period has yet to be clarified. The American Academy of Pediatrics (AAP) Committee on the Fetus and Newborn reiterated in a 2018 early-onset sepsis guideline update that lab tests alone should not be used to diagnose sepsis. Cytokines (both proinflammatory cytokines such as interleukin [IL]-6 and tumor necrosis factor-α and antiinflammatory cytokines such as IL-4 and IL-10), chemokines, and other biomarkers are increased in infected infants.

Tables 148.8 and 148.9 list clinical features and laboratory parameters that are useful in the diagnosis of neonatal infection or sepsis.

GENERAL APPROACH TO MANAGEMENT

In the absence of specific signs of focal infection, therapy for presumed infection in the neonate is often empirical and initiated on the basis of fever or hypothermia, listlessness, irritability, or apneic episodes. Antibiotics are chosen to cover the organisms typically causing neonatal sepsis, including GBS, gram-negative organisms, *Listeria*, and *Enterococcus*. Because the latter two organisms are intrinsically resistant to cephalosporins, ampicillin is generally included in the empirical treatment of infants with presumed neonatal infection (Table 148.10). Initiation of antibiotics within 1 hour of onset is recommended and has a survival advantage.

An empirical regimen for suspected **early-onset infection** in a term or late preterm infant includes ampicillin and gentamicin. This has long been a standard regimen for early-onset sepsis and provides coverage for the most prevalent organisms, predominantly GBS and *E. coli*. Resistance of *E. coli* to ampicillin or gentamicin has been reported; approximately 1 in 10 isolates are resistant to both ampicillin and gentamicin. Ampicillin plus cefotaxime (if available) or cefepime may be substituted if the patient presents with infection after discharge from the nursery, or when infection with resistant *E. coli* is suspected. Ceftriaxone is typically not used in the neonatal period due to precipitation with intravenous calcium and displacement of bound bilirubin causing hyperbilirubinemia. There is concern that cephalosporins may be associated with higher rates of mortality in neonates compared to ampicillin and gentamicin. Alterations to the standard regimen may be appropriate in some circumstances, such as for critically ill newborns, with illness out of proportion to degree of prematurity, at highest risk of infection given maternal risk factors and delivery characteristics.

HSV infection may present without cutaneous signs, in the absence of maternal history of infection, and in mothers receiving suppressive antiviral therapy. Therefore management of the ill newborn requires a high index of suspicion for HSV infection. Surface swabs, blood, and CSF are obtained for HSV culture or polymerase chain reaction (PCR), and empirical acyclovir is often recommended while the results of these studies are pending (see Chapters 220 and 299).

Systemic infection caused by *Candida* spp. is a concern in hospitalized infants, particularly extremely preterm infants with central venous access catheters and prior antibiotic and steroid exposure. Empirical therapy for fungal infection may be indicated for those at highest risk, as well as those with specific clinical signs such as erythematous rash, thrombocytopenia, hyperglycemia, and invasive devices.

Definitive therapy is based on identification and susceptibility of the offending organism. In almost all circumstances, the *narrowest* antibiotic with activity against the organism is chosen. Duration of therapy depends on the organism and the site of infection. In neonates with culture-proven sepsis, the usual course of therapy is typically 7-10 days. Longer treatment courses may be warranted if a specific focus of infection is identified (e.g., meningitis, osteomyelitis, septic arthritis). Antimicrobial therapy should be altered based on the susceptibility profile of the pathogen isolated. In infants with a negative blood culture but a clinical status that remains concerning for a systemic inflammation, other etiologies and potential focal sources of infection should be investigated. Sepsis is unlikely in these infants if appropriately obtained blood cultures are sterile by 48 hours.

PREVENTION

Intrapartum antibiotics are used to reduce vertical transmission of GBS (Table 148.11), as well as to lessen neonatal morbidity associated with preterm labor and preterm premature rupture of membranes (see Chapter 230). With introduction of selective intrapartum antibiotic prophylaxis to prevent perinatal transmission of GBS, rates of early-onset neonatal GBS infection in the United States declined from 1.7/1,000 live births to 0.25/1,000. Intrapartum chemoprophylaxis does *not* reduce the rates of late-onset GBS disease and has no effect on the rates of infection with non-GBS pathogens. Of concern is a possible increase in gram-negative infections (especially *E. coli*) despite a reduction in early GBS sepsis by intrapartum antibiotics.

Table 148.9 Culture-Based and Non–Culture-Based Diagnostics for Neonatal Sepsis

CATEGORY	PARAMETER	OPTIMAL TIMING, VOLUME OF SPECIMEN, ROUTINE/INVESTIGATIONAL*	APPLICABILITY FOR NEONATAL SEPSIS
CULTURE BASED			
Blood	Culture	>1 mL of whole blood, from two sites	Gold standard for bacteremia
CSF	Culture	When clinically feasible	Gold standard for bacterial meningitis
Urine	Culture	>72 hr of life	Not useful for EOS; indicated for LOS evaluation
Tracheal aspirate	Culture	Neonates with endotracheal tube in place and signs of progressive respiratory distress	Usually reflects colonization
NON–CULTURE BASED			
Neutrophil indices	Neutropenia Absolute neutrophil count Absolute immature neutrophil count	After 12 hr of life Consider GA, delivery mode, altitude, arterial versus venous sampling, time since birth	Neutropenia better predictor for sepsis than leukocytosis
Neutrophil markers	CD64	Elevated for 24 hr after infection Requires 50 μL blood Results within hours Investigational	Cut points between 2.38 and 3.62 optimal sensitivity, specificity, and NPV for EOS
Platelet count	Thrombocytopenia and thrombocytosis	Late findings; slow to respond	Thrombocytopenia associated with fungal infection
CSF cell count	CSF WBC	Uninfected neonates: mean 10 cells/mm^3; range up to 20 cells/mm^3	Does not predict culture-proven meningitis
CSF chemistries	CSF protein CSF glucose	Term <100 mg/dL Preterm higher; 70–80% of serum glucose	Elevated in fungal meningitis Low glucose specific for bacterial meningitis
Acute phase reactants	CRP Procalcitonin	8-24 hr after infection 2-12 hr after infection	Good NPV Better sensitivity but less specificity than CRP

**Investigational* refers to an assay or parameter that is undergoing evaluation for clinical use and applicability.
CSF, Cerebrospinal fluid; EOS, early-onset sepsis; GA, gestational age; LOS, late-onset sepsis; MHC II, major histocompatibility complex class II; NPV, negative predictive value; TNF, tumor necrosis factor; WBC, white blood cell count.
From Shane AL, Stoll BJ. Recent developments and current issues in the epidemiology, diagnosis, and management of bacterial and fungal neonatal sepsis. *Am J Perinatol.* 2013;30(2):131–141.

Aggressive management of suspected maternal chorioamnionitis with antibiotic therapy during labor, along with rapid delivery of the infant, reduces the risk of early-onset neonatal sepsis. Vertical transmission of GBS and early-onset GBS disease is significantly reduced by selective intrapartum chemoprophylaxis (see Fig. 230.4) but does still occur. Neonatal infection with *Chlamydia* can be prevented by identification and treatment of infected pregnant women (see Chapter 272). Mother-to-child transmission of HIV is significantly reduced by maternal antiretroviral therapy during pregnancy, labor, and delivery, by cesarean delivery before rupture of membranes, and by antiretroviral treatment of the infant after birth (see Chapter 322).

Prevention of congenital and perinatal infections predominantly focuses on maternal health. The Centers for Disease Control and Prevention (CDC) recommends the following screening tests and treatment when indicated:

1. All pregnant women should be offered voluntary and confidential HIV testing at the first prenatal visit, as early in pregnancy as possible. HIV screening should be part of routine prenatal testing, unless the mother declines testing (opt-out screening). For women at high risk of infection during pregnancy (multiple sexual partners or STIs during pregnancy, intravenous drug use, HIV-infected partners), repeat testing in the third trimester is recommended. Rapid HIV screening is indicated for any women who presents in labor with an undocumented HIV status, unless she declines testing.
2. A serologic test for syphilis should be performed on all pregnant women at the first prenatal visit. Repeat screenings early in the third trimester and again at delivery are recommended for women in whom syphilis test results in the first trimester were positive and for those at high risk for infection during pregnancy. Infants should not be discharged from the hospital unless the syphilis status of the mother has been determined at least once during pregnancy and preferably again at delivery.
3. Serologic testing for hepatitis B surface antigen (HBsAg) should be performed at the first prenatal visit, even if the woman has been previously vaccinated or tested. Women who were not screened prenatally, those who are at high risk for infection (multiple sexual partners, intravenous drug use, HBsAg-positive sex partner), and those with clinical hepatitis should be retested at the time of delivery.
4. A maternal genital culture for *C. trachomatis* should be performed at the first prenatal visit. Young women (<25 years) and those at increased risk for infection (new or multiple partners during pregnancy) should be retested during the third trimester.
5. A maternal culture for *N. gonorrhoeae* should be performed at the first prenatal visit. Those at high risk for infection should be retested in the third trimester.
6. All pregnant women at high risk for hepatitis C infection (intravenous drug use, blood transfusion or organ transplantation before 1992) should be screened for hepatitis C antibodies at the first prenatal visit.
7. Evidence does not support routine testing for bacterial vaginosis in pregnancy. For asymptomatic women at high risk for preterm delivery, testing may be considered. Symptomatic women should be tested and treated.
8. The CDC recommends universal screening for vaginorectal GBS colonization of all pregnant women at 36 0/7 and 37 6/7 weeks of gestation and a screening-based approach to selective intrapartum antibiotic prophylaxis against GBS (see Table 148.11) (see Figs. 230.2 and 230.3).

Table 148.10 Management and Prevention of Neonatal Sepsis

CONDITION	THERAPY	ADDITIONAL CONSIDERATIONS
EMPIRICAL MANAGEMENT		
Early-onset sepsis	Ampicillin + aminoglycoside 10 days for bacteremia; 14 days for GBS and uncomplicated meningitis; extend to 21-28 days for complicated infections	• Consider a third-generation cephalosporin or carbapenem for meningitis or severe illness with high suspicion for gram-negative infection • Tailor therapy to pathogen • Should discontinue empiric therapy if pathogen not isolated
Late-onset sepsis	Vancomycin or antistaphylococcal penicillin (i.e., nafcillin, oxacillin) + aminoglycoside Duration dependent on pathogen and site	• Gram-positive coverage should be based on local epidemiology, MRSA colonization, CONS risk factors, and clinical presentation • Aminoglycoside-based regimen preferred to cephalosporin given reduced risk of resistance • Consider cephalosporin if meningitis suspected • Consider a carbapenem if third-generation cephalosporin recently received • Consider amphotericin for fungal etiologies • Tailor therapy to pathogen • Consider discontinuation of therapy if pathogen not isolated
NONANTIMICROBIAL TREATMENT STRATEGIES		
Recombinant G-CSF Recombinant GM-CSF	Enhance neutrophil number and function, but no reduction in infection when administered as prophylaxis or improvement in survival when administered as therapy	Insufficient evidence to support the clinical use of G-CSF or GM-CSF either as treatment or prophylaxis to prevent systemic infections
IVIG	Augments antibody-dependent cytotoxicity and improves neutrophilic function, *but* no evidence that IVIG in suspected or proven sepsis reduces death	Insufficient evidence from 10 RCTs or quasi-RCTs to support use in neonates with confirmed or suspected sepsis
PREVENTION STRATEGIES		
IAP	Administration of penicillin or ampicillin 4 hr before parturition	Successfully reduces rates of EOS caused by GBS No effect on LOS GBS
Fluconazole prophylaxis	Administration of weight-based dosing to neonates <1,500 g	Most beneficial in NICUs with high baseline rates of invasive candidiasis
BLF supplementation with a probiotic, *Lactobacillus rhamnosus* (GG)	BLF is a human milk glycoprotein with a role in innate immune response LGG enhances the activity of lactoferrin	BLF supplementation with and without LGG reduced the incidence of 1st LOS in 472 VLBW neonates in large randomized, double-blind RCT Additional confirmatory studies warranted

BLF, Bovine lactoferrin supplementation; CONS, coagulase-negative staphylococci; EOS, early-onset sepsis; GBS, group B *Streptococcus*; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IAP, intrapartum antimicrobial prophylaxis; IVIG, intravenous immunoglobulin, LGG, *Lactobacillus rhamnosus* GG; LOS, late-onset sepsis; MRSA, methicillin-resistant *Staphylococcus aureus*; NICU, neonatal intensive care unit; RCTs, randomized controlled trials; VLBW, very low birthweight.

Table 148.11 Indications for Intrapartum Antibiotic Prophylaxis to Prevent Early-Onset Group B *Streptococcus* Disease

INTRAPARTUM GBS PROPHYLAXIS INDICATED	INTRAPARTUM GBS PROPHYLAXIS NOT INDICATED
Previous infant with invasive GBS disease	Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
GBS bacteriuria during any trimester of the current pregnancy	GBS bacteriuria during previous pregnancy (unless another indication for GBS prophylaxis is present for current pregnancy)
Positive GBS screening culture during current pregnancy (unless a cesarean delivery is performed before onset of labor or amniotic membrane rupture)	Cesarean delivery before onset of labor or amniotic membrane rupture, regardless of GBS colonization status or gestational age
Unknown GBS status at the onset of labor (culture not done, incomplete, or results unknown) and any of the following: Delivery at <37 weeks' gestation* Amniotic membrane rupture ≥18 hr Intrapartum temperature ≥38.0°C (100.4°F)† Intrapartum NAAT‡ positive for GBS	Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors

*Recommendations for the use of intrapartum antibiotics for prevention of early-onset GBS disease in the setting of threatened preterm delivery are presented in Chapter 230.
†If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.
‡If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at <37 wk gestation, amniotic membrane rupture ≥18 hr, or temperature ≥38.0°C/100.4°F) is present, intrapartum antibiotic prophylaxis is indicated.
GBS, Group B streptococcus; NAAT, nucleic acid amplification test.

Chapter 149

Congenital and Perinatal Infections

Sallie R. Permar and Emma L. Mohr

Infections are a frequent and important cause of neonatal morbidity and mortality. **Congenital** or **intrauterine** infections (i.e., those transmitted across the placenta) and **perinatal** infections (i.e., those transmitted from the mother to the fetus or newborn infant during the birth process) represent two major routes of neonatal infection.

149.1 Congenital Infections

Sallie R. Permar and Emma L. Mohr

In utero infections are caused by a variety of etiologic agents, including bacteria, viruses, fungi, and protozoa. Clinical manifestations of congenital infectious diseases in neonates can range from asymptomatic or subclinical to life-threatening disease. History and physical examination findings, in addition to laboratory testing and/or radiologic imaging, provide insight into the best approach for prevention and treatment of congenital infectious diseases in this immunologically immature population (see Fig. 148.2 and Table 148.2).

GENERAL APPROACH

Prenatal counseling on methods to prevent congenital infections is the best approach for improving infant outcomes. Once a fetus or infant is suspected of having a congenital or perinatal infection, infectious as well as noninfectious processes, such as underlying congenital heart disease, genetic disorders, and inborn errors of metabolism, should be considered in the differential diagnosis. Because maternal infection is a prerequisite for infection in the fetus, a thorough history is essential to assess the mother for her symptoms, travel, diet, medication use, occupational exposures, and any **sexually transmitted infections (STIs)** during pregnancy. Clinical manifestations are varied and overlap for many of the pathogens causing intrauterine infection. Laboratory testing and/or radiologic imaging is often required to confirm the diagnosis. Treatment depends on the specific pathogen and can range from symptomatic management with close follow-up for long-term sequelae to targeted antimicrobial therapy.

PATHOGENESIS

The route and timing of infection can provide helpful clues as to the potential infectious etiology (Fig. 149.1 and Table 149.1). First-trimester infection may alter embryogenesis and result in malformations of the heart and eyes, as seen in congenital rubella syndrome. Third-trimester infection (e.g., congenital toxoplasmosis) can result in active infection with signs of hepatomegaly, splenomegaly, and generalized lymphadenopathy at birth. Infections that occur late in gestation (e.g., congenital syphilis) may lead to a delay in clinical manifestations until weeks to years after birth.

Intrauterine infection from cytomegalovirus (CMV), *Treponema pallidum*, *Toxoplasma gondii*, rubella virus, varicella-zoster virus (VZV), and human parvovirus B19 may cause minimal or no symptoms in the mother but still may be transmitted across the placenta to the fetus. The presence of maternal antibodies to rubella prevents maternal infection and congenital transmission, but transmission across the placenta of CMV can occur despite preexisting immunity, albeit at a lower rate compared to primary maternal CMV infection. Regardless of the mother's immune status, the placenta may act as a barrier, and the fetus may or may not be infected. If infection occurs, signs may or may not be noted in the fetus during pregnancy. Infection can result in spontaneous abortion, congenital malformation, intrauterine growth restriction (IUGR), premature birth, stillbirth, acute or delayed disease in the neonate, or asymptomatic persistent infection with sequelae later in life.

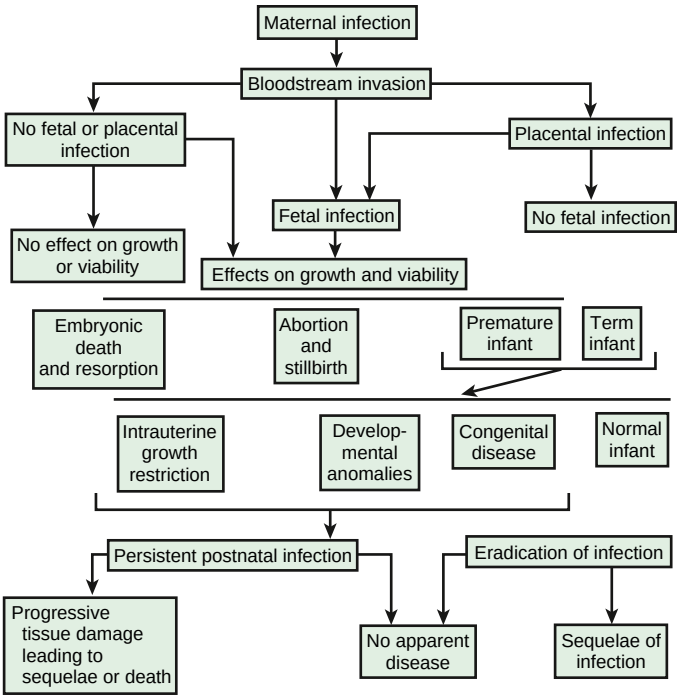

Fig. 149.1 Pathogenesis of hematogenous transplacental infections. (*Adapted from Klein JO, Remington JS. Current concepts of infections of the fetus and newborn infant. In: Remington JS, Klein JO, eds. Infectious Diseases of the Fetus and Newborn Infant, 8th ed. Philadelphia: Saunders; 2002.*)

PREVENTION

Prevention of congenital infections includes behavioral and therapeutic interventions. Counseling-based interventions are effective in reducing CMV infection, but few healthcare providers report counseling their patients on CMV prevention. Counseling on hygienic practices, such as washing hands after diaper changes and avoiding contact with saliva, decreases CMV transmission risk. Safer sex practices, safe food preparation practices, and preventing mosquito bites are some of the recommendations that prevent congenital and perinatal infections. Prenatal and maternal vaccination and control of existing maternal infections are other strategies of preventing congenital infection. Prevention recommendations are presented in Table 149.2.

CLINICAL MANIFESTATIONS

The clinical manifestations of intrauterine infections can range from asymptomatic to severe multiorgan system complications. For some agents (e.g., CMV, *T. pallidum*), ongoing injury after birth can lead to late sequelae as well. The specific clinical signs in the newborn period are usually not sufficient to make a definitive diagnosis but are useful to guide more specific laboratory testing. Symptomatic congenital infections often affect the central nervous system (CNS; brain and eyes) and the reticuloendothelial system (RES; bone marrow, liver, and spleen). Table 149.3 presents the clinical manifestations of some specific congenital infections. Congenital Zika virus infection has features that are rarely seen with other congenital infections (Table 149.4). For example, no hematologic or hepatic laboratory abnormalities have been documented in infants with congenital Zika virus infection. Table 149.5 provides late sequelae of some congenital infections.

DIAGNOSIS

During Pregnancy

The presence of IUGR or a physical abnormality on a prenatal fetal ultrasound raises concern for a congenital infection. The well-known acronym **TORCH**—***T****. gondii*, **O**ther (*T. pallidum*, human parvovirus B19, HIV, Zika virus, others), **R**ubella, **C**ytomegalovirus, and **H**erpes simplex virus (HSV)—is a historical mnemonic but is less useful given the number of *other* infections that need to be considered. The routine ordering of TORCH serology panels *is not* recommended because the presence of a pathogen-specific IgG response in the mother indicates past infection but does not establish if the infection occurred during pregnancy. Maternal IgM titers to *specific* pathogens are only moderately sensitive, and a negative result cannot be used to exclude infection. Testing the mother for the pathogen of concern itself, such as testing for CMV, HIV, or Zika viremia, can shed some light onto the potential congenital pathogens of concern.

In certain cases, a fetal blood sample with cordocentesis can be obtained and tested for total and pathogen-specific IgM assays, polymerase chain reaction assays (PCRs), or cultures. A positive *pathogen-specific* IgM test is strongly suggestive of infection, but a negative test does not rule out the organism as the cause of the fetopathy. Amniotic fluid can also be obtained and sent for PCR or culture. The presence of CMV, *T. gondii*, or human parvovirus B19 in amniotic fluid indicates the fetus likely is infected but cannot establish the severity of disease. Although HSV is included in the TORCH acronym, it is rarely isolated from amniotic fluid and is rarely transmitted across the placenta from mother to fetus. Fetal blood can be collected to test for human parvovirus B19 IgM and PCR.

Newborn Infant

When a congenital infection is suspected because clinical signs are present at birth, a complete blood count with differential and platelet count along with measurements of transaminases and total/direct bilirubin are routinely performed. Additional evaluations may include a dilated funduscopic examination for retinopathy, auditory brainstem response (ABR) for those failing the newborn hearing screen, and CNS imaging. If available, pathologic examination of the placenta and/or cord may be informative. Infectious diseases consultation is valuable in guiding the evaluation.

Neonatal antibody titers for specific pathogens are often difficult to interpret because IgG is acquired from the mother by transplacental passage, and a positive result may reflect the mother's past infection and not infection of the newborn. Neonatal IgM antibody titers to specific pathogens have high specificity and only moderate sensitivity; a negative result cannot be used to exclude infection. Paired maternal and fetal-neonatal IgG antibody titers showing higher or rising infant IgG antibodies can diagnose some congenital infections (e.g., syphilis). Total cord blood IgM and IgA are not actively transported across the placenta to the fetus yet are not specific or sensitive enough for intrauterine infection.

PCR testing of infant saliva, urine, and/or blood for CMV and other viral infections is sensitive, specific, and widely accepted over virus cultures, yet should be performed within the first 2 weeks of life to distinguish congenital infection from perinatal or postnatal infection. The Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL; Palo Alto, CA: www.pamf.org/serology/; telephone: (650) 853-4828; e-mail: remingtonlab@sutterhealth.org) offers specialized tests and physician experts to aid in the diagnosis of congenital toxoplasmosis. Testing for Zika virus with real-time reverse-transcription PCR (rRT-PCR) from neonatal urine and serum and IgM enzyme-linked immunosorbent assay (ELISA) from neonatal serum is recommended. However, the most reliable method of testing has not been established. In endemic areas, this workup

Table 149.2 Prevention Strategies for Congenital and Perinatal Infections

PATHOGEN	PREVENTION STRATEGY
CMV	Hygienic education to avoid direct contact with toddler urine/saliva, avoid new sexual partners
HSV	Prevention of maternal STI near delivery and exposure of newborn to active maternal lesions
VZV	Vaccination of nonpregnant women of childbearing age with a negative varicella history or vaccine immunity
Rubella virus	Vaccination of nonpregnant women of childbearing age with no immunization history
HIV	Safe sex practices; maternal treatment with HAART on infection
SARS-CoV-2	Prenatal and maternal vaccination, masking, and social distancing
Zika virus	Prevention of mosquito bites and safe sex practices with persons who have recently traveled to endemic areas
Toxoplasma gondii	Avoiding undercooked meat, avoiding unpasteurized goat milk, avoiding raw mollusks, avoid contact with litter or soil potentially contaminated with cat feces
Treponema pallidum	Safe sex practices; screening in nonpregnant populations

HSV, Herpes simplex virus; CMV, cytomegalovirus; VZV, varicella-zoster virus; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; STI, sexually transmitted infection; HAART, highly active antiretroviral therapy.

From Auriti C, De Rose DU, Santisi A, et al. Pregnancy and viral infections: Mechanisms of fetal damage, diagnosis and prevention of neonatal adverse outcomes from cytomegalovirus to SARS-CoV-2 and Zika virus. *Biochim Biophys Acta Mol Basis Dis.* 2021;1867:1–17; Maldonado YA, Read JS. American Academy of pediatrics committee on infectious diseases: diagnosis, treatment, and prevention of congenital toxoplasmosis in the United States. *Pediatrics.* 2017;139(2):e20163860; US Preventive Services Task Force: Screening for syphilis infection in pregnant women, February 2018.

should be done soon after delivery because it is difficult to distinguish congenital from perinatal and postnatal infection if testing is done later.

SPECIFIC INFECTIOUS AGENTS

Important congenital infections include more than the TORCH agents. The following is a list of pathogens that may be transmitted across the placenta and the respective chapters where they are discussed in more detail, including treatment.

Bacteria

Listeria monocytogenes (Chapter 234)
Syphilis *(Treponema pallidum)* (Chapter 264)

Viruses

Cytomegalovirus (Chapter 302)
Hepatitis B (Chapter 406)
Hepatitis C (Chapter 406)
Herpes simplex virus (Chapter 299)
Human immunodeficiency virus (Chapter 322)
Human parvovirus B19 (Chapter 298)
Lymphocytic choriomeningitis virus (Chapter 318)
Rubella (Chapter 294)
Varicella-zoster virus (Chapter 300)
Zika virus (Chapter 314.12)
Parasite
Toxoplasmosis (*Toxoplasma gondii)* (Chapter 336)

149.2 Perinatal Infections

Sallie R. Permar and Emma L. Mohr

Perinatal infections are defined as those that are transmitted from the mother to the fetus or newborn infant during the birth process. Despite recommended universal screening of pregnant women for *Chlamydia trachomatis*, gonorrhea, and group B streptococcus (GBS), transmission to the newborn still occurs. In addition to these STIs, other bacteria, viruses, and *Candida* spp. may cause perinatal infections. Similar to congenital infections, their presentation can range from asymptomatic to a sepsis-like syndrome.

GENERAL APPROACH

The general approach is like that for congenital infections and includes a detailed maternal history and a careful examination of the newborn (see Chapter 148). Many clinical syndromes overlap; therefore laboratory testing is usually required to establish a specific microbiologic etiology and guide management decisions.

PATHOGENESIS

The human birth canal is colonized with aerobic and anaerobic bacteria. **Ascending amniotic infection** may occur with either apparently intact membranes or relatively brief duration of membrane rupture. Infectious agents can also be acquired as the newborn infant passes through the vaginal canal. This acquisition may result in either colonization or disease. Factors influencing which colonized infants will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies.

Chorioamnionitis has been historically used to refer to microbial invasion of the amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane for >18 hours. The term *chorioamnionitis* is confusing because it does not convey the spectrum of inflammatory or infectious diseases, it leaves out other intrauterine components that can be involved (e.g., decidua), and it results in significant variability in clinical practice, with the potential for a significant number of well newborns being exposed to antimicrobial agents. The term **intrauterine inflammation or infection at birth**, abbreviated as **Triple I**, is preferred because of the heterogeneous nature of conditions that can affect the mother and neonate (Table 149.6). Regardless of the definition used, prematurity (<37 weeks) is associated with a greater risk of early-onset sepsis, especially with GBS.

Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (failure to breathe, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.

CLINICAL MANIFESTATIONS

Most perinatal infections present clinically during the first month of life. Initial signs and symptoms may be either nonspecific or focal (see Chapter 148). Additional information on specific infectious agents and their management are reviewed in the chapters indicated below.

SPECIFIC INFECTIOUS AGENTS

Bacteria

Chlamydia trachomatis (Chapter 272)
Escherichia coli (Chapter 246)
Genital mycoplasmas (Chapter 270)
Group B streptococci (Chapter 230)
Neisseria gonorrhoeae (Chapter 238)
Syphilis *(Treponema pallidum)* (Chapter 264)

Table 149.4 Syndromes in the Neonate Caused by Congenital Infections

ORGANISM	SIGNS
Toxoplasma gondii	Hydrocephalus, diffuse intracranial calcification, chorioretinitis
Rubella virus	Cardiac defects, sensorineural hearing loss, cataracts, microcephaly, "blueberry muffin" skin lesions, hepatomegaly, interstitial pneumonitis, myocarditis, disturbances in bone growth, intrauterine growth restriction
CMV	Microcephaly, periventricular calcifications, jaundice, petechiae or purpura, hepatosplenomegaly, intrauterine growth restriction, sensorineural hearing loss
HSV	Skin vesicles or scarring, eye scarring, microcephaly or hydranencephaly, vesicular skin rash, keratoconjunctivitis, meningoencephalitis, sepsis with hepatic failure
Treponema pallidum	Bullous, macular, or eczematous skin lesions involving palms and soles; rhinorrhea; dactylitis and other signs of osteochondritis and periostitis; hepatosplenomegaly; lymphadenopathy
VZV	Limb hypoplasia, cicatricial skin lesions, ocular abnormalities, cortical atrophy
Parvovirus B19	Nonimmune hydrops fetalis
HIV	Severe thrush, failure to thrive, recurrent bacterial infections, calcification of basal ganglia
Zika virus	Microcephaly, lissencephaly, cerebellar hypoplasia, akinesia syndrome, macular scarring, retinal mottling, subcortical calcifications, hypertonia

HSV, Herpes simplex virus; CMV, cytomegalovirus; VZV, varicella-zoster virus.
From Maldonado YA, Nizet V, Klein JO, et al. Current concepts of infections of the fetus and newborn infant. In Wilson CB, Nizet V, Maldonado Y, et al., eds. *Remington and Klein's Infectious Diseases of the Fetus and Newborn*, 8th ed. Philadelphia: Elsevier; 2016: Tables 1–7.

Table 149.6 Classification of Triple I and Isolated Maternal Fever

TERMINOLOGY	FEATURES
Isolated maternal fever	Maternal oral temperature ≥39°C is considered a "documented fever" If the oral temperature is ≥38°C but ≤39°C, repeat the measurement in 30 min If the repeat value is ≥38°C, it is considered a "documented fever"
Suspected Triple I	Fever without a clear source with *any* of the following: 1. Baseline fetal tachycardia (>160 beats/min for 10 min) 2. Maternal WBC >15,000/mm^3 in the absence of corticosteroids 3. Purulent fluid from the cervical os
Confirmed Triple I	All the above (from suspected Triple I) with *any* of the following: 1. Amniocentesis-proven infection through positive Gram stain 2. Low glucose of amniotic fluid or positive amniotic fluid culture 3. Placental pathology consistent with infection

Triple I, Intrauterine inflammation or infection at birth; WBC, white blood cell count.
Adapted from Higgins RD, Saade G; Chorioamnionitis Workshop participants: Evaluation and management of women and newborns with a maternal diagnosis of chorioamnionitis: summary of a workshop. *Obstet Gynecol* 2016;127(3):426–436.

Table 149.7 Laboratory Tests in the Diagnosis of Specific Perinatal Infections

INFECTIOUS AGENT	ACCEPTABLE SPECIMEN(S) FROM INFANT UNLESS OTHERWISE INDICATED	LABORATORY TEST
Chlamydia trachomatis	Conjunctiva, nasopharyngeal swab, tracheal aspirate	DFA or culture using special transport media NAATs are not FDA-approved for specimens from neonates*
Genital mycoplasmas (*Mycoplasma hominis, M. genitalium, Ureaplasma urealyticum*)	Tracheal aspirate, blood, CSF	Culture using special transport media NAATs
Neisseria gonorrhoeae	Conjunctiva, blood, CSF, synovial fluid	Finding gram-negative intracellular diplococci on Gram stain is suggestive Culture on special media establishes the diagnosis
Syphilis *(Treponema pallidum)*	Serum (mother)	A nontreponemal test (RPR or VDRL) and if reactive, a specific treponemal test† or reverse-sequence screening: specific treponemal test and if reactive, a quantitative nontreponemal test
	Serum	RPR/VDRL
	CSF	VDRL
Cytomegalovirus	Urine, saliva (with confirmational urine), blood, or CSF (if CNS involvement)	CMV DNA PCR Obtained within 3 wk of birth
Enteroviruses	Blood, nasopharyngeal swab, throat swab, conjunctival swab, tracheal aspirate, urine, stool, rectal swab, vesicle fluid, CSF	PCR Cell culture (sensitivity depends on serotype and cell lines used)
Hepatitis B	Serum (mother) Serum	HBsAg If mother's HBsAg is positive, at age 9 mo, test the infant for HBsAg and hepatitis B surface antibody
Herpes simplex viruses 1 and 2	Conjunctiva, skin vesicle scraping, whole blood, mouth vesicles	PCR or cell culture
	CSF	PCR
	"Surface cultures" (mouth, nasopharynx, conjunctiva, and anus)	PCR or cell culture
HIV	Serum (mother) Whole blood (infant)	Fourth-generation HIV antigen/antibody test HIV DNA PCR (performed on peripheral blood mononuclear cells) or RNA PCR (performed on plasma)
Candida species	Blood, skin biopsy, or CSF	Culture
Zika virus	Blood, urine	RNA PCR Also assay CSF for RNA if obtained for other reasons
	Blood	IgM antibodies Also assay CSF for IgM if obtained for other reasons
SARS-CoV-2	Nasopharynx, oropharynx, nose, saliva, trachea	RT-PCR or direct antigen testing

*Published evaluations of NAATs for these indications are limited, but sensitivity and specificity is expected to be at least as high as those for culture.
†Treponemal tests include the *T. pallidum* particle agglutination (TP-PA) test, *T. pallidum* enzyme immunoassay (TP-EIA), *T. pallidum* chemiluminescent assay (TP-CIA), and fluorescent treponemal antibody absorption (FTA-ABS) test.
DFA, Direct immunofluorescence assay; NAAT, Nucleic acid amplification test; FDA, U.S. Food and Drug Administration; CSF, Cerebrospinal fluid; VDRL, Venereal Disease Research Laboratories; RPR, rapid plasma reagin; HBsAg, hepatitis B surface antigen; PCR, polymerase chain reaction; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; RT-PCR, reverse-transcription polymerase chain reaction.
Created with data from pathogen-specific chapters within Kimberlin DW, Barnett ED, Lynfield R, Sawyer MH, eds. *Redbook: 2021-2024 Report of the Committee on Infectious Diseases*, 32nd ed. Itasca, IL: American Academy of Pediatrics; 2018; p. 729–744.

DIAGNOSIS

The maternal history provides important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired), and obstetric risk factors (prematurity, prolonged ruptured membranes, chorioamnionitis). STIs acquired by a pregnant woman, including syphilis, *N. gonorrhoeae*, and *C. trachomatis,* have the potential for perinatal transmission.

Neonates with perinatal infections often present with nonspecific symptoms and signs; therefore the general diagnostic evaluation for the ill neonate as discussed in Chapter 202 should be followed. Table 149.7 provides a summary of laboratory tests that are useful to diagnose specific perinatal infections.

Adolescent Medicine

PART XI

Chapter 150

Adolescent Physical and Social Development

Cynthia M. Holland-Hall and Maria D. Brown

See also Part XXIV and Chapters 599 and 600.

During the preteen, teenage, and young adult years, young people undergo not only dramatic changes in physical appearance but also rapid changes in physiologic, psychologic, and social functioning. Hormonally driven physiologic changes and ongoing neurologic development occur in the setting of social structures that foster the transition from childhood to adulthood. This period of development comprises **adolescence**, which is divided into three phases—early, middle, and late adolescence—each marked by a characteristic set of biologic, cognitive, and psychosocial milestones (Table 150.1). Although individual variations in the timing and pace of development undoubtedly exist, these changes follow a predictable pattern of occurrence. Gender and culture profoundly affect the developmental course, as do physical, social, and environmental influences (Fig. 150.1). Given the interaction of these domains, a biopsychosocial perspective is best suited to approach the healthcare of the adolescent.

PHYSICAL DEVELOPMENT

Puberty is the biologic transition from childhood to adulthood. Pubertal changes include the appearance of the secondary sexual characteristics, increase in height, change in body composition, and development

Table 150.1 Milestones in Early, Middle, and Late Adolescent Development

VARIABLE	EARLY ADOLESCENCE	MIDDLE ADOLESCENCE	LATE ADOLESCENCE
Approximate age range	10-13 yr	14-17 yr	18-21 yr
Sexual maturity rating*	1-2	3-5	5
Physical	• *Females:* secondary sex characteristics (breast, pubic, axillary hair), start of growth spurt • *Males:* testicular enlargement, start of genital growth	• *Females:* peak growth velocity, menarche (if not already attained) • *Males:* growth spurt, secondary sex characteristics, nocturnal emissions, facial and body hair, voice changes • Change in body composition • Acne	• Physical maturation slows • Increased lean muscle mass in males
Cognitive and moral	• Concrete operations • Egocentricity • Unable to perceive long-term outcome of current decisions • Follow rules to avoid punishment	• Emergence of abstract thought (formal operations) • May perceive future implications, but may not apply in decision-making • Strong emotions may drive decision-making • Sense of invulnerability • Growing ability to see others' perspectives	• Future-oriented with sense of perspective • Idealism • Able to think things through independently • Improved impulse control • Improved assessment of risk vs reward • Able to distinguish law from morality
Self-concept/identity formation	• Preoccupied with changing body • Self-consciousness about appearance and attractiveness	• Concern with attractiveness • Increasing introspection	• More stable body image • Attractiveness may still be of concern • Consolidation of identity
Family	• Increased need for privacy • Exploration of boundaries of dependence vs independence	• Conflicts over control and independence • Struggle for greater autonomy • Increased separation from parents	• Emotional and physical separation from family • Increased autonomy • Reestablishment of "adult" relationship with parents
Peers	• Same-gender peer affiliations	• Intense peer group involvement • Preoccupation with peer culture • Conformity	• Peer group and values recede in importance
Sexual	• Increased interest in sexual anatomy • Anxieties and questions about pubertal changes • Limited capacity for intimacy	• Testing ability to attract partner • Initiation of relationships and sexual activity • Exploration of sexual identity	• Consolidation of sexual identity • Focus on intimacy and formation of stable relationships • Planning for future and commitment

*See text and Figures 150.2 and 150.3.

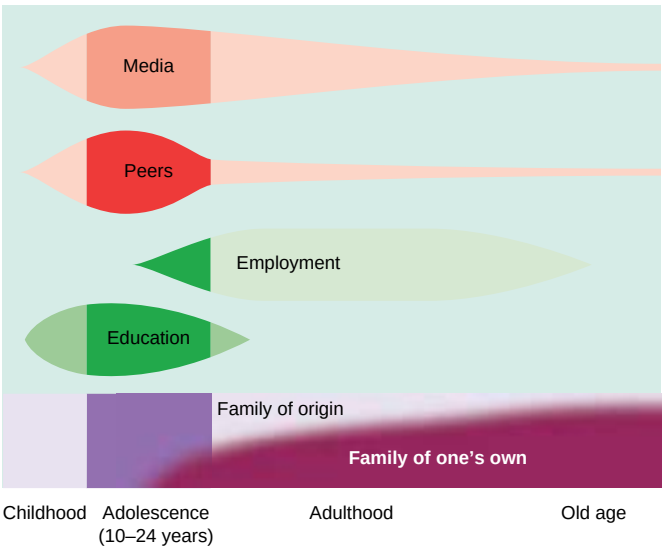

Fig. 150.1 Changing proximal social determinants of health across the life course. During adolescence, social determinants from outside the family become greater, with major influences of peers, media, education, and the beginning of workplace influences. Community and structural determinants remain consistently influential, as shown by the background shading. *(From Patton GC, Sawyer SM, Santelli JS, et al. Our future: a Lancet commission on adolescent health and wellbeing. Lancet. 2016;387:2423–2478, Fig. 2.)*

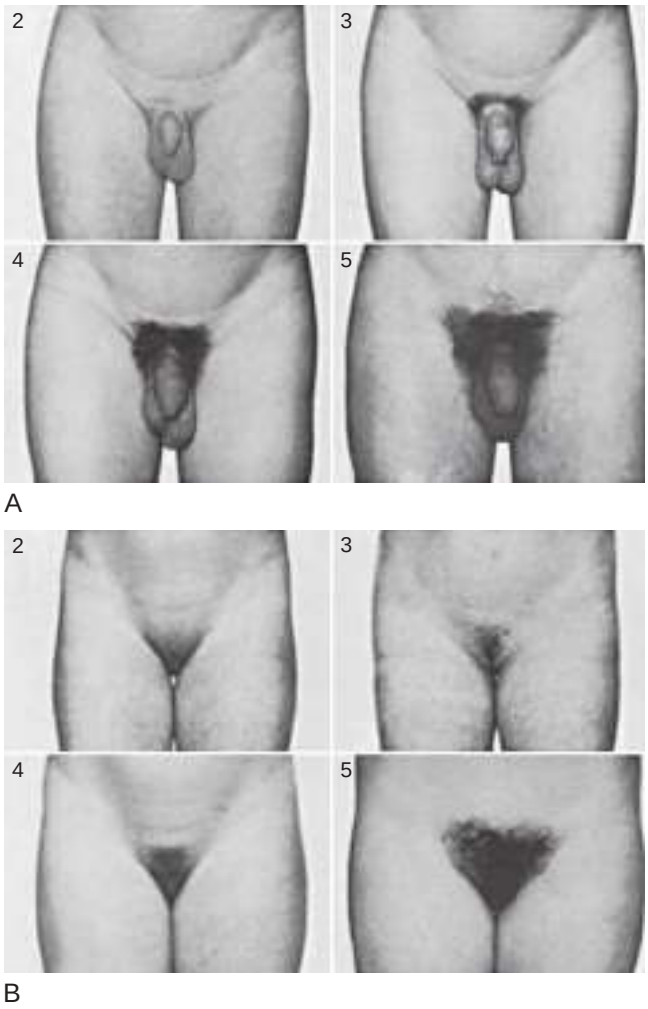

Fig. 150.2 Sexual maturity ratings (2-5) of pubic hair changes in adolescent males (A) and females (B) (see Tables 150.2 and 150.3). *(Courtesy J.M. Tanner, MD, Institute of Child Health, Department for Growth and Development, University of London.)*

of reproductive capacity. Two principal physiologic events occur during puberty: adrenarche and gonadarche. Adrenal androgen production, chiefly dehydroepiandrosterone sulfate (DHEAS), rises in response to adrenocorticotropic hormone (ACTH). Increases in serum concentrations of DHEAS result in the development of adult-like body odor and faint genital hair **(adrenarche)**, occurring as early as 6-8 years of age. Gonadal sex steroid production occurs with activation of the hypothalamic-pituitary-gonadal (HPG) axis **(gonadarche)**. Maturation of the gonadotropin-releasing hormone (GnRH) pulse generator is among the earliest neuroendocrine changes associated with the onset of puberty. Under the influence of GnRH, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH); initially this occurs in a pulsatile fashion primarily during sleep, but this diurnal variation diminishes throughout puberty. LH and FSH stimulate corresponding increases in gonadal androgens and estrogens. The triggers for these changes are incompletely understood. The activation of the HPG axis may be mediated by increasing adiposity and associated insulin resistance, hyperinsulinemia, elevated androgens, and leptin. Both genetic and environmental (epigenetic) factors contribute to the regulation of pubertal timing.

Sexual Development

The progression of the development of the secondary sex characteristics may be described using the **sexual maturity rating (SMR)** scale (ranging from 1, prepubertal, to 5, fully mature adolescent) or **Tanner stages**. Figures 150.2 and 150.3 depict the physical findings of breast and pubic hair maturation at each SMR (Tables 150.2 and 150.3). Although the ages at which individual pubertal changes occur may vary, the timing and sequence of these changes relative to one another is predictable (Figs. 150.4 and 150.5). The wide range of normal progress through sexual maturation is affected by genetics, the psychosocial environment, nutrition, and overall health status. Environmental exposures may also play a role.

In **males** the first visible sign of puberty and the hallmark of SMR 2 is testicular enlargement, beginning as early as 9.5 years, followed by the development of pubic hair. This is followed by penile growth during SMR 3. Peak growth occurs when testis volumes reach approximately 9-10 cm^3 during SMR 4. Under the influence of LH and testosterone, the seminiferous tubules, epididymis, seminal vesicles, and prostate enlarge. Sperm may be found in the urine by SMR 3; nocturnal emissions may be noted at this time as well. Some degree of breast tissue growth, typically bilateral, occurs in 40–65% of males during SMR 2-4 as a presumed consequence of a relative excess of estrogenic stimulation. This usually resolves with ongoing maturation.

In **females**, typically the first visible sign of puberty and the hallmark of SMR 2 is the appearance of breast buds **(thelarche)**, between 7 and 12 years of age. A significant minority of females develops pubic hair **(pubarche)** prior to thelarche. Less visible changes include enlargement of the ovaries, uterus, labia, and clitoris and thickening of the endometrium and vaginal mucosa. A clear vaginal discharge may be present before menarche (physiologic leukorrhea). Menses typically begins within 3 years of thelarche, during SMR 3-4 (average age 12.5 years; normal range 9-15 years) (see Fig. 150.5). The timing of **menarche** is determined largely by genetics; contributing factors likely include adiposity, chronic illness, nutritional status, and the physical and psychosocial environment. Early menstrual cycles often are anovulatory and thus somewhat irregular, but typically occur every 21-45 days and include 3-7 days of bleeding, even during the first year after menarche.

The **onset of puberty** and menarche appear to be occurring at earlier ages than previously reported in the United States (see Chapter 599). Several studies from 1948 to 1981 identified the average age for the onset of breast development as ranging from 10.6 to 11.2 years of age. A subsequent prospective study suggests an earlier average age of onset of 8.8 years in Black females and 9.6 years in White females. Almost 25% of Black females and 10% of White females initiate breast development

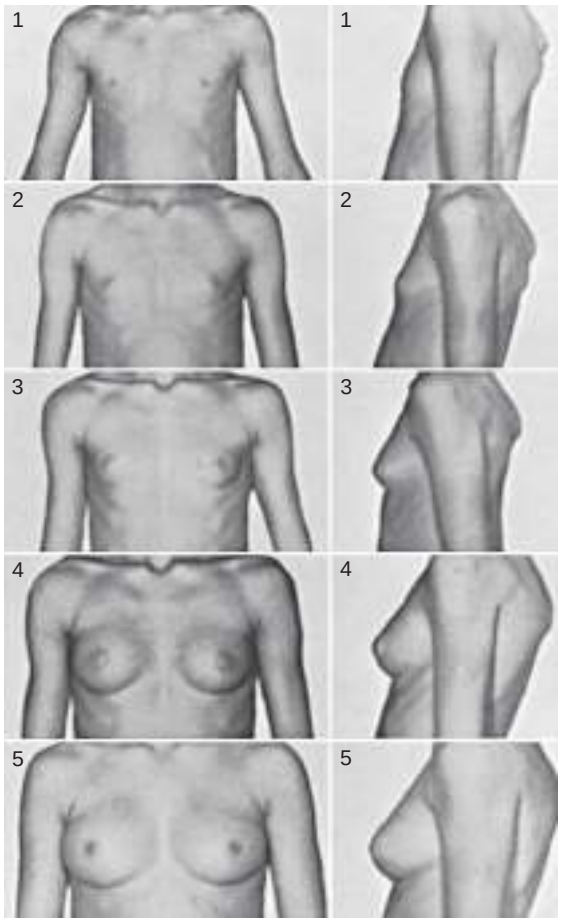

Fig. 150.3 Sexual maturity ratings (1-5) of breast changes in adolescent females. *(Courtesy J.M. Tanner, MD, Institute of Child Health, Department for Growth and Development, University of London.)*

by 7 years of age. A 2020 systematic review and meta-analysis demonstrated an almost 3 months per decade decrease in age of thelarche between 1977 and 2013 worldwide. Early breast development may be associated with a slower tempo of puberty (i.e., longer time to menarche). There also appears to be a trend toward decreasing ages for the onset of pubic hair development and menarche. Data from the National Health and Nutrition Examination Survey (NHANES), a nationally representative, longitudinal survey in the United States, show a decline in the average age of menarche of 4.9 months between the 1960s and 2002. This may be partially explained by changes in the ethnic makeup of the sample. Changes in the timing of menarche *within* ethnic groups were significantly smaller. The reasons for the larger decrease in age for breast development have been postulated to include the epidemic of childhood obesity and exposure to estrogen-like environmental agents (endocrine disruptors), but further research in this area is needed.

Although fewer data are available on changes in the timing of puberty in males, they appear to be experiencing a similar trend. Although the method of assessing the onset of puberty (i.e., inspection vs palpation of the testes) varies between studies, it appears that the average age for the onset of genital and pubic hair development may have decreased by 1-2 years over the past several decades in many industrialized countries. Evidence for an association of obesity with the timing of puberty in males has been inconsistent.

Somatic Growth

Linear growth acceleration begins in early adolescence for all genders, with 15–20% of adult height accrued during puberty. Females attain a **peak height velocity (PHV)** of 8-9 cm/year at SMR 2-3, approximately 6 months before menarche. Males typically begin their growth acceleration at a later SMR stage and achieve a PHV of 9-10 cm/year later in the course of puberty (SMR 3-4). Males continue their linear growth for approximately 2-3 years after females have stopped growing, accounting for an average difference of 11-13 cm in height between adult males and females (Fig. 150.6). The growth spurt begins distally, with enlargement of the hands and feet, followed by the arms and legs, and finally the trunk and chest. This growth pattern imparts a characteristic "awkward" appearance to some early adolescents. Body

Table 150.2 Sexual Maturity Rating (SMR) Stages in Females

SMR STAGE	PUBIC HAIR	BREASTS
1	Preadolescent	Preadolescent
2	Sparse, lightly pigmented, straight, medial border of labia	Breast and papilla elevated as small mound; diameter of areola increased
3	Darker, beginning to curl, increased amount	Breast and areola enlarged, no contour separation
4	Coarse, curly, abundant, but less than in adult	Areola and papilla form secondary mound
5	Adult feminine triangle, spread to medial surface of thighs	Mature, nipple projects, areola part of general breast contour

From Tanner JM. *Growth at Adolescence,* 2nd ed. Oxford, England: Blackwell Scientific; 1962.

Table 150.3 Sexual Maturity Rating (SMR) Stages in Males

SMR STAGE	PUBIC HAIR	PENIS	TESTES
1	None	Preadolescent	Preadolescent
2	Scant, long, slightly pigmented	Minimal change/enlargement	Enlarged scrotum, pink, texture altered
3	Darker, starting to curl, small amount	Lengthens	Larger
4	Resembles adult type, but less quantity; coarse, curly	Larger; glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

From Tanner JM. *Growth at Adolescence,* 2nd ed. Oxford, England: Blackwell Scientific; 1962.

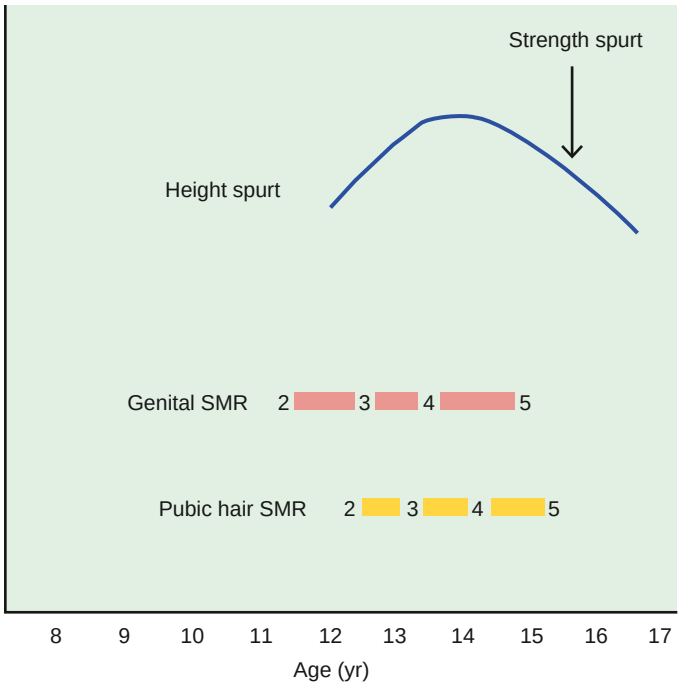

Fig. 150.4 Sequence of pubertal events in males. Although the age of onset of puberty is variable, the sequence of events relative to one another is predictable. SMR, Sexual maturity rating.

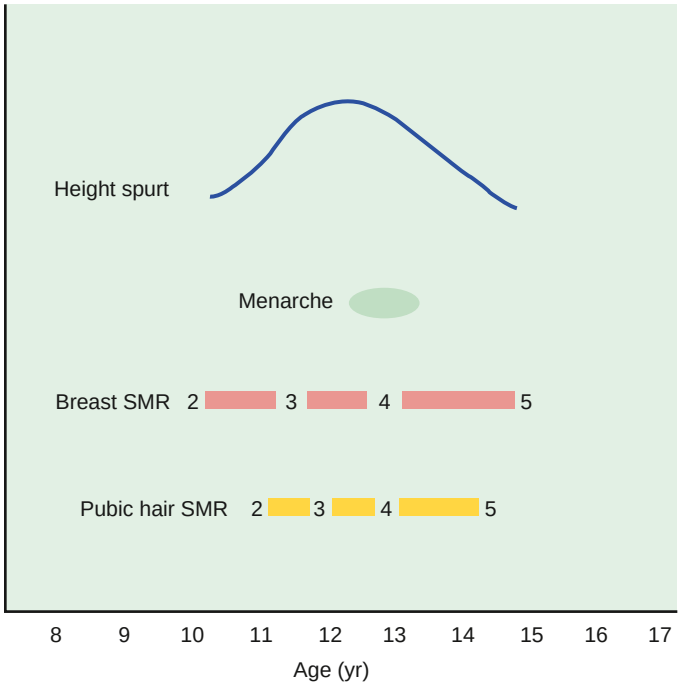

Fig. 150.5 Sequence of pubertal events in females. Although the age of onset of puberty is variable, the sequence of events relative to one another is predictable. SMR, Sexual maturity rating.

composition changes as well after attainment of PHV. Males undergo an increase in lean body mass ("strength spurt"), whereas females develop a higher proportion of body fat. Scoliosis, if present, may progress with rapid axial skeleton growth (see Chapter 720.1). From 50% to 65% of total body calcium is laid down during puberty. Bone growth precedes increases in bone mineralization and bone density, which may increase the adolescent's risk of fracture during times of rapid growth.

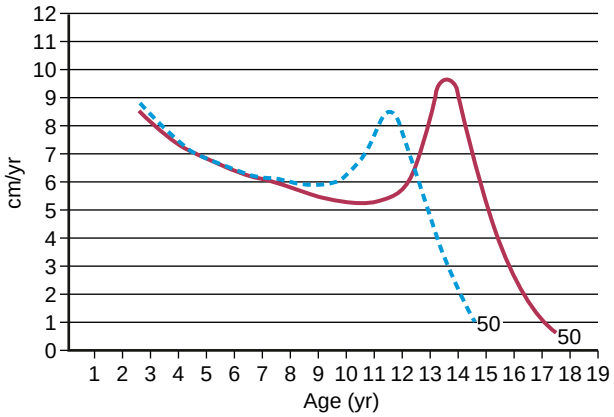

Fig. 150.6 Height velocity curves for American males *(solid line)* and females *(dashed line)* who have their peak height velocity at the average age (i.e., average growth tempo). *(From Tanner JM, Davies PSW. Clinical longitudinal standards for height and height velocity for North American children. J Pediatr. 1985;107:317.)*

Because skeletal growth precedes muscle and tendon growth, sprains and strains may be more common during this time as well.

Cardiovascular changes in middle adolescence include increased heart size, higher blood pressure, and increases in blood volume and hematocrit, particularly in males. Coupled with an increase in lung vital capacity, these changes lead to greater aerobic capacity. Androgenic stimulation of sebaceous and apocrine glands may result in acne and body odor. Rapid enlargement of the larynx, pharynx, and lungs leads to changes in vocal quality in males, typically preceded by vocal instability (voice cracking). Elongation of the optic globe may result in the development of myopia (see Chapter 660). Dental changes include jaw growth, loss of the final deciduous teeth, and eruption of the permanent cuspids, premolars, and finally, molars (see Chapter 353). Orthodontic appliances may be needed, secondary to growth exacerbations of bite disturbances. Physiologic changes in sleep patterns and increased sleep requirements occur, causing many adolescents to delay sleep onset at night, with subsequent difficulty awakening for early school start times in the morning (see Chapter 31). The mechanism of delayed circadian rhythm has not been elucidated but likely involves changes in both circadian and homeostatic sleep regulatory processes.

NEUROLOGIC, COGNITIVE, AND MORAL DEVELOPMENT

As children progress through adolescence, they develop and refine their ability to use formal operational thought processes. Abstract, symbolic, and hypothetical thinking replaces the need to manipulate concrete objects. Middle and late adolescents develop the ability to consider multiple options and to assess the long-term consequences of their actions. The capacity for verbal expression is enhanced. Because adolescents' decision-making and subsequent behaviors are the primary determinants of their mortality and morbidity, understanding these cognitive processes is of critical importance.

Both structural and functional brain development continue throughout adolescence. Cortical gray matter volume peaks in preadolescence, then decreases because of selective "pruning" of rarely used synaptic connections, slowly declining as the third decade of life is approached. Cerebral white matter volume increases until mid-to-late adolescence, reflecting increasing myelination and subsequent facilitation of integrated brain activity and more efficient transmission of information between different regions of the brain, enhancing the "signal-to-noise" ratio. Although the frontal lobes and prefrontal cortex, regions of the brain associated with executive function, have been considered to be among the last regions to mature, other cortical regions show similarly prolonged trajectories of maturation. Without question, adolescents are capable of the complex cognitive processes attributed to frontal lobe function. *Cognitive control,* however, continues to improve into adulthood, with progressive maturation and *integration* of component

processes such as working memory, inhibition and impulse control, performance monitoring, and motivational circuitry.

The behavioral correlates of adolescent neurodevelopment remain speculative but are increasingly supported by a rapidly expanding body of research. Adolescents appear to demonstrate a unique sensitivity to the effects of dopamine on reward-relevant subcortical structures such as the ventral striatum and the ventral tegmental area, with some studies demonstrating increased activation in this region when receiving rewards relative to children or adults. Other studies show reduced responsiveness to aversive stimuli in adolescents. This altered responsiveness to risk vs reward, paired with incomplete frontal lobe myelination and thus immature impulse control, may underlie the increased risk taking and novelty seeking seen in adolescents. Early maturation and distinct patterns of neural reactivity in the amygdala and other limbic structures may explain the strong role that social and emotional stimuli play in adolescents, sometimes overwhelming the frontal executive function systems that facilitate the interpretation and regulation of those social and emotional experiences. This may explain why adolescents are more likely to make poor decisions in highly emotionally charged situations relative to mature adults. These "hot cognition" processes may result in the adolescent making a different decision in the context of a strong affective experience than he or she would in a less emotional state ("cool cognition"). These two types of cognitive processes may not develop at the same rate; the adolescent may be able to use higher brain structures and functions more effectively when in states of lower emotional arousal.

Early adolescents often continue to employ the concrete operational cognitive processes of childhood. Although formal operational cognition is developing, it may be applied inconsistently across different domains. A young adolescent may be able to use abstract thought when completing schoolwork, but not when working through a personal dilemma. Early adolescence also is characterized by egocentricity—the belief of some adolescents that they are the center of everyone's attention. Despite being largely imagined, this perception of always being "on stage" can be stressful for adolescents, who may feel that others are constantly judging or evaluating them. Early adolescents express a greater need for privacy than they did in childhood and begin to appreciate the privacy of their own thoughts. With ongoing cognitive development, **middle adolescents** are more able to consider the needs and feelings of other people. Their creativity and intellectual abilities are enhanced. Because of their increased capacity for abstract thought in combination with a persistent perception of uniqueness, middle adolescents may feel a sense of immortality and immunity to the consequences of risky behaviors. **Late adolescents** are more future oriented and able to delay gratification. They can think more independently, consider others' views, and compromise. They have a stronger sense of self and more stable interests. Under times of stress, adolescents may temporarily revert to the cognitive processes and coping strategies used at younger ages.

Moral development generally accompanies cognitive development. Preadolescents, concrete and individualistic, follow rules to please authority figures and avoid punishment. As they move into early adolescence, they develop a stronger sense of right and wrong but are likely to perceive these as absolute and unquestionable. Middle and late adolescents may establish a sense of morality driven by their desire to be seen as a good person, to behave in a manner according to their perceived place in society, or by their sense of obligation to care for others. Moral decision-making, however, still may be highly subject to emotional context. Late adolescents may develop a rational conscience and an independent system of values, although these often are largely consistent with parental values. While going through this complex developmental process, religious or political organizations that promote simple answers to complex social or moral questions may hold great appeal to the adolescent.

PSYCHOSOCIAL DEVELOPMENT

In contrast to cognitive development, psychosocial development correlates more strongly with pubertal status and physical maturation than with chronological age. Whereas cognitive development is more biologically determined, psychosocial development is subject to greater environmental and cultural influences. Indeed, cultural variation can be dramatic. Some late adolescents move immediately from high school into marriage, childbearing, working, and financial independence; others remain dependent on the parents while pursuing their own education for several more years, in a period sometimes referred to as *emerging adulthood*. Psychosocial development also may be nonlinear, with different domains of growth progressing along different timelines. An overriding theme of psychosocial development is the concept of identity formation and consolidation as the adolescent moves away from the nurturing protection of the family, develops an increased affiliation with the peer group(s), and ultimately defines himself or herself as an individual.

Separation from the parents is a hallmark of adolescent development. Early adolescents start to seek out more privacy at home, spending less time with the parents. They begin to reject parental advice and involvement in their decision-making as they explore the boundaries of their dependence on, and independence from, their parents. With evolving cognitive skills, an adolescent can conceive of an ideal parent and contrast this ideal with his or her own parents. Adolescents may seek out alternative adult role models, such as teachers, coaches, or parents of friends. Parent–child conflict often peaks during middle adolescence, with disagreements over privileges, independence, and other limits set by the parents. Adolescents may appear intermittently to seek and reject parental acceptance. It is theorized that perhaps the adolescent *needs* to conceive of the parents as "wrong" in order to ameliorate the pain of separating from them. Throughout this time, however, the parents remain a critical source of nurturing and support for the adolescent and continue to exert significant influence over the adolescent's decision-making. Paradoxically, frequent arguments and conflict may coexist with strong emotional bonds and closeness. The late adolescent may reestablish a more "adult–adult" type of relationship with the parents, once again seeking out and considering parental advice and guidance as they enter adulthood.

Increasing importance of the **peer group** also may buffer the emotional trauma of separating from the parents (see Fig. 150.1). Early adolescents tend to socialize largely with same-gender peers, both in their individual friendships and larger groups. Females' peer groups tend to be more relationship oriented, whereas males' peer groups are more likely to be centered around a particular interest or activity. In both cases, group cohesion and a sense of belonging become important. Peers become increasingly important in middle adolescence, during which time the adolescent may experiment with being a part of different groups and "try on" different identities. These groups may include all genders. Peer groups may arise from organized activities, such as sports or clubs, or may simply be friendship based. Gang membership is another form of peer acceptance. **Conformity** with the peers in manners of dress, speech, and behavior is a normal part of this process and should not necessarily be viewed negatively. Similarly, **peer pressure** may exist, but its influence over the adolescent's decision-making may be positive, negative, or negligible. Acceptance and successful navigation of peer groups during adolescence may give the individual more confidence to move into and out of various social, academic, and professional groups in the future. Late adolescents are less vulnerable to peer group influence, having moved closer to establishing their own stable identity. Their cognitive skills allow them to choose selectively among different peer groups, endorsing and adopting individual values and behaviors that best reflect who they are becoming.

Early adolescents have increased **sexual awareness and interest**, which may manifest as sexual talk and gossip, and often is focused on sexual anatomy. Masturbation and other sexual exploration, sometimes with same-sex peers, are common. The prevalence of other forms of sexual behavior varies by culture; in general, these behaviors are less common in early adolescents. Romantic relationships, if they exist at all, lack emotional depth. Sexual curiosity, experimentation, and activity become more common among

middle adolescents. Same-sex attraction is common; sexual orientation may become clear to some adolescents, but still may be evolving in others during this time. Dating behaviors may be seen, but this is culture dependent and may not be a popular construct for all adolescents. Individual relationships often continue to emphasize sexual attraction over emotional intimacy. Relationships that occur during middle adolescence may be short and intense. Emotional intimacy and more permanent relationships may not be seen until late adolescence. At that time, relationships increasingly involve love and commitment and demonstrate greater stability.

Body image may affect (and be affected by) adolescents' psychosocial development as well. Early and middle adolescence are usually the ages during which poor or distorted body image and eating disorders develop. Early adolescents undergo rapid physical changes and may experience uncertainty about whether all these anatomic and physiologic changes are progressing normally. Reassurance from adults, including their healthcare providers, may be comforting. As puberty comes to an end and these changes slow, the middle adolescent's preoccupation may shift to whether they are attractive to others. A strong emphasis on physical appearance during this time is common. Although this focus on physical appearance may continue into adulthood, late adolescence generally is characterized by a shifting balance toward introspection, with somewhat less emphasis placed on external characteristics.

The **timing of pubertal changes** also can affect psychosocial development and well-being. The progression of pubertal changes in males is generally associated with a positive self-image. Early-maturing males tend to have greater self-confidence, social, and academic success, whereas later-maturing males are at risk for more internalizing behaviors and diminished self-esteem. Females may initially perceive changes in their physical appearance more negatively. This appears to be especially true for early-maturing females, some of whom experience greater decreases in self-esteem, engage in more disruptive behaviors, and have more conflict with their parents than do on-time or late-maturing females. Early-maturing females may be more comfortable associating with older peers and may subsequently be exposed to peer pressure around things like sexual activity and substance use at younger ages. Still lacking the cognitive skills to effectively navigate these situations, they may be vulnerable to making poor decisions that place their health and safety at risk. Many other factors influence how adolescents experience puberty, and supportive peers and adults can have a positive impact on psychosocial development at any maturational stage. With successful navigation of these domains, emerging adults move into the world with a strong sense of personal identity and their place in society. They are able to work toward a vocation and financial independence and to manage the responsibilities of adulthood.

IMPLICATIONS FOR PROVIDERS, PARENTS, AND POLICYMAKERS

Providers can help parents approach their child's adolescent years by reframing some of the "challenges" of adolescence as normal developmental milestones that should be anticipated and accepted. Puberty and emerging sexuality should be approached as positive and health-affirming life changes, rather than focusing discussions only on the negative reproductive risks and outcomes. Even good-natured teasing about bodily changes can be detrimental to the adolescent's self-image. Early-maturing females and late-maturing males should be supported, recognizing their potential increased exposure to psychosocial challenges. Identification of strengths and emerging positive coping strategies should be promoted in all youth, particularly those with chronic illness or other challenges. Providers need to determine the young adolescent's cognitive development and capacity for abstract thought and tailor their communication and counseling style accordingly. Physical examinations should be performed in private with the parent outside the exam room (provided the adolescent is comfortable with this), which also affords the adolescent and provider an opportunity to discuss confidential issues. Reassurance of normal development should be provided.

As adolescents develop more independence and parent–child conflict peaks, providers should remind parents that this is typical and that arguing does not mean the adolescent does not value the parents' input and perspectives. Although some may rebel initially, most adolescents ultimately adopt a value system very similar to that of their parents. Even if discussions feel ineffective to parents, they should continue to demonstrate and model these values to their child. Similarly, rather than categorically dismissing their child's "negative" interests, such as playing a violent video game, parents should be encouraged to use these opportunities to model critical thinking about the impact of such an activity. Potentially negative peer groups may be approached the same way, while fostering the development of positive peer networks. **Authoritative parenting**, in which clear and appropriate negotiated limits are set in the context of a caring and mutually respectful parent–child relationship, is most strongly associated with positive psychosocial development. Parental connectedness and close supervision or monitoring of the youth's activities and peer group can be protective against early onset of sexual activity and involvement in behaviors that may threaten their safety and can foster positive youth development. Parents should also assume an active role in their adolescent's transition to adulthood to ensure that their child receives appropriate preventive health services.

Parents and providers may each work with adolescents to foster good decision-making. In addition to providing adolescents with accurate and complete health information, the adolescent's cognitive ability to use this information in various contexts must be considered. Visits with providers can be used to promote independence among adolescents by spending time separately with both caregivers and the adolescent, allowing the adolescent space to voice concerns and receive appropriate information about making healthy decisions and recognizing behaviors that may be placing their health at risk.

Adolescents may find themselves needing to make important decisions in highly charged situations where they may be unable to manage their emotions and use their higher cognitive functions to examine the consequences of their decision. For example, a couple in a sexual situation with high emotional arousal may make the decision to proceed with unprotected intercourse. By anticipating this situation ahead of time, under conditions of lower emotional arousal, and making a plan to deal with this, they may make a different decision (e.g., stick with their prior decision never to have sex without protection) when the time comes. Parents and healthcare providers are in a position to encourage and foster this anticipation and planning under conditions of "cool cognition."

Providers may need to help parents distinguish normal adolescent development and risk-taking behaviors from possible signs of a more serious mental health or conduct problem. Bids for **autonomy**, such as avoiding family activities, demanding privacy, and increasing argumentativeness, are normal; extreme **withdrawal** or **antagonism** may be dysfunctional, signaling a mental health or substance use concern. Bewilderment and dysphoria at the start of middle school are normal; continued failure to adapt several months later suggests a more serious problem. Although some degree of risk taking is normal, progressive escalation of risk-taking behaviors is problematic. In general, when the adolescent's behaviors cause significant dysfunction in the domains of home life, academics, or peer relationships, they should be addressed by the parents and healthcare provider, and referral to a mental health provider may be considered. In most cases, parents can be reassured that although adolescence can pose unique challenges, their adolescent, like most adolescents, will come through it to become a successful and happy adult.

At national and international levels, adolescents are at risk for environmental, health, behavioral, and societal challenges. Table 150.4 provides suggestions to address these issues.

Chapter 151

Delivery of Healthcare to Adolescents

Samantha V. Hill and Tamera Coyne-Beasley

Healthcare providers play an important role in nurturing healthy behaviors among adolescents, because the leading causes of death and disability among adolescents are preventable. Adolescence provides a unique opportunity to prevent or modify health conditions arising from behaviors that develop in the second decade of life and that can lead to substantial morbidity and mortality, such as trauma, suicide, cardiovascular and pulmonary disease, type 2 diabetes, reproductive health issues, and cancer (see Chapter 150, Table 150.4).

Health systems in each community should be in place to ensure comprehensive and high-quality care to adolescents. **Health insurance coverage** that is affordable, continuous, confidential, and not subject to exclusion for preexisting conditions should be available for all adolescents and young adults. **Comprehensive, coordinated benefits** should meet the developmental needs of adolescents, particularly for reproductive, mental health, dental, and substance use services. **Safety net providers and programs** that provide confidential services, such as school-based health centers, federally qualified health centers, family planning services, and clinics that treat sexually transmitted infections **(STIs)** in adolescents and young adults, need to have assured funding for viability and sustainability. **Quality-of-care** data should be collected and analyzed by age so that the performance measures for age-appropriate healthcare needs of adolescents are monitored. **Affordability** is important for access to preventive services. Family involvement should be encouraged, but **confidentiality** and adolescent consent are critically important and should be addressed with intentionality at each visit.

Healthcare providers, trained and experienced in adolescent care, should be available in all communities. Healthcare providers should be adequately compensated to support the range and intensity of services required to address the developmental and health service needs of adolescents. The development and dissemination of provider education about **adolescent preventive health guidelines** have been demonstrated to improve the content of recommended care (Table 151.1). The ease of recognition or expectation that an adolescent's needs can be addressed in a setting relates to the visibility and flexibility of sites and services. Staff at sites should be approachable, linguistically capable, culturally humble, and able to balance trauma-informed care with healing-centered engagement approaches with attention to equity and social determinants of health. Health services should be coordinated to respond to goals for adolescent health at the local, state, and national levels. The coordination should address service financing and delivery in a manner that reduces disparities in care.

Although most adolescents in the United States have seen a healthcare provider in the past year and report a usual source of healthcare, adolescents are less likely to receive preventive care services. According to the 2019 National Health Interview Survey, an estimated 92% of 12- to 17-year-old U.S. adolescents had a well child visit within the past year. Uninsured adolescents are the least likely to receive care. The National Health Interview Survey found that 8% of 15- to 18-year-olds were uninsured, whereas 61% and 31% had private and public insurance in 2016, respectively.

Table 151.1 Bright Futures/American Academy of Pediatrics Recommendations for Preventive Healthcare for 11- to 21-Year-Olds

	PERIODICITY AND INDICATIONS
HISTORY	Annual
MEASUREMENTS	
Body mass index	Annual
Blood pressure	Annual
SENSORY SCREENING	
Vision	At 12 yr and 15 yr visits or if risk assessment positive
Hearing	Screen with audiometry, including 6,000- and 8,000-Hz high frequencies once at 11-14 yr, once at 15-17 yr, and once at 18-21 yr.
DEVELOPMENTAL/BEHAVIORAL ASSESSMENT	
Developmental surveillance	Annual
Psychosocial/behavioral assessment	Annual
Depression screening	Annual for 12 yr and older
Tobacco, alcohol, and drug use assessment	If risk assessment positive
PHYSICAL EXAMINATION	Annual
PROCEDURES	
Immunization*	Annual
Hematocrit or hemoglobin	If risk assessment positive
Tuberculin test	If risk assessment positive
Dyslipidemia screening	Once at 9-11 yr, and once at 17-21 yr
STI screening	If sexually active
HIV screening†	Once between ages 15 and 18 yr Discuss and offer at earlier age and annually if risk assessment positive.
Cervical dysplasia screening‡	Beginning at age 21 yr
ORAL HEALTH	Annual; refer to dental home
ANTICIPATORY GUIDANCE	Annual§

*Schedules per the Advisory Committee on Immunization Practices, published annually at http://www.cdc.gov/vaccines/schedules/hcp/index.html and http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx.

†The CDC recommends universal, voluntary HIV screening of all sexually active people beginning at age 13 yr. The American Academy of Pediatrics recommends offering routine HIV screening to all adolescents at least once by 16-18 yr of age and to those younger if at risk. The U.S. Preventive Services Task Force recommends offering routine HIV screening to all adolescents age 15 yr and older at least once and to those younger if at risk. Patients who test positive for HIV should receive prevention counseling and referral to care before leaving the testing site.

§Refer to specific guidance by age as listed in *Bright Futures* guidelines.

HIV, Human immunodeficiency virus; STI, sexually transmitted infection.

Adapted from Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, 4th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2017.

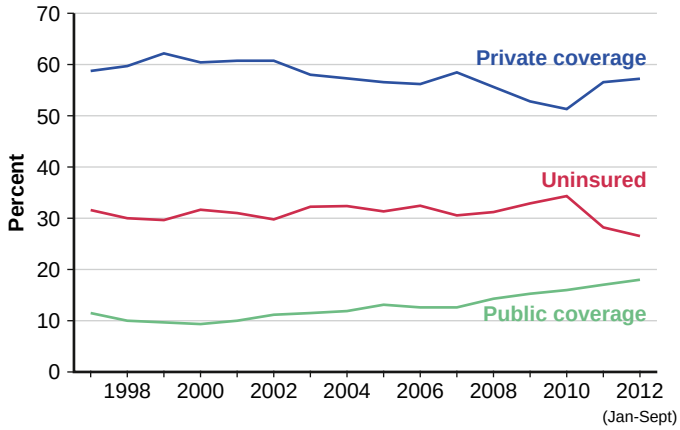

Fig. 151.1 Percentage of adults 19-25 years of age with health insurance by coverage type and percentage uninsured at the time of the interview: United States, 1997 to September 2012. *Note:* Estimates for 2012 are based on data collected in January through September. Data are based on household interviews of a sample of the civilian noninstitutionalized population. (*Data from CDC/NCHS, National Health Interview Survey, 1997–2012, Family Core Component.*)

The **Patient Protection and Affordable Care Act (ACA)** has expanded access to both commercial health plans and Medicaid for young adults age 19-26 years (Fig. 151.1); the proportion of young adults with insurance increased from 65.7% to 73.8%. ACA provisions require that commercial health plans continue dependent coverage to 26 years, regardless of the young adult's financial or dependent status, marriage, or educational enrollment; mandate university and college student health plans enhance consumer protections for students; provide financial assistance for young adults to enroll into health insurance exchanges with incomes ranging from 133% to 399% of the federal poverty level in Medicaid expansion states; and offer preventive healthcare services (to include contraceptive care) free of any cost sharing, deductibles, or copayments. In states that have expanded Medicaid coverage, all adults with incomes <133% of the federal poverty level are eligible to enroll. After passage of the ACA, 14% of 18- to 24-year-olds still remained uninsured.

The complexity and interaction of physical, cognitive, and psychosocial developmental processes during adolescence require sensitivity and skill on the part of the health professional (see Chapter 150). Health education and promotion, as well as disease prevention, should be the focus of every visit (Table 151.2).

The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) currently recommends routine adolescent vaccines for universal administration beginning at the 11- to 12-year-old visit or as soon as possible: (1) tetanus-diphtheria-acellular pertussis vaccine (Tdap), (2) the meningococcal conjugate vaccine (MCV4) with a booster at age 16 years, (3) the human papillomavirus vaccine (HPV) series, and (4) the COVID-19 vaccine (see Chapter 215). ACIP recommends annual influenza vaccination and hepatitis A virus (HAV) vaccination to adolescents and young adults who have not previously received the HAV vaccine series if immunity against HAV is desired or for those at increased risk for infection, such as men who have sex with men (MSM), injection drug users (IDUs), and those with chronic liver disease or clotting factor disorders, or those who live in endemic areas. Although another meningococcal vaccine (MenB) is not routinely recommended for all adolescents, the ACIP recommends a MenB vaccine series for people ages 16-23 based on shared clinical decision-making with the patient (or parent/guardian) to provide short-term protection against serogroup B meningococcal disease.

The time spent on various elements of the screening will vary with the issues that surface during the assessment. However, time for screening and assessment is important for all adolescents, and the ideal model of adolescent care requires a minimum of 20 minutes per visit. For lesbian, gay, bisexual, trans, intersex, and asexual youth (see Chapters 153 and 154), emotional and psychologic concerns related to their experiences, from fear of disclosure to the trauma of discrimination or bullying or violence, may direct the clinician to spend more time assessing emotional and psychologic supports in the young person's environment. For youth with chronic illnesses or special needs, the assessment of at-risk behaviors should not be omitted or deemphasized by assuming they do not experience the "normal" adolescent vulnerabilities.

151.1 Legal Issues

Samantha V. Hill and Tamera Coyne-Beasley

The rights of an individual, including those of adolescents, vary widely between nations. In the United States, the right of a minor to consent to treatment without parental knowledge differs between states and is governed by **state-specific minor consent laws**. Some consent laws are based on a minor's status, such as minors who are emancipated, parents, married, pregnant, in the armed services, or mature. In some states, minors can be considered *emancipated* if they are or have served in the armed services or are living apart from parents and are economically independent through gainful employment. A *mature minor* is a minor who is emotionally and intellectually mature enough to give informed consent and who lives under the supervision of a parent or guardian. Courts have held that if a minor is mature, a physician is not liable for providing beneficial treatment. There is no formal process for recognition of a mature minor. The determination is made by the healthcare provider.

Some minor consent laws are based on services a minor is seeking, such as emergency care, sexual healthcare, substance abuse, or mental healthcare (Table 151.3). All 50 states and the District of Columbia explicitly allow minors to consent for their own health services for **STIs**. Approximately 25% of states require that minors be a certain age (generally 12-14 years) before they can consent for their own care for STIs. No state requires parental consent for STI care or requires that providers notify parents that an adolescent minor child has received STI services, except in limited or unusual circumstances.

Minors' right to consent for **contraceptive services** varies from state to state. Almost 50% of states and the District of Columbia explicitly authorize all minors to consent for their own contraceptive services, and 50% of states permit minors to consent for their own contraceptive services under specific circumstances, such as being married, a parent, currently or previously pregnant, over a certain age, or a high school graduate, or per physician's discretion. The FDA has approved a nonprescription daily oral contraceptive (norgestrel) intended to reduce barriers to access to an effective birth control measure.

A minor's right to consent for **mental healthcare** and **substance use** treatment services varies by state and age of the minor, whether care is medical vs nonmedical (e.g., counseling), and whether care is delivered as an inpatient vs outpatient basis. Minor consent laws often contain provisions regarding confidentiality and disclosure, even when general state consent laws do not have such provisions.

The **confidentiality** of medical information and records of a minor who has consented for his or her own *reproductive healthcare* is governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI or contraceptive services for which minors have given their own consent and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents.

The confidentiality of medical information and records of a minor who has consented for their own healthcare is also governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI, contraceptive, or mental health services for which minors have given their own consent and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents. Title X and Medicaid both provide confidentiality protection for family planning services provided to minors with funding from these programs.

Federal regulations issued under the Federal Health Insurance Portability and Accountability Act, known as the **HIPAA Privacy Rule**, defer to state and "other applicable laws" with respect to the question of whether parents have access to information about care for which a minor has given consent. Thus both the state laws that either prohibit or permit disclosure of confidential information and the federal Title X and Medicaid laws that protect the confidentiality of care for adolescents are important under the HIPAA Privacy Rule in determining when confidential information about health services for minors can be disclosed to parents.

Billing for confidential services is complex. Commercial health plans send home an *explanation of benefit (EOB)* to the primary insured or the primary beneficiary, listing services rendered by the provider and reimbursed by the health plan. An EOB documenting that confidential health services were rendered to their adolescent dependent that is received by a parent may disclose those services. In addition, copayments automatically generated with certain billing codes for office visits and medications can be a barrier for adolescents receiving care, including treatment. One way to circumvent a breach of confidentiality from EOBs is to have the adolescent call the insurance company; however, this can be a time-consuming process.

Table 151.3 Types of Minor Consent Statutes or Rules of Common Law That Allow for Medical Treatment of a Minor Patient Without Parental Consent

LEGAL EXCEPTIONS TO INFORMED CONSENT REQUIREMENT	MEDICAL CARE SETTING
The "emergency" exception	• The child is suffering from an emergent condition that places his or her life or health in danger • The child's legal guardian is unavailable or unable to provide consent for treatment or transport • Treatment or transport cannot be safely delayed until consent can be obtained • The professional administers only treatment for emergent conditions that pose an immediate threat to the child
The "emancipated minor" exception	• Married • Economically self-supporting and not living at home • Active-duty status in the military • In some states, a minor who is a parent or pregnant • Some states might require a court to declare the emancipation of a minor
The "mature minor" exception	Most states recognize a mature minor, in which a minor, usually ≥14 yr, displays sufficient maturity and intelligence to understand and appreciate the benefits, risks, and alternatives of the proposed treatment and to make a voluntary and reasonable choice on the basis of that information; states vary or whether a judicial determination is required
Exceptions based on specific medical condition (state laws vary)	Minor seeks: • Mental health services • Pregnancy and contraceptive services • Testing or treatment for HIV infection or AIDS • Sexually transmitted infection testing and treatment • Drug and alcohol addiction treatment

Data from American Academy of Pediatrics: consent for emergency medical services for children and adolescents. *Pediatrics* 2011;128:427–433.

In March 2020, in response to the COVID-19 pandemic, the Coronavirus Aid, Relief, and Economic Security Act (CARES Act) was passed. Part of this act requires rapid release of all patient documentation (e.g., notes, laboratory results, problem and medication lists) and poses a new challenge to the provision of confidential health services to adolescents.

Providers may elect to establish a policy of discussing with their adolescent patients when medical records and other information will be disclosed and developing a mechanism to alert office staff as to what information in the chart is confidential. For legal and other reasons, a chaperone should be present whenever an adolescent patient's genitalia is examined.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

151.2 Screening Procedures

Samantha V. Hill and Tamera Coyne-Beasley

INTERVIEWING THE ADOLESCENT

The preparation for a successful interview with an adolescent patient varies based on the history of the relationship with the patient. Patients (and their parents) who are going from preadolescence to adolescence while seeing the same provider should be guided through the transition. Although the rules for confidentiality are the same for new and continuing patients, the change in the **physician–patient relationship**, allowing more privacy during the visit and more autonomy in the health process, may be threatening for the parent and the adolescent. For new patients, the initial phases of the interview are more challenging given the need to establish rapport rapidly with the patient in order to meet the goals of the encounter. Issues of **confidentiality and privacy** should be explicitly stated along with the conditions under which that confidentiality may need to be altered, that is, in life- or safety-threatening situations. For new patients, the parents should be interviewed with the adolescent or before the adolescent to ensure that the adolescent does not perceive a breach of confidentiality. The clinician who takes time to listen, avoids judgmental statements and the use of street jargon, and shows respect for the adolescent's emerging maturity will have an easier time communicating with the adolescent. The use of *open-ended questions,* rather than closed-ended questions, will further facilitate history taking. (The closed-ended question, "Do you get along with your father?" leads to the answer "yes" or "no," in contrast to the question, "What might you like to be different in your relationship with your mother?" which may lead to an answer such as, "I would like her to stop always worrying about me.")

The goals of the interview or clinical encounter are to establish an information base, identify problems and issues from the patient's perspective, and identify problems and issues from the perspective of the clinician, based on knowledge of the health and other issues relevant to the adolescent age-group. The adolescent should be given an opportunity to express concerns and the reasons for seeking medical attention. The adolescent and the parent should be allowed to express the strengths and successes of the adolescent, in addition to communicating problems.

The effectiveness of an interview can be compromised when the interviewer is distracted by other events or individuals in the office, when extreme time limitations are obvious to either party, or when there is expressible discomfort with either the patient or the interviewer. The need for an **interpreter** when a patient is hearing impaired or **a translator** if the patient and interviewer are not language compatible provides a challenge, but not necessarily a barrier, under most circumstances (see Chapter 12). Observations during the interview can be useful to the overall assessment of the patient's maturity, presence or absence of depression, and the parent–adolescent relationship. Given the key role of a successful interview in the screening process, excellent training and experience should be sought by clinicians providing comprehensive care to adolescent patients.

PSYCHOSOCIAL ASSESSMENT

A few questions should be asked to identify the adolescent who is having difficulty with **peer relationships** (Do you have a best friend with whom you can share even the most personal secret?), **self-image** (Is there anything you would like to change about yourself?), **depression** (In the past year have you felt depressed or sad most days, even if you felt okay sometimes?), **school** (How are your grades this year compared with last year?), **personal decisions** (Are you feeling pressured to engage in any behavior for which you do not feel you are ready?), **substance use** (Have you ever tried smoking, vaping, alcohol, weed, or prescription drugs that were not prescribed for you?), and an **eating disorder** (Do you ever feel that food controls you, rather than vice versa?). Standardized screening for depression with validated tools such as the PH-Q9 modified for teens is also helpful. The **HEADS/SF/FIRST** mnemonic, basic or expanded, can be useful in guiding the interview if encounter forms are not available (Table 151.4). Based on the assessments,

Table 151.4 Adolescent Psychosocial Assessment: HEADS/SF/FIRST Mnemonic

***H*ome.** Space, privacy, frequent geographic moves, neighborhood
***E*ducation/School.** Frequent school changes, repetition of a grade/in each subject, teachers' reports, vocational goals, after-school educational clubs (e.g., language, speech, math), learning disabilities
***A*buse.** Physical, sexual, emotional, verbal abuse; parental discipline
***D*rugs.** Tobacco, electronic cigarettes or vaping devices, alcohol, marijuana, inhalants, "club drugs," "rave" parties, others; drug of choice, age at initiation, frequency, mode of intake, rituals, alone or with peers, quit methods, number of attempts
***S*afety.** Seat belts, helmets, sports safety measures, hazardous activities, driving while intoxicated
***S*exuality/*S*exual Identity.** Reproductive health (use of contraceptives, presence of sexually transmitted infections, feelings, pregnancy)
***F*amily and *F*riends**
Family: Family constellation; genogram; single/married/separated/divorced/blended family; family occupations and shifts; history of addiction in first- and second-degree relatives; parental attitude toward alcohol and drugs; parental rules; chronically ill, physically or mentally challenged parent
Friends: Peer cliques and configuration ("preppies," "jocks," "nerds," "computer geeks," cheerleaders), gang or cult affiliation
***I*mage.** Height and weight perceptions, body musculature and physique, appearance (including dress, jewelry, tattoos, body piercing as fashion trends or other statement)
***R*ecreation.** Sleep, exercise, organized or unstructured sports, recreational activities (television, video games, computer games, internet and chat rooms, church or community youth group activities [e.g., Boy (BSA)/Girl Scouts; Big Brother/Sister groups, campus groups]). How many hours per day, days per week involved?
***S*pirituality and Connectedness.** Use HOPE* or FICA† acronym; adherence, rituals, occult practices, community service or involvement
***T*hreats and Violence.** Self-harm or harm to others, running away, cruelty to animals, guns, fights, arrests, stealing, fire setting, fights in school

*HOPE, *H*ope or security for the future; *o*rganized religion; *p*ersonal spirituality and *p*ractices; *e*ffects on medical care and end-of-life issues.
†FICA, *F*aith beliefs; *i*mportance and influence of faith; *c*ommunity support.
From Dias PJ: Adolescent substance abuse: assessment in the office. *Pediatr Clin North Am* 2002;49:269–300.

appropriate counseling or referrals are recommended for more thorough probing or for in-depth interviewing.

PHYSICAL EXAMINATION

Vision Testing

The pubertal growth spurt may involve the optic globe, resulting in its elongation and myopia in genetically predisposed individuals (see Chapter 658). Vision testing should therefore be performed to detect this problem before it affects school performance.

Audiometry

Highly amplified music of the kind enjoyed by many adolescents may result in hearing loss or tinnitus (see Chapter 676). A hearing screening is recommended by the *Bright Futures* guidelines for adolescents who are exposed to loud noises regularly, have had recurring ear infections, or report problems.

Blood Pressure Determination

Criteria for a diagnosis of hypertension are based on age-specific norms that increase with pubertal maturation (see Chapter 471). Individuals younger than 13 years old whose blood pressure (BP) exceeds the 95th percentile for their age are suspect for having hypertension, regardless of the absolute reading, and a BP between the 90th and 95th percentiles should receive appropriate counseling relative to weight and have a follow-up examination in 6 months. Individuals 13-18 years old with a BP of 130-139/80-89 are suspect for having hypertension, and those with a BP of 120-129/80 should receive appropriate counseling relative to weight and have a follow-up examination in 6 months. Those with elevated BPs should have their BP measured on three separate occasions to determine the stability of the elevation before moving forward with an intervention strategy. The technique is important; false-positive results may be obtained if the cuff covers less than two thirds of the upper arm. The patient should be seated, and an average should be taken of the second and third consecutive readings, using the change rather than the disappearance as the diastolic pressure. Most adolescents with BP elevation have labile hypertension. If BP is below 2 standard deviations (SD) for age, anorexia nervosa and Addison disease should be considered.

Scoliosis

See Chapter 720.

Approximately 5% of male and 10–14% of female adolescents have a mild curvature of the spine. This is 2-4 times the rate in younger children. Scoliosis is typically manifested during the peak of the height velocity curve, at approximately 12 years in females and 14 years in males. Females should be screened twice, once between 11 and 12 and again between 13 and 14, and males should be screened between 12 and 13. Curves measuring >10 degrees should be monitored by an orthopedist until growth is complete.

Breast Examination

See Chapters 158 and 588.

Visual inspection of the young and middle adolescent female's breasts is performed to evaluate progression of sexual maturation and provide reassurance about development. The American Cancer Society no longer recommends a clinical breast exam as a screening method for women in the United States. Breast self-exam is also no longer recommended as an option for women of any age.

Scrotum Examination

Visual inspection of the young and middle adolescent male testicles is performed to evaluate progression of sexual maturation and provide reassurance about development. The peak incidence of germ cell tumors of the testes is in late adolescence and early adulthood. Because varicoceles often appear during puberty, the examination also provides an opportunity to explain and reassure the patient about this entity (see Chapter 582). Self-examination is no longer recommended because of the low incidence and high recovery rates of testicular cancer in this age-group. Palpation of the scrotum along with visual inspection should be performed to document bilaterally descended testicles.

Pelvic Examination

See Chapter 585.

Laboratory Testing

The increased incidence of iron-deficiency anemia after menarche directs the performance of a hematocrit annually in females with moderate to heavy menses. The reference standard for this test changes with progression of puberty, as estrogen suppresses erythropoietin (see Chapter 496). Populations with nutritional risk should also have the hematocrit monitored. Androgens have the opposite effect, causing the hematocrit to rise during male puberty; sexual maturity rating (SMR) 1 males have an average hematocrit of 39%, whereas those who have completed puberty (SMR 5) have an average value of 43%. **Tuberculosis (TB)** testing is important in adolescents with risk factors, such as an adolescent with HIV, living in a household with someone with HIV, incarcerated, homeless, from a country where TB is common, or those with other risk factors, because puberty has been shown to activate this disease in those not previously treated. **Hepatitis C virus (HCV)** screening should be offered to all adolescents 18 years and older regardless of their risks. It should also be offered to adolescents who report risk factors, such as IDU, received blood products or organ donation before 1992, or long-term hemodialysis. The rate of acute hepatitis C has remained the highest among persons age 20-39 years, similar to age-groups at highest risk for fatal overdose in the United States and age at initiation of IDU among certain U.S. populations. Compared with 2018, the greatest increase in the rates of acute hepatitis C were observed among those age 40-49 years (31% increase), followed by those age 30-39 years (23% increase). For the first time in more than a decade, the rate of acute hepatitis C decreased slightly among those age 20-29 years. Rates have consistently been lowest among those age <20 years or ≥60 years. Sexually active adolescents should undergo screening for **STIs** per CDC guidelines, regardless of symptoms (see Chapter 163). There are clear indications for chlamydia and gonorrhea screening of females ≤24 years old, but less sufficient evidence to support routine screening in young men. Based on feasibility, efficacy, and cost-effectiveness, evidence is insufficient to recommend routine chlamydia screening in all sexually active young men. However, screening of sexually active young males should be considered in clinical settings associated with a high prevalence of chlamydia (e.g., adolescent clinics, correctional facilities, sexually transmitted disease clinics) and should be offered to all young MSM. **HIV** screening should be discussed and offered at least once to all adolescents age 15-18 years and to younger and older adolescents who are at increased risk. Routine screening of adolescents who are asymptomatic for certain STIs (e.g., syphilis, trichomoniasis, herpes simplex virus, HPV) is not recommended. However, young MSM and pregnant adolescent females might require more thorough evaluation for all sexually transmitted diseases. Because cervical cancer incidence is low and complications from procedures may outweigh benefits of screening adolescent females, cervical cancer screening should not begin until age 21 years.

Chapter 152

Transitioning to Adult Care

Joseph M. Truglio and Nikita Barai

The importance of thoughtfully and intentionally transitioning care of adolescents from pediatric to adult services, particularly for adolescents with **special healthcare needs (SHCN)**, has been recognized for more than 2 decades. The Society of Adolescent Health and Medicine defines health care transitions as "the purposeful, planned movement of adolescents and young adults (AYA) with chronic physical and medical conditions from child-centered to the adult-oriented health care system." For adolescents with SHCN, successful transition is associated with improved health outcomes and quality of life, whereas poorly managed transitions may lead to loss of a medical home and worsening of chronic disease control. All adolescents, regardless of SHCN, are likely to benefit from the autonomy, continuity of care, and self-management skills that are facilitated by a successful transition.

Guidelines emphasize that **transition** is a process, not an event, and encompasses much more than simply the transfer of care from one clinician to another. The guidelines make recommendations and provide practice-based resources for implementing elements of transition support in pediatric, family medicine, internal medicine, and combined internal medicine–pediatric practices. This includes providing assistance for the patient in adapting to an adult model of healthcare delivery as they transition from one practice/clinician to another or as they transition between models of care within the same practice. It also emphasizes the importance of the many members of the patient's care team (primary and specialty care, physical and occupational therapy, school and/or vocational support, mental health clinicians, and so on) that support the patient before, during, and after the transition process. Table 152.1 represents the key elements of healthcare transition. Tools to assist providers with these steps are available online from the National Center for Health Care Transition Improvement (www.gottransition.org).

The process begins with the development of a transition policy and its dissemination to all families of young adolescents, ensuring families understand that transition planning will be an element of health maintenance and chronic care management visits throughout the adolescent years. By middle adolescence, a transition plan should be developed with the youth and family caregivers and updated at subsequent visits until the patient is ready for implementation of the adult care model in early adulthood. Periodic **readiness assessments** are key to planning and anticipating challenges. Critical to the transition process is **skills training** for the adolescent in communication, self-advocacy, and self-care. Some youth with SHCN depend on caregivers for navigating the healthcare system on their behalf, and it is not realistic to expect increased independence. For these youth, addressing guardianship, long-term care planning, and advance directives are important. **Care coordination** facilitates navigation and engagement in an adult-oriented health system, especially for adolescents with SHCN. The goal is to help all youth maximize their potential as they become young adults.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 152.1 Key Elements of the Transition of Healthcare Process

- **Written transition policy** to be shared with youth, families, providers, and staff, explaining the process and the responsibilities of all team members
- **Transitioning youth registry** to track the progress of each patient through the transition process
- **Longitudinal readiness checklists** assessing the youth's ability for independence, self-management, and communicating with the adult healthcare system, as well as the family's readiness to assist the patient in achieving these goals
- **Written transition plan** documenting the steps to be conducted to meet the needs identified in the readiness assessment and identifying appropriate adult care resources
- For youth with SHCN, expanded transition services, including attention to insurance, entitlements, guardianship, and vocational needs, in addition to adult subspecialty care
- Appropriate communication between the pediatric and adult medical home and subspecialists, including a **portable medical summary** and care plan delivered to the patient and caregivers
- Transfer of care, within the 18- to 21-yr-old range, to adult providers, to whom pediatric providers continue to serve as a resource until transition is complete

Chapter 153

Gender Identity and Transgender Care

Abby Walch and Stephen M. Rosenthal

TERMINOLOGY

Sex refers to the physical or genetic characteristics that differentiate between biologic maleness or femaleness (e.g., sex chromosomes, gonads, internal and external genital structures). **Sex designated (assigned) at birth** is typically based on the appearance of the external genitalia. In the absence of atypical genitalia, which may indicate a difference of sexual development requiring further evaluation, sex is designated at birth as either male or female.

Gender identity refers to one's internal core sense of gender. Gender is not binary, and although most people identify their gender as being male (boy or man) or female (girl or woman), others may identify as both, neither, or another gender completely. The gender identity of an individual cannot be known until they reach a certain level of psychosocial development and self-awareness to identify it themself. Development of gender identity likely results from a complex interplay of biologic, environmental, and cultural factors. This concept is supported by compelling studies in several biomedical disciplines including genetics, endocrinology, and neurology. **Gender expression** refers to one's external manifestations of gender (e.g., choice of name, pronouns, clothing, hairstyle), whereas **gender role** describes the behaviors, attitudes, and personality traits considered to be masculine or feminine by a society or culture during a particular period.

Many cultures recognize and accept as normal more than two genders. In the Philippines, *Bakla* is considered a third gender; many are community leaders. In India, the third gender is *Hijras,* and Aboriginal (Australian) terms such as *brotherboy* and *sistergirl* are used to refer to transgender and gender-diverse people.

Indigenous Nations (America) peoples may have three to five genders: male, female, Two Spirits female, Two Spirits male, and transgender. Navajo refer to Two Spirits as *Nádleehí* (transformed), and the Cheyenne term for Two Spirits is *Hemaneh* (half man, half woman). In all these societies, Two Spirits people are honored and often leaders in their tribe.

Cisgender refers to people who have a gender identity that aligns with their sex designated at birth. **Gender incongruence** is the term used when gender identity does not align with the sex designated at birth. **Transgender and gender diverse (TGD)** is an umbrella term used to describe a diverse group of people with gender incongruence. *All TGD gender identities are normal, healthy variations within the spectrum of possible gender identities.* Individuals with gender identities that are not exclusively male or female may describe themselves as **gender nonbinary**, **genderqueer**, or **genderfluid**. Some of these individuals may also identify as transgender while others may not.

Gender dysphoria refers to the distress experienced by TGD individuals caused by gender incongruence. This term replaced "gender identity disorder" in the most recent *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-5 published in 2013, focusing the clinical concern on the distress an individual may experience because of gender dysphoria and underscoring the *nonpathologic* nature of TGD gender identities. Not all TGD individuals experience gender dysphoria, and use of this term, although sometimes necessary to obtain gender-affirming therapies, may be considered offensive and stigmatizing by some.

It is important to distinguish gender identity as separate from **sexual orientation**, which refers to an individual's sexual attraction to another person. Gender identity does not predict sexual orientation, and a person with any gender identity may have any sexual orientation.

EPIDEMIOLOGY

Early studies likely underestimated the size of the TGD population due to reliance on reports of individuals who accessed gender-related mental health or medical care and because of the lack of questions related to gender identity on population-based surveys. With newer study methods and increased societal recognition and acceptance of the diverse spectrum of genders, it is now evident that the prevalence of TGD persons is higher than previously thought. With improved access to multidisciplinary gender clinics, TGD youth are seeking gender-affirming medical treatment at increasing rates.

In 2022, a report from the Williams Institute of the University of California Los Angeles School of Law, informed by the Center for Disease Control and Prevention's (CDC's) Behavior Risk Factor Surveillance System and the Youth Risk Behavior Survey carried out from 2017 to 2020 and 2017 to 2019, respectively, revealed that 0.5% of U.S. adults (18 years and older) and 1.4% of adolescents and young adults (13-17 years) identify as transgender. A population-based study of self-reported gender identity in high school students carried out in Minnesota in 2016 reported a 2.7% prevalence of TGD individuals. An international review in 2016 estimated the TGD population worldwide to be 25 million with 0.5–1.3% of birth-designated males and 0.4–1.2% of birth-designated females having TGD gender identities.

There has been a striking inversion in the sex ratio of TGD youth seeking services for gender dysphoria. Reports from Europe and North America prior to 2005–2006 revealed a predominance of birth-designated males. Since then, and for unclear reasons, there has been a predominance of birth-designated females. A 2017 survey of 25 gender centers in the United States, Europe, and Chile demonstrated that 63% of youth being treated were transitioning from female to male.

Clinical Presentation

TGD youth may recognize and reveal their gender identity to others at any age. Some will communicate their identity in early childhood as soon as they are able to talk. Others may not acknowledge or share their identity until adulthood, largely influenced by a cis-heteronormative society in which TGD individuals encounter significant oppression and discrimination. What is evident is the importance of accepting and valuing the gender identities as reported by TGD children at any point in time and the recognition that gender may not be binary and may change over time.

Gender incongruence that occurs in young children does not invariably persist into adolescence and adulthood. Studies based on earlier versions of the DSM demonstrate that gender dysphoria or gender incongruence in prepubertal children persists in a minority of these individuals. Future studies may reveal different persistence rates, as DSM-5 criteria for the diagnosis of gender dysphoria are narrower compared to previous versions. Although it is currently not possible to predict which children will persist in their asserted TGD identity, certain factors are associated with persistence of a TGD identity. Receipt of a gender dysphoria diagnosis in childhood, increased intensity of gender dysphoria as measured on gender dysphoria scales, social gender transition in childhood, sex designated as female at birth, and older age at clinic intake have been associated with higher persistence rates of TGD identities. Although not well studied, the assigned male at birth verbal toddler who asserts "I am a girl" (rather than "I want to be a girl") has a high likelihood of persistence.

Recognition that social gender transition in prepubertal children is associated with a higher likelihood of persistence should not prevent children from making this transition. Social transition, when completed early, may result in more favorable outcomes for some TGD children and should be done with input from a qualified mental health provider. Currently, persistence of gender incongruence and gender dysphoria can only reliably be assessed after the onset of puberty. Gender dysphoria that emerges or worsens with puberty onset is associated with a very high rate of persistence of that individual's TGD identity into adulthood, an observation that is fundamental to the rationale for the provision of medical interventions in TGD youth who meet criteria for treatment.

Diagnostic Evaluation

Optimally, the diagnostic evaluations of TGD youth are performed by a multidisciplinary team comprising medical and mental health professionals. Current clinical practice guidelines recommend that gender incongruence and gender dysphoria be diagnosed by a qualified mental health gender specialist after a thorough psychodiagnostic evaluation. Specific criteria for the mental health gender specialist in their role providing care for TGD youth are outlined elsewhere, whereas the recommendations in this chapter are intended for medical providers.

Although the involvement of a mental health gender specialist in the diagnostic evaluation of TGD youth is recommended by current clinical practice guidelines prior to initiating any medical therapies, it is recognized that this may not always be possible. Mental health gender specialists may be inaccessible in certain areas, and the insistence that a TGD child establish mental healthcare in this circumstance could delay care indefinitely. Additionally, if an early pubertal TGD child presents with significant gender dysphoria, and if requiring input from a mental health gender specialist before initiating puberty blockers would create a significant delay in care, resulting in the development of irreversible secondary sexual characteristics, this could be harmful. Therefore in limited circumstances it may be reasonable to initiate gender-affirming medical therapies without input from a mental health gender specialist, though with the increasing use of telehealth, there may be greater access to mental health gender specialists. Providers involved in the diagnostic evaluation of TGD youth should be thoughtful about their strengths and limitations and refer for further evaluation as needed to provide optimal care.

At the initial clinic visit, medical providers should obtain information from TGD youth and their families about the child's gender journey. This information should include their current understanding of their gender identity, challenges faced in addition to support received in their families and surrounding communities, any distress associated with their body and if so whether it changed with puberty, and a full medical and mental health history. After obtaining this information, in TGD youth seeking gender-affirming medical therapies, the medical provider then must decide whether the individual fulfills criteria for treatment (Table 153.1) for gender dysphoria/gender incongruence according to the DSM-5 (Table 153.2).

Table 153.1 Criteria for Gender-Affirming Hormone Therapy for Adolescents

Adolescents are eligible for GnRH agonist treatment if:

1. A QUALIFIED MHP HAS CONFIRMED THAT:
   - The adolescent has demonstrated a long-lasting and intense pattern of gender nonconformity or gender dysphoria (whether suppressed or expressed)
   - Gender dysphoria worsened with the onset of puberty
   - Any coexisting psychologic, medical, or social problems that could interfere with treatment (e.g., that may compromise treatment adherence) have been addressed, such that the adolescent's situation and functioning are stable enough to start treatment
   - The adolescent has sufficient mental capacity to give informed consent/assent to this (reversible) treatment
2. AND THE ADOLESCENT:
   - Has been informed of the effects and side effects of treatment (including potential loss of fertility if the individual subsequently continues with sex hormone treatment) and options to preserve fertility
   - Has given informed consent/assent and (particularly when the adolescent has not reached the age of legal medical consent, depending on applicable legislation) the parents or other caretakers or guardians have consented to the treatment and are involved in supporting the adolescent throughout the treatment process
3. AND A PEDIATRIC ENDOCRINOLOGIST OR OTHER CLINICIAN EXPERIENCED IN PUBERTAL ASSESSMENT:
   - Agrees with the indication for GnRH agonist treatment
   - Has confirmed that puberty has started in the adolescent (Tanner stage ≥G2/B2)
   - Has confirmed that there are no medical contraindications to GnRH agonist treatment

Adolescents are eligible for subsequent sex hormone treatment if:

1. A QUALIFIED MHP HAS CONFIRMED:
   - The persistence of gender dysphoria
   - Any coexisting psychologic, medical, or social problems that could interfere with treatment (e.g., that may compromise treatment adherence) have been addressed, such that the adolescent's situation and functioning are stable enough to start sex hormone treatment
   - The adolescent has sufficient mental capacity (which most adolescents have by age 16 years) to estimate the consequences of this (partly) irreversible treatment, weigh the benefits and risks, and give informed consent/assent to this (partly) irreversible treatment
2. AND THE ADOLESCENT:
   - Has been informed of the (irreversible) effects and side effects of treatment (including potential loss of fertility and options to preserve fertility)
   - Has given informed consent/assent and (particularly when the adolescent has not reached the age of legal medical consent, depending on applicable legislation) the parents or other caretakers or guardians have consented to the treatment and are involved in supporting the adolescent throughout the treatment process
3. AND A PEDIATRIC ENDOCRINOLOGIST OR OTHER CLINICIAN EXPERIENCED IN PUBERTAL INDUCTION:
   - Agrees with the indication for sex hormone treatment
   - Has confirmed that there are no medical contraindications to sex hormone treatment

MHP, mental health professional.
Data from Coleman E, Radix AE, Bouman WP, et al. Standards of care for the health of transgender and gender diverse people, Version 8. *Int J Transgend Health*. 2022;23(Suppl 1):S1-S259.

Table 153.2 DSM-5 Criteria for Gender Dysphoria in Adolescents and Adults

A. A marked incongruence between one's experienced/expressed gender and natal gender of at least 6 mo in duration, as manifested by at least two of the following:
   1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics)
   2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics)
   3. A strong desire for the primary and/or secondary sex characteristics of the other gender
   4. A strong desire to be of the other gender (or some alternative gender different from one's designated gender)
   5. A strong desire to be treated as the other gender (or some alternative gender different from one's designated gender)
   6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's designated gender)

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning

Specify if:

1. The condition exists with a disorder of sex development
2. The condition is posttransitional, in that the individual has transitioned to full-time living in the desired gender (with or without legalization of gender change) and has undergone (or is preparing to have) at least one sex-related medical procedure or treatment regimen—namely, regular sex hormone treatment or gender reassignment surgery confirming the desired gender (e.g., penectomy, vaginoplasty in natal males; mastectomy or phalloplasty in natal females)

Gender-Affirmative Care

TGD youth have historically faced high rates of discrimination and barriers in medical care settings. Pediatric primary care providers play a vital role in assessing the gender identities of their patients during routine well child checks, and they should be relied upon as a trusted source of validation, support, and reassurance to TGD youth and their families (Table 153.3). If a provider feels unable to address gender-related issues, then referral to another provider who can is recommended. If additional information on gender-affirming medical therapies is desired, referral to a provider with expertise in the care of TGD youth is appropriate. Available resources for youth, family, and providers are noted in Table 153.4.

Pediatric providers should follow a gender-affirmative care model (GACM) in their practices. In a GACM, providers offer a supportive, open-minded environment while facilitating discussion and exploration of their patients' gender identities. Within this care model, the following messages are relayed: (1) TGD identities and diverse gender expressions are normal, healthy variations, (2) gender identity develops through a complex interplay of biologic, environmental, and cultural factors, and (3) coexisting mental health issues are more often *caused* by stigma and discrimination than by internal psychologic disturbances within the TGD child. Key components of gender-affirming clinics are highlighted in Figure 153.1.

Pediatric providers should help TGD youth explore the various options available for gender affirmation. Some TGD youth will require medical or surgical interventions for affirmation of their gender, whereas others will not. Social transition is a nonmedical intervention that may occur gradually or all at once. It may occur in only some environments and not in others, or it may occur in all spaces in which TGD individuals find themselves. Social transition may include adaptions to name and/or pronouns, changes to hairstyle and/or clothing, use of devices to hide unwanted physical features (e.g., binders to create a smoother contour of the chest) or to create the appearance of desired physical features (e.g., packers to achieve the appearance of a genital bulge), and steps to access appropriate restroom facilities at school, work, or other public locations. Social transition may also include legal

Table 153.3 Strategies for Supporting TGD Youth

DOMAIN	STRATEGIES
Clinical settings	Use of affirmed name and pronouns in clinical spaces and inclusion of this information in the electronic medical record (EMR) Training for clinical staff Use of affirming imagery, inclusive intake forms Gender-neutral bathroom spaces Open-ended, nonjudgmental discussion about gender identity Sensitive, trauma-informed care History taking using nongendered language
Relationships with family/ caregivers	Assistance with disclosure of identity to family when desired by the youth Psychoeducation on gender development and the benefits of supporting TGD youth Promoting practices such as use of affirmed name and pronouns Education about social transitioning Providing space and support for parents to express concerns without youth present Support for disclosure to extended family or other important people Referrals to support groups or family counseling
Educational settings	Education for school staff on gender concepts and zero tolerance for transphobia Advocating for the use of affirmed name and pronouns Advocacy for inclusive sexual education curriculum Advocacy for youth to use preferred bathrooms, locker rooms, and dorms and participate with desired sports teams
Public identification	Assistance with documentation for changing legal name and/or gender marker Documentation of the patient's gender identity to ensure safe passage during travel

affirmation in which an individual updates their name and/or gender marker on legal documents.

MENTAL HEALTH CONSIDERATIONS

Although the vast majority of TGD youth do not have any underlying severe psychiatric illnesses, they are at increased risk of internalizing disorders and life-threatening behaviors. Studies have demonstrated an increased prevalence of anxiety, depression, obsessive-compulsive disorder, posttraumatic stress disorder, eating disorder, self-harm behavior, suicidal ideation, and suicide attempts in TGD youth compared to cisgender controls. These conditions and behaviors are not inherent to an individual's gender identity, but rather often occur secondary to a lack of societal acceptance, stigma, discrimination, and poor

access to gender-affirming mental health and medical care. A higher co-occurrence of autism spectrum disorder among individuals with gender dysphoria and vice versa has also been demonstrated in addition to higher rates of homelessness, physical violence, substance abuse, and high-risk sexual behaviors compared to the general population.

In addition to determining the presence or absence of gender dysphoria as part of the psychodiagnostic evaluation, there are many important reasons to consider involving a mental health gender specialist in the evaluation and care of TGD youth *before* and *during* the provision of gender-affirming medical care. Mental health gender specialists may (1) evaluate for the presence of and provide treatment for coexisting mental health concerns, (2) provide family counseling and supportive psychotherapy to assist youth with the exploration of their gender identity and alleviate any distress secondary to gender dysphoria, (3) provide education, assist in decision-making, and refer as indicated for gender-affirming medical therapies, (4) educate and advocate for TGD youth and their families in their community, and (5) provide TGD youth and their families with information for support groups. An emphasis should be placed on the nonpathologic nature of TGD gender identities, and conversion or reparative therapies aimed at changing an individual's gender identity are ineffective and unethical (and illegal in certain places) practices that should not be pursued.

Despite the increased risk for mental health comorbidities in TGD youth, studies have provided evidence of protective factors resulting in positive mental health outcomes. Education regarding and access to gender-affirming medical interventions at early pubertal stages resulted in less gender dysphoria and better mental health and well-being in TGD youth. Additionally, TGD youth with supportive family environments have better mental health outcomes and quality of life. This knowledge underscores the importance of involving a qualified mental health professional to facilitate supportive home environments as needed and educating TGD youth and their families on options for gender-affirming medical therapies.

Another aspect of support is to provide access to other children/adolescents who are TGD. Many have identified like-minded friends in their own community, but others may develop a community through summer camps, group meetings associated with a treatment center, or the internet.

Gender-Affirming Medical Care

Affirming medical and surgical options in TGD individuals who require them to bring their body into alignment with their gender identity are essential, medically necessary interventions that have clear mental health benefits, some of which might even be lifesaving. Mental health benefits of gender-affirming medical therapies include the alleviation of gender dysphoria and the avoidance of worsening of any underlying psychologic distress. Options available to TGD youth vary depending on their pubertal and developmental stage, and care should be individualized based on the goals of the child rather than applied as a blanket algorithm. At each decision point, careful consideration should be given to the potential risks, benefits, and likely outcomes of each treatment, and use of signed consent forms, or informed assent forms in the case of individuals <18 years of age, attesting to an understanding of these considerations are advised before initiating any gender-affirming medical therapies. Medical care for TGD youth is based primarily on the World Professional Association for Transgender Health (WPATH) Standards of Care (SOC) published in 2022 and the Endocrine Society's clinical practice guidelines, last published in 2017. TGD seeking gender-affirming hormone therapy must satisfy certain criteria before proceeding (see Table 153.1).

Current standards of care and clinical practice guidelines for the gender-affirming medical care of TGD youth are based on compelling research from short- to medium-term studies, a 22-year follow-up case report, and expert opinion. Although large longitudinal observational outcome studies are ongoing, there remains a paucity of long-term outcome data currently available. Nevertheless, refusing to deliver timely medical interventions for TGD youth is not a neutral option. A delay or withholding of care may prolong or worsen gender dysphoria and mental health and lead to the development of irreversible physical changes that may require invasive surgical interventions in the future.

PUBERTY BLOCKERS

Treatment Criteria and Timing

Pubertal hormone suppression is recommended in TGD youth who meet criteria for treatment (see Table 153.1). No medical interventions are recommended before the onset of puberty. TGD youth are eligible for treatment *only after* the onset of puberty. Medical providers should monitor for physical exam findings consistent with Tanner stage 2, including breast buds in youth designated female at birth and testicular volume ≥4 mL in youth designated male at birth. Laboratory assays, including ultrasensitive gonadotropin and sex steroid levels obtained in the early morning, can be used to confirm the onset of puberty. However, gonadotropin-releasing hormone (GnRH) is released from the hypothalamus in a pulsatile manner, and in early puberty, gonadotropin and sex steroid hormone levels may overlap with prepubertal ranges if checked at random times.

Goals of Therapy

When initiated early in puberty, pubertal suppression allows for expansion of the diagnostic phase with additional time for gender identity exploration before deciding whether or not to proceed with gender-affirming sex hormone (GAH) therapy. Pubertal suppression also prevents the development of undesirable, irreversible secondary sex characteristics not aligned with the individual's gender identity. These irreversible characteristics include breast development, female body habitus, and possibly short stature in individuals designated female at birth and low voice, laryngeal prominence, male bone configuration, tall stature, and male hair pattern on the face and extremities in individuals designated male at birth. Some, but not all, of these features can only be addressed later with surgery, but pubertal suppression is preferred. Pubertal suppression initiated in early puberty is thought to be fully reversible; if suspended or discontinued, endogenous puberty will resume.

Pubertal suppression can also be considered in TGD youth in later stages of puberty with the goal of achieving menstrual suppression in individuals designated female at birth or the goal of blocking androgen effects in individuals designated male at birth. However, studies do not currently exist that inform whether pubertal blockers can be used as a monotherapy (and for how long) in adolescents older than 14 without posing a risk to skeletal health, given that prolonged deficiency of sex steroids could result in impaired bone mineral density (BMD) during later adolescence and adulthood.

Treatment Options

GnRH agonists are the preferred agents for pubertal suppression in TGD youth. GnRH agonists are long-acting medications that are highly effective in suppressing gonadotropin release through GnRH receptor desensitization. Once started, GnRH agonists may result in some regression of previously developed secondary sex characteristics, including atrophy of breast tissue and a reduction in testicular size. GnRH agonists are available as injectables given every 1-6 months or as subcutaneous implants that last 1-2 years.

Although GnRH agonists are the most effective and preferred option for pubertal suppression, they are costly and may be inaccessible to TGD individuals without insurance coverage. Antiandrogens and progestins with antiandrogen properties, including spironolactone, cyproterone, bicalutamide, and medroxyprogesterone, provide additional options for pubertal suppression. These medications are not as efficacious in suppressing the HPG axis as compared to GnRH agonists, and concern regarding potential side effects have limited their use. The various medications available for pubertal suppression can be found in Table 153.5.

Potential Adverse Effects

Before initiating treatment for pubertal suppression, it is important to discuss potential adverse effects with TGD youth and their guardians. The primary risks of treatment with GnRH agonists

Table 153.5 Available Formulations of Medications Used for Pubertal Blockade

	MEDICATION	ROUTE OF ADMINISTRATION	DOSING FREQUENCY	DOSE
GnRH agonists	Leuprolide acetate	Intramuscular	Every 1-3 mo	11.25-30 mg
	Triptorelin	Intramuscular	Every 24 wk	22.5 mg
	Histrelin	Subcutaneous implant	Every 1-2 yr	50 mg
Progestins	Medroxyprogesterone	Oral	Daily	Up to 40 mg
		Intramuscular	Every 3 mo	150 mg
Antiandrogens	Spironolactone	Oral	1-2 times/day	25 mg initially, up to 100-300 mg divided twice daily
	Cyproterone acetate	Oral	Daily	Up to 100 mg
	Bicalutamide	Oral	Daily	50 mg

include impaired bone mineralization, compromised fertility (if followed by GAH therapy), and unknown effects on brain development and metabolism.

Bone Health

GnRH agonist treatment initiated early in puberty is associated with an increased risk of compromised BMD. Assessment of BMD in TGD individuals is challenging in part because it is not clear whether scores should be compared to norms for the individual's sex designated at birth or to norms for their gender identity. Previous studies have demonstrated an expected stabilization or decline in BMD Z-scores during treatment with GnRH agonists without recovery to baseline after treatment with GAH therapy in all instances. In one study, BMD Z-scores normalized in transmales but remained below zero in transfemales 3 years after the addition of GAH therapy. Potential explanations for differences include differences in lifestyle, exercise, and vitamin D levels. In early pubertal TGD youth treated with GnRH agonists, vitamin D status should be monitored and supplemented, if necessary, and adequate dietary calcium intake and weight-bearing exercise should be encouraged to optimize bone health. BMD should also be monitored every 1-2 years during GnRH agonist treatment and, if the individual undergoes phenotypic transition with gender-affirming sex hormones, should continue to be monitored as described in the Endocrine Society's clinical practice guideline (Tables 153.6 and 153.7).

Fertility

Before initiating treatment for pubertal suppression, counseling must be provided regarding options for fertility preservation. TGD adolescents and their families should be given the opportunity to meet with a specialist in reproductive endocrinology before initiating therapy or at any point during gender-affirming medical therapy as desired. When initiated early in puberty, GnRH agonists inhibit gonadal tissue maturation. If discontinued, the effects of GnRH agonists on fertility are reversible, and gamete maturation will resume. However, if followed by GAH therapy, fertility is likely to be compromised. If TGD youth desire fertility preservation, delaying or temporarily discontinuing pubertal suppression to promote spermatogenesis and oocyte maturation to allow for gamete collection is an option. The attainment of mature gametes occurs during the later stages of puberty when irreversible secondary sexual characteristics have developed, however, features that are undesirable for many TGD youth. Individuals who decide to continue pubertal suppression may elect to preserve immature gonadal tissue in the hopes that ongoing studies and future preservation techniques will allow for the maturation and preservation of viable gametes. Although in vitro maturation of human germ cells has not yet been accomplished, a report described in vivo maturation and subsequent cryopreservation of oocytes in a transgender male adolescent treated with a GnRH agonist starting in early puberty. This was achieved 2 years after the initiation of GnRH agonist therapy and without the discontinuation of pubertal suppression.

In contrast to TGD youth who initiate GnRH agonist therapy in early puberty, cryopreservation of mature sperm or eggs is an option before initiating gender-affirming medical therapy in late puberty or postpuberty (Table 153.8). If GAH therapy is initiated without fertility preservation in these individuals, it may be possible to discontinue hormone therapy in the future to allow for recovery of the hypothalamic-pituitary-gonadal (HPG) axis and subsequent gamete maturation. Stopping estrogen in individuals designated male at birth may allow for recovery of testicular function and collection of sperm. Discontinuation of testosterone in individuals designated female at birth may allow for ovarian recovery and release of eggs, and some who have desired this have had successful pregnancies. Unfortunately, even when counseling is provided, very few TGD youth pursue fertility preservation because of the high associated costs and invasiveness of some procedures and concerns regarding potential delays to medical transition.

Brain Development

Very few studies thus far have assessed the impact of GnRH agonist therapy on brain development. Attainment of executive functioning is a milestone that is typically achieved during puberty. A single cross-sectional study comparing TGD adolescents treated with GnRH agonists

Table 153.7 Baseline and Follow-Up Protocol During Induction of Puberty

Anthropometry	Height,* sitting height,* weight, blood pressure, Tanner stages*	Every 3-6 mo
Laboratory studies	Testosterone: testosterone, hemoglobin/hematocrit, lipids, 25-OH vitamin D* Estrogen: estradiol, prolactin, 25-OH vitamin D*	Every 3-12 mo
Imaging*	DXA to evaluate bone mineral density†	Every 1-2 yr
	Left hand radiograph to evaluate bone age (as clinically indicated)	

*Only indicated in individuals previously treated with pubertal blockers.
†BMD should be monitored into adulthood (until the age of 25-30 yr or until peak bone mass has been reached).

to untreated TGD adolescents found no significant differences in executive functioning. However, animal studies have suggested that GnRH agonists may affect cognitive function, and one transgender adolescent was reported to demonstrate a lack of expected variation in white matter fractional anisotropy (a measure of brain maturation thought to typically occur during puberty) and a 9-point drop in operational memory testing after approximately 2 years of treatment with a GnRH agonist. A subsequent systematic review and meta-analysis found no adverse impacts of hormone therapy on cognitive function in transgender young adults. Additional long-term studies are necessary to assess the impact of GnRH agonist therapy more fully on brain development in TGD youth.

Metabolism and Other Effects

A few studies have evaluated the effects of GnRH agonists on various metabolic and physiologic parameters and future surgical outcomes. A decrease in lean body mass, an increase in fat percentage, and weight gain have been reported in studies of TGD adolescents treated with GnRH agonists. TGD youth designated female at birth who start GnRH agonist therapy may also experience hot flashes, especially if this treatment is initiated in the later stages of puberty. TGD youth designated male at birth who initiate pubertal suppression in early puberty will have limited growth of their genitalia, which may require alternative techniques for penile inversion-vaginoplasty if gender-affirming genital surgery is desired in the future, and counseling should be provided in this regard before initiating treatment with a pubertal blocker.

Alternative Therapy Side Effects

GnRH agonist therapy for pubertal suppression may not be an option for all TGD youth, and alternative therapies are also associated with potential adverse effects. Spironolactone may cause electrolyte abnormalities, polyuria, and orthostasis. Concern for potential hepatotoxicity associated with cyproterone acetate and bicalutamide treatment has limited their use. Progestin treatment may cause hot flashes, headaches, acne, depression, weight gain, lipid changes, and irregular menstrual bleeding in individuals designated female at birth.

Monitoring Protocol

Efficacy and potential adverse effects of treatment should be monitored closely in TGD youth treated with pubertal suppression according to the protocol outlined in Table 153.6. For individuals treated with spironolactone, serum electrolytes should be monitored every 3 months for the first year of therapy and then annually.

A clear endpoint for pubertal suppression can be difficult to determine. It is generally recommended that GnRH agonists not be continued as monotherapy past age 14 years (nor initiated as a monotherapy past age 14 years) because of the potential adverse effects on bone health. The decision must ultimately be made to discontinue pubertal suppression all together or to initiate concurrent treatment with GAH therapy. It is recognized that this decision point can be difficult for TGD adolescents, particularly for some with nonbinary gender identities who may not desire certain physical changes that may occur with sex hormone therapy. Although current guidelines suggest that GnRH

Table 153.9 Protocol Induction of Puberty

	MEDICATION	ROUTE OF ADMINISTRATION	DOSING FREQUENCY	INITIAL DOSE	DOSE ESCALATION	ADULT DOSE
Estrogen	17β–estradiol	Oral/sublingual	Daily	PB: 5 μg/kg/day	5 μg/kg every 6 mo	2-6 mg/day
				PP: 1 mg	1 mg every 6 mo	
		Transdermal	Every 3-5 days	PB: 6.25-12.5 μg/24 hr	12.5 μg/24 hr every 6 mo	50-200 μg/24 hr
				PP: 25-50 μg/24 hr	25 μg/24 hr every 6 mo	
Testosterone	Testosterone enanthate/ cypionate	Subcutaneous	Weekly	PB: 12.5 mg/m^2	12.5 mg/m^2 every 6 mo	30-100 mg/wk
				PP: 37.5 mg	37.5 mg every 6 mo	
		Intramuscular	Every 2 wk	PB: 25 mg/m^2	25 mg/m^2 every 6 mo	60-200 mg every 2 wk
				PP: 75 mg	75 mg every 6 mo	

PB, Pubertal blocker initiated in early puberty; PP, postpuberty.

Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2017;102:3869–3903, Table 8; and from Allen BJ, Rosenthal SM. Care of transgender, nonbinary, and gender diverse youth. In: Allen DB, Nadeau K, Kappy MS, Geffner ME, eds. *Pediatric Endocrinology: Principles and Practice*, 3rd ed. New York: McGraw Hill; 2020, Fig. 7-2.

agonist therapy may be continued in conjunction with sex hormone therapy until gonadectomy (if pursued), it is often possible to discontinue this therapy in individuals designated female at birth who initiate treatment with testosterone once adult levels of testosterone have been reached.

GENDER-AFFIRMING SEX HORMONE THERAPY

Treatment Criteria and Timing

GAH therapy is a medically necessary intervention for many TGD adolescents. GAH therapy is partially reversible, and it is the responsibility of the medical provider to ensure the adolescent meets criteria for treatment before initiating therapy (see Table 153.1). *GAH treatment may be initiated in TGD adolescents who request this therapy after a multidisciplinary team of medical and mental health providers has confirmed the persistence of gender dysphoria/gender incongruence and if the adolescent has sufficient mental capacity to give informed consent/assent.* Most adolescents are felt to have sufficient mental capacity to provide informed consent by age 16 years; however, there may be compelling reasons to initiate therapy earlier. TGD youth treated with pubertal suppression at Tanner stage 2, which may occur as early as 8-9 years of age, may incur certain risks if this treatment is continued as monotherapy until 16 years of age. Prolonged pubertal suppression may be detrimental to bone health, and it may have detrimental effects on mental health if puberty is delayed well beyond the majority of an individual's peers. Treatment with GAH therapy therefore should be individualized with consideration given to earlier initiation as clinically indicated. Initiation of GAH should follow an evaluation by a qualified mental health gender specialist (separate from any evaluation focused on prior use of pubertal suppression), the signing of consent/assent forms, the obtainment of baseline labs, and consideration of fertility preservation.

Goals of Therapy

The goals of GAH therapy are (1) to reduce *endogenous* sex hormone levels to prevent the development of secondary sex characteristics in individuals previously treated with pubertal blockers or to reduce secondary sex characteristics in those who have already progressed through any degree of puberty and (2) to provide *exogenous* sex hormones to allow for phenotypic changes aligned with an individual's gender identity. GAH therapy must be individualized based on the adolescent's goals rather than applying a one-size-fits-all approach, though it is important to achieve a level of either testosterone or estrogen that is in the normal range for a person's developmental stage.

Treatment Options

In TGD adolescents whose puberty was blocked in early Tanner stages, puberty induction with GAH treatment should be initiated using a gradually increasing dose schedule (Table 153.9). Initial exogenous sex hormone levels are insufficient to suppress endogenous sex hormone secretion, and pubertal blockade should be continued. As sex hormone doses increase, GnRH agonist treatment may often be discontinued in individuals designated female at birth who are treated with testosterone therapy. Adult doses of exogenous testosterone therapy are often sufficient to suppress the HPG axis. In contrast, pubertal suppression must often be continued in individuals designated male at birth who are treated with estrogen therapy. Adult doses of estrogen therapy are insufficient in suppressing the HPG axis and testosterone release. Ongoing adjunctive therapy with a GnRH agonist or antiandrogen therapy (e.g., spironolactone) to block testosterone secretion and/or action is required indefinitely or until gonadectomy, if pursued. Not all TGD adolescents will pursue gonadectomy, and long-term studies are needed to determine the potential risks of prolonged treatment with GnRH agonists.

In TGD adolescents who present for gender-affirming medical therapy in late puberty or after completion of puberty, pubertal induction with sex hormones can start at higher doses and can occur more rapidly (see Table 153.9).

At this time, no evidence has demonstrated that any of the following medically approved types or methods of administering hormones is superior to others in yielding the desired phenotypic changes. Protocols for some formulations of estrogen and testosterone are not available. Protocols that do exist are outlined in Table 153.9. It is important to emphasize to patients that individual variations in outcomes will occur based on several factors including genetics, body type, and compliance.

Estrogen

Estrogen can be given via transdermal, oral, or injectable routes. The naturally occurring form, 17β–estradiol, is preferred to synthetic (e.g., ethinyl estradiol) and conjugated estrogens (e.g., Premarin), which cannot easily be monitored in the serum. Compared to synthetic estrogens, 17β–estradiol is also associated with a lower risk of venous thromboembolism (VTE). Serum estradiol levels can be monitored, with the eventual goal of achieving values in the normal range for premenopausal females (100-200 pg/mL).

TGD individuals who pursue estrogen therapy should be educated on the expected timeline of physical changes (Table 153.10).

Table 153.10 Timeline of Effects from Gender-Affirming Sex Hormone Therapy

	EFFECT	ONSET	MAXIMUM	REVERSIBILITY
Estrogen	Redistribution of body fat	3-6 mo	2-3 yr	Likely
	Decreased muscle mass/strength	3-6 mo	1-2 yr	Likely
	Softening of skin/decreased oiliness	3-6 mo	Unknown	Likely
	Decreased sexual desire	1-3 mo	3-6 mo	Likely
	Decreased spontaneous erections	1-3 mo	3-6 mo	Likely
	Breast growth	3-6 mo	2-3 yr	Not possible without surgery
	Decreased testicular volume	3-6 mo	2-3 yr	Unknown
	Decreased sperm production	Unknown	>3 yr	Unknown
	Decreased terminal hair growth	6-12 mo	>3 yr	Possible
	Scalp hair	Variable		
Testosterone	Skin oiliness/acne	1-6 mo	1-2 yr	Likely
	Facial/body hair growth	6-12 mo	4-5 yr	Unlikely without electrolysis
	Scalp hair loss	6-12 mo		Unlikely
	Increased muscle mass/strength	6-12 mo	2-5 yr	Likely
	Fat redistribution	1-6 mo	2-5 yr	Likely
	Cessation of menses	1-6 mo		Likely
	Clitoral enlargement	1-6 mo	1-2 yr	Unknown
	Vaginal atrophy	1-6 mo	1-2 yr	Unknown
	Deepening of voice	6-12 mo	1-2 yr	Not possible without surgery

Adapted from Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2017;102:3869–3903, Table 12; and from Allen BJ, Rosenthal SM. Care of transgender, nonbinary, and gender diverse youth. In Allen DB, Nadeau K, Kappy MS, Geffner ME, eds. *Pediatric Endocrinology: Principles and Practice*, 3rd ed. New York: McGraw Hill; 2020, Tables 7-11 and 7-12.

Treatment will lead to some changes that are likely reversible and others, such as breast development, that are irreversible without surgery.

Testosterone

Naturally occurring testosterone may be given transdermally via gels or patches, through subcutaneous or intramuscular injections, or via implantation of subcutaneous pellets. Oral testosterone undecanoate is Food and Drug Administration (FDA)–approved for use in the United States but is not currently in wide use. It is important to counsel patients on the potential transfer to others via direct contact when transdermal formulations are used. Testosterone levels can be monitored in the serum, with the eventual goal of achieving values in the normal male range (typically 320-1,000 ng/dL, depending on the specific assay).

TGD individuals treated with testosterone should be educated on the expected timeline of physical changes (see Table 153.10). Treatment will lead to some changes that are likely reversible and others that are not, such as facial hair growth, which is irreversible without electrolysis. Adult levels of testosterone are typically sufficient to suppress the HPG axis and induce amenorrhea in TGD individuals designated female at birth. However, unplanned pregnancies have been reported, emphasizing the need for *ongoing contraceptive counseling* in these individuals. If undesired uterine bleeding persists, or if menstruation is causing significant dysphoria before the initiation of testosterone therapy, a progestin or other agent may be used for menstrual suppression. If estrogen is tolerable, combined continuous oral contraceptives (with limited intervals for breakthrough menses) are more effective in achieving menstrual suppression and are better for maintaining bone health than progestin-only options. For TGD adolescents who prefer nonestrogen-containing medications, progesterone-only pills, medroxyprogesterone acetate shots, and progesterone-containing intrauterine or implantable devices are available.

Potential Adverse Effects

Clinicians should inform TGD adolescents of the potential for adverse effects of GAH treatment. Risk for adverse effects is higher when supraphysiologic or inadequate doses of sex hormones are used, which should be avoided. Before initiating therapy, risk factors for adverse effects should be assessed and minimized when possible. GAH treatment has implications for fertility, which must be discussed before initiating therapy as noted previously.

Risks with Estrogen

The most serious risks associated with estrogen therapy include VTE, cardiovascular disease, and cerebrovascular accident. The risk increases with higher estrogen doses and supraphysiologic estradiol levels. Risk factors for these conditions should be assessed and addressed before initiating estrogen therapy. Tobacco cessation counseling should be provided as indicated. Oral ethinyl estradiol in particular appears to increase the risk of VTE, and it should not be used for GAH therapy in individuals at high risk. Estrogen may also cause growth of pituitary lactotroph cells and hyperprolactinemia, which resolves with a reduction or discontinuation of therapy in most individuals. Other potential adverse effects include weight gain, cholelithiasis, and hypertriglyceridemia. TGD adults treated with estrogen therapy have been shown to have an increased risk for developing breast cancer compared with a general population of men in a retrospective Dutch study, although the risk was still lower than in the general population of women. Another retrospective Dutch study spanning five decades demonstrated an increased mortality risk in TGD individuals treated with estrogen therapy compared with a general population of men and general population of women with high risks of death because of cardiovascular

disease, lung cancer, HIV-related disease, and suicide; however, the study was not designed to attribute the cause of the increased mortality risk to a specific effect of estrogen therapy. Absolute contraindications to estrogen therapy include previous VTE related to an underlying hypercoagulable condition, history of estrogen-sensitive neoplasm, and end-stage chronic liver disease.

Risks with Testosterone

Testosterone therapy is primarily associated with potential risks of developing acne, weight gain, hypertension, polycythemia, and a more atherogenic lipid profile (i.e., elevated low-density lipoprotein, elevated triglyceride, and decreased high-density lipoprotein cholesterol levels). Risk increases with sustained, supraphysiologic testosterone levels. Risk factors for these conditions should be assessed and addressed before initiating testosterone therapy. Despite being associated with a more atherogenic lipid profile, numerous studies have shown no increased risk of cardiovascular disease in individuals treated with testosterone. Additional studies are needed to determine if therapy is associated with an increased risk for cerebrovascular disease. Historically, oral testosterone formulations have been associated with increased risk for transaminitis and severe liver dysfunction, whereas injectable formulations are not. Because of the concern that aromatization of testosterone to estradiol may increase risk in patients with a history of estrogen-sensitive malignancies, consultation with an oncologist should be considered before initiating therapy in such patients. Absolute contraindications to testosterone therapy include current pregnancy, unstable coronary artery disease, and untreated polycythemia (hematocrit ≥55%).

Monitoring Protocol

Efficacy and potential adverse effects of treatment should be monitored closely in TGD youth treated with GAH therapy at baseline and follow-up according to the protocol outlined in Table 153.7. Clinical evaluation and laboratory monitoring are recommended every 3 months during the first year of GAH therapy and then 1-2 times annually thereafter. All evaluations should include a physical exam, including measurement of weight and blood pressure. Chest and genitourinary exams may be sensitive issues for TGD youth and should only be conducted as needed to guide management. Evaluations should include questions regarding occurrence of potential adverse events and satisfaction with phenotypic changes on medical therapies. Medication dosing adjustments should occur as needed with the goal of avoiding supraphysiologic and subphysiologic hormone levels that may increase the risk for adverse effects.

Surgical Therapy

Gender-affirming surgeries may be pursued by some TGD individuals to better align their bodies with their gender identities. In these individuals, surgery is medically necessary and an essential step to alleviate their gender dysphoria. Surgeries are irreversible interventions, and most, including those that directly affect fertility such as gonadectomy and/or hysterectomy, are not recommended until an individual reaches age 18 years or the age of legal majority in their country. The Endocrine Society clinical practice guideline and WPATH SOC acknowledge that mastectomy may be considered in TGD adolescents before age 18 years, taking into consideration the physical and mental health status of the individual. Hormone therapy should not be considered a prerequisite to accessing gender-affirming surgical procedures in individuals who do not desire hormone therapy nor in those in whom it is medically contraindicated. Surgeries may occur after the appropriate assessments by qualified medical and mental health professionals responsible for the care of the TGD individual have been performed and confirm that criteria for surgery are met. Individuals who undergo gonadectomy will require ongoing hormone replacement therapy to prevent adverse effects, including osteoporosis.

Table 153.11 Recommendations for Breast and Reproductive Tract Cancer Screening

ORGAN	TRANSGENDER WOMEN	TRANSGENDER MEN
Breast/chest	Discuss mammography in transwomen age >50 yr with additional risk factors for breast cancer (body mass index >35 kg/m^2, estrogen and/or progestin use >5 yr, family history) • Family history of *BRCA* mutations: prophylactic mastectomy could be recommended, with consecutive primary reconstruction	Patients who have not undergone bilateral mastectomy should follow cisgender women recommendations for breast cancer screening Patients who have undergone chest reconstructive surgery should be offered physical examination and/or chest ultrasound
Cervix	Not recommended (transwomen do not have a cervix) • Patients should be routinely examined to detect HPV-related lesions	Patients with an intact cervix should follow the recommendations for cisgender women • Consider self-collected vaginal swabs to test for high-risk HPV DNA • Pathologists should be aware if patient is taking testosterone • Patients who have undergone total hysterectomy and have no history of high-grade cervical precancerous lesion or cervical cancer can discontinue cervical cancer screening
Ovarian	N/A	Do not routinely screen • Transmen at increased risk (identified *BRCA* gene mutation and family history) should be referred for genetic counseling • Consider risk-reduction salpingo-oophorectomy
Endometrial	N/A	Do not routinely screen • Unexplained bleeding (in patients under testosterone who had reached amenorrhea) should be evaluated
Prostate	Monitor the following framework for cisgender men • PSA cutoffs may be lower in transgender men receiving antiandrogens • Consider transvaginal digital examination and ultrasound	N/A

N/A, Not applicable; *PSA*, prostate-specific antigen.
From Labanca T, Manero I, Pannunzio M. Transgender patients: considerations for routine gynecologic care and cancer screening. *J Gynecol Cancer*. 2020;30:1990–1996, Table 4.

Primary Care: Screening

Not all TGD adults have had gender-affirming chest or reproductive organ surgery. Because of this, they may be at risk for cancers not typically screened for based on their affirmed or biologic gender. Suggested breast and reproductive cancer screening recommendations are noted in Table 153.11.

THERAPY FOR NONBINARY YOUTH

Youth with nonbinary gender identities are increasingly presenting for gender-affirming medical care. Although current clinical care guidelines recognize that gender exists on a spectrum and may not always be binary, research and guidelines to date have been largely grounded in the binary gender narrative. Some individuals with nonbinary gender identities will seek treatment as outlined in current clinical practice guidelines, but not all will. The Endocrine Society clinical practice guidelines state that tailoring of current protocols to the individual may be acceptable if done within the context of accepted safety guidelines using a multidisciplinary approach including mental health support. Additionally, the WPATH SOC state they are intended to be flexible to meet the diverse healthcare needs of the individual, and health professionals may modify them in consultation with their TGD patients. However, evidence-based protocols are not yet available for nonbinary individuals, and neither the Endocrine Society nor the WPATH provide guidelines specific to the care of nonbinary youth. Nonbinary individuals have been shown to have higher rates of depression, anxiety, and self-harm compared to their binary transgender peers. In addition, they often encounter more barriers in their attempts to access gender-affirming medical care, even when care is accessed at specialized gender clinics. As a result, some feel forced to identify within the gender binary to obtain desired medical therapies or choose to not seek care.

Until future studies inform clinical practice guidelines outlining therapeutic approaches specific to nonbinary youth, gender-affirming care for nonbinary youth should be individualized. Providers should frame care using the concept of *embodiment rather than transition,* the latter implying a linear path within the gender binary. Ongoing dialogue and support are essential in helping nonbinary youth navigate a potentially nonlinear path. Providers should explore the individual's internal awareness of self, specific areas of gender dysphoria, and their embodiment goals to offer specific therapies toward affirming the individual's gender. Specific expected outcomes of the possible interventions (e.g., increased facial hair with testosterone or chest growth with estrogen) should be discussed rather than describing therapies as masculinizing or feminizing in nature. Difficult decisions may need to be made, particularly for nonbinary youth treated with pubertal suppression who do not desire any secondary sex characteristics. There is the potential for negative impacts on bone health from prolonged monotherapy with pubertal blocking agents, and this should be avoided. Providers should expect to have conversations about balancing the individual's priorities in their specific embodiment goals and to discuss the known potential risks and benefits of various treatment options in order to provide optimal care to their nonbinary patients. Patients should be counseled about the importance of maintaining a minimum threshold level of sex steroids—typically a normal adult range of either estrogen or testosterone—to preserve general health.

Like TGD youth with binary gender identities, available medical interventions for nonbinary youth may include pubertal suppression, sex hormones, and surgeries. Desired and unwanted effects should be discussed and balanced in decision-making regarding therapies. Existing treatment protocols may be modified to achieve patient embodiment goals if deemed safe with a plan for close follow-up monitoring. Potential modifications may include gradual titration or tapering of doses, low-dose or limited testosterone therapy, lower doses of estrogen therapy, intermittent hormone dosing, use of both estrogen and testosterone, and use of adjunctive medications. After initiating a new treatment, follow-up visits should include a discussion of physical changes noted and whether they are in alignment with the patient's embodiment goals, with adjustments made as needed.

Mental Health Outcomes of Treatment

Multiple studies have demonstrated the positive impact of gender-affirming medical and surgical interventions on mental health outcomes in TGD adolescents. A prospective study of 55 TGD adolescents and young adults in the Netherlands published in 2014 demonstrated resolution of gender dysphoria and improvement in general psychologic functioning after sequential treatment with GnRH agonist therapy, GAH treatment, and gender reassignment surgery. These individuals were also shown to have a sense of well-being equivalent or superior to that seen in age-matched controls from the general population, and none regretted treatment. A cross-sectional survey administered by the National Center for Transgender Equality to more than 20,000 U.S. TGD adults age 18-36 years demonstrated that those treated with GnRH agonists for pubertal suppression during adolescence had a significantly lower odds of lifetime suicidal ideation compared to those who wanted, but did not receive, such treatment. The largest observational study assessing the impact of gender-affirming medical care on the mental health of TGD adolescents and young adults in the United States (n = 315, age 12-20 years) demonstrated significant improvements in psychosocial functioning, decreases in depression and anxiety, and increases in appearance congruence, positive affect, and life satisfaction. Other studies have also reported on improvement of mental health measures, quality of life, global psychosocial functioning, and body image in response to treatment with gender-affirming medical care.

Challenges to Care

TGD youth not only face high levels of discrimination in their lived environments, but those who succeed in accessing medical care often encounter stigma and discrimination within healthcare settings. Research on the experiences of TGD persons of color, a group that faces startingly high rates of violence and homicide, is an area in need of much attention. In the United States, gender-affirming medical therapies are currently not FDA-approved for use in TGD youth, and insurance companies often deny coverage of these medically necessary, essential, and even lifesaving interventions. Some families can pay out-of-pocket for treatments when coverage is denied, whereas others cannot, furthering the socioeconomic divide between wealthy and impoverished. Efforts in multiple U.S. states to criminalize the medical care of TGD youth are ongoing and in need of significant advocacy and education. In addition, participation in same-gender sporting activities has created significant barriers among TGD athletes. Some athletic bodies have placed barriers to same-gender participation, requiring transfemales to start suppressive therapy early in puberty or to monitor testosterone levels, with a cutoff level prohibiting participation.

Chapter 154

Gay, Lesbian, and Bisexual Adolescents

Stewart L. Adelson and Mark A. Schuster

Understanding a child's or adolescent's sexual and emotional development is an essential part of any comprehensive pediatric evaluation. For youth who are or might be gay, lesbian, or bisexual **(GLB also noted as LGB in the LGBT abbreviation)**, such understanding is particularly important. GLB youth as a group have the same health and developmental needs typical of youth in general, and their sexual orientation is part of the normal spectrum of human sexuality. However, they encounter distinct developmental challenges and can have additional physical and mental health needs related to their orientation and others' reaction to it. Their sexual orientation may be different from that expected by some families, peers, and society; they are at risk of peer rejection, bullying, violence, or family nonacceptance more frequently than most youth. Although the majority of GLB adolescents grow up physically and mentally healthy, they are at increased risk for certain health problems as a result of these stresses and the epidemiology of health threats such as HIV and other sexually transmitted infections (STIs). In addition, healthcare providers may also have biases and assumptions about the GLB community (Table 154.1).

Sexual orientation refers to an individual's attraction to others based on sex or gender. It encompasses emotional and erotic desires, physiologic arousal, sexual behavior, sexual identity, and social role. As sexuality develops, youth can be oriented entirely toward a particular sex or gender, or more than one, to various degrees on a continuum. **Homosexuality** involves orientation toward people of one's same sex or gender, and **bisexuality** involves orientation toward males and females. **Gay** is a common term for both males and females who have same-sex attractions; **lesbian** refers to gay females. Increasing numbers of youth describe themselves as having a nonbinary gender identity (see Chapter 153). Accordingly, some do not fit binary categories of sexual orientation and use other terms to describe themselves, such as **pansexual** (attracted to all genders). Those unsure of their orientation are **curious** or **questioning**. The term **young men who have sex with men (YMSM)** is sometimes used in the research literature to denote male youth who engage in sexual activity with other males, regardless of how they identify themselves.

PREVALENCE OF HOMOSEXUALITY AND BISEXUALITY IN YOUTH

Some junior high and high school students self-identify as gay, lesbian, or bisexual (Fig. 154.1). Some who do not identify as GLB report same-sex attraction, fantasies, or behavior. Some are unsure of their sexual orientation. Certainty about sexual orientation tends to increase through adolescence with sexual experience, although one can be aware of one's orientation without having had sexual partners. Those who fear nonacceptance may try to suppress or deny their orientation. Consequently, various aspects of an individual's orientation—attraction, behavior, and identity—may not always be consistent with each other throughout development. Not all youth with homosexual attraction or experience identify as *gay,* consistent in part with reluctance about having or revealing a gay identity and underscoring the differences among attraction, behavior, and identity. A report providing national estimates of the number of high school students with GLB identity in 2019 found that 2.5% said they were gay or lesbian, 8.7% said they were bisexual, and 4.5% reported being unsure of their sexual orientation (see Fig. 154.1).

Table 154.1 Common Assumptions to Avoid When Caring for Lesbian, Gay, Bisexual, and Queer Patients

ASSUMPTION TYPE	DO NOT ASSUME THAT…
Identity	• Lesbian, gay, or bisexual people are cisgender • A person has to identify as either male or female • A person's gender or sexual orientation is a major aspect of a person's identity • Being lesbian, gay, bisexual, or queer is always hard • LGBQ people cannot adjust to stressors
Sexual orientation	• All patients are heterosexual • People exploring their sexuality have a need to categorize into established sexual orientations • Bisexuality is a phase or that bisexual people are confused • Sexual orientation aligns with sexual behavior
Sexual behavior	• All LGBQ people are sexually active (some are celibate or asexual) • Gay men do not have sex with women or lesbian women do not have sex with men • All gay men have multiple partners and engage in high-risk behavior • Sexual behavior will remain stable over time • Lesbians are not at risk of HPV or other STIs • Bisexual people are promiscuous or are always unfaithful
Relationships and family	• Lesbian women do not want to be pregnant or are not at risk of pregnancy • Interpersonal violence does not occur in LGBQ couples • LGBQ patients do not have children or do not wish to have children • All adults of reproductive age have an interest in parenting • LGBQ people do not have strong family ties • LGBQ patients have ties to their families of origin
Anatomy	• Queer people all want to change their bodies with surgeries or hormones • Anything about the body of an LGBQ patient

HPV, Human papillomavirus; STI, sexually transmitted illness.

DEVELOPMENT OF SEXUAL ORIENTATION IN CHILDHOOD AND ADOLESCENCE

Sexual orientation development appears to begin prenatally and continue through childhood and adolescence and into adulthood. Both gender role behavior in childhood and sexual orientation in puberty and adolescence are partly influenced by prenatal genetic and neuroendocrine factors. Sociocultural and psychologic factors also influence sexual development. A gay or lesbian sexual orientation is sometimes preceded developmentally in childhood by nonconforming gender expression or variation from population averages in expression of gender-related behavior such as activities, interests, styles, and other attributes recognized as masculine or feminine, like toy preferences and preference for playmates of a particular gender. Childhood gender nonconformity is significantly associated with nonheterosexual orientation, especially in males. However, it is not experienced by all gay or lesbian people, and not all children with nonconforming gender role behavior are gay or lesbian. When present, however, nonconformity causes many gay people to feel different from peers during childhood, even before sexual desire or identity emerges. Depending on the setting, gender-nonconforming children may experience ostracism, bullying, or family nonacceptance. These reactions to gender nonconformity can lead to later difficulty with gender-related self-esteem and long-term mental health problems.

Less frequently, gay or lesbian sexual orientation in adolescence is preceded by childhood **gender variant identity**, a phenomenon in which the gender identity of an individual at any age differs from phenotypic sex and assigned sex at birth (see Chapter 153).

STIGMA, RISK, AND RESILIENCE

People experiencing same-sex attraction and behavior exist in all societies. The meaning, acceptance, and legality of non-heterosexual attraction vary greatly with cultural, historical, and social contexts. Although gay people are more visible and accepted in some societies, youth are often exposed to antigay attitudes. For many GLB youth, revealing their sexual orientation *(coming out)* to family, peers, healthcare providers, and others is a significant step. Specific racial, ethnic, religious, and other demographic groups may experience distinct developmental stressors. A comprehensive understanding of a youth's sexual development and health must consider intersecting sociodemographic factors influencing a youth's experience of a nonheterosexual orientation. For example, race, ethnicity, and religious affiliation—and the reactions of others to one's demographic characteristics—can influence comfort disclosing an GLB identity, involvement in GLB socialization, access to religious affirmation, and processes of coming out.

Some GLB youth experience difficulty coping with **stigma**. A longitudinal study that investigated **bullying** and **victimization** among youth from 5th through 10th grade found that the females and males who identified as GLB in 10th grade were more likely than their peers to report that they had been bullied and victimized across grades. GLB youth may be perceived by others as different before they themselves have any GLB attraction or experience or identify as GLB. Even when not overtly threatened, GLB youth frequently encounter negative attitudes that force them to hide at a time when family and peer acceptance holds great developmental significance. Family nonacceptance, feeling unsafe due to school harassment, and peer bullying related to sexual orientation elevate risk in GLB adolescents for depression, anxiety, substance abuse, suicidal thoughts and attempts, and social problems such as truancy, dropping out, running away, and homelessness. Mental health problems, sexual risk-taking, or substance use may increase exposure to HIV and other STIs. Stigma may also impede access to healthcare in some communities.

Nevertheless, most GLB youth are resilient, with good physical and mental health despite possible pervasive stresses. Family connectedness and school support and safety are important protective factors against depression, suicidal thoughts and attempts, and substance abuse. GLB antiharassment policies and organizations such as **genders and sexualities alliances** (also sometimes called gay-straight alliances) and antibullying programs are associated with increased school safety for GLB youth. It is therefore important to reduce stigma, support acceptance, and promote resilient coping.

HEALTH

Depression and Suicidality

Compared to their heterosexual peers, GLB youth and those who are not sure of their sexual orientation have a higher prevalence of suicidality. Family rejection, bullying, and other victimization motivated by homophobia account statistically for increased depression and suicidal thoughts and attempts in GLB adolescents. Suicidal thoughts or attempts are highest during the interval after recognition of same-sex attraction or a same-sex sexual experience but before self-acceptance as gay.

Sexually Transmitted Infections

The epidemiology of STIs, related to specific sexual practices and prevalence of certain STIs in GLB communities, informs recommended counseling, screening, and treatment strategies (Table 154.2). Anal intercourse has been shown to be the most efficient route of infection by hepatitis B (see Chapter 406), cytomegalovirus (see Chapter 302), and HIV (see Chapter 322). Oral-anal and digital-anal contact can transmit enteric pathogens, such as hepatitis A. Unprotected oral sex also can lead to oropharyngeal disease in the receptive partner and gonococcal and nongonococcal urethritis in the insertive partner. Certain STIs, particularly ulcerative diseases, such as syphilis and herpes simplex virus infection, facilitate spread of HIV. YMSM are also at risk for infections with Shigella spp. and Mpox (see Chapter 163).

Among U.S. adolescents and young adults, YMSM, and especially Black YMSM, continue to face the greatest prevalence of HIV/AIDS. Although possible, female-to-female sexual transmission of HIV is inefficient, and females who only engage in sex with females are less likely than other youth to acquire an STI. However, males and females who identify as gay or lesbian may engage in sexual activity with partners who are not of the same gender; counseling and screening for all types of STIs are still relevant.

Substance Abuse

Compared with their heterosexual peers, GLB youth appear to use alcohol and other substances at higher rates, including more binge drinking and earlier onset and more rapid trajectory of substance use.

More substantial substance use may be greatest in youth who, although they do not identify as GLB, have attraction to or engage in sexual behavior with others of their gender.

Obesity and Disordered Eating

Compared with heterosexual females, lesbian and bisexual females are generally more likely to be obese or overweight. In contrast, young gay and bisexual males are more likely to have body image concerns and to restrict eating or engage in compensatory weight loss strategies compared to heterosexual boys. Binge eating may also be more common in GLB youth.

Psychosocial Problems

Academic underachievement, truancy, and dropping out of school are frequently associated in GLB adolescents with homophobic victimization, harassment, violence, and feeling unsafe at school. Studies suggest that youth who eventually identify as GLB have higher rates than other youth of experiencing child abuse and of running away or being kicked

Table 154.2 The 6 Ps of a Complete Sexual History

P	OBJECTIVES	QUESTIONS
Partners	• Determine the number and gender/sex of partners • Determine partner risk factors (other partners, drug use)	"Are you currently sexually active?" "Have you ever been sexually active?" "When you have sex, what is the gender of your partners? What anatomy is used for sex?" "How do you describe your sexual orientation?" "How many partners have you had in the past 6 (or 12) months?" "Has anyone ever forced themselves on you sexually or touched you sexually in an unwanted way?"* Remember to ask about opposite-sex partners
Practices	• If a patient has had more than one partner in the past 12 mo (or has a partner who has other sex partners) • Explore their sexual practices and behaviors, because they will guide assessment of risk and determination of testing	"What types of sex are you having?" "When having sex, do you have vaginal, anal, and/or oral sex?" "If you have anal sex, do you have insertive sex, receptive sex, or both?" In colloquial words, "Are you a top, a bottom, or vers?" "Do you have any alternative sexual practices?" (i.e., kinks, BDSM, fisting) "Do you use alcohol or drugs during sex?" "Have you ever exchanged sex for money, drugs, food, or shelter?" "Do you use lubricants during sex? What kind?" "Do you use sex toys? How often? Do you share them? Do you clean them?" Put bluntly, questions should aim to answer who is putting what, where, when, and how
Protection from STI	• If a patient has had more than one partner in the past 12 mo (or has a partner who has other sex partners)† • Based on patient risk profile, ask these questions accordingly • Explore the patient's use of barrier methods • Explore the patient's use of PrEP	"How do you keep yourself safe during sex" "Do you use condoms/dental dams when having vaginal, anal, and/or oral sex? How often? All the time? Most of the time? About half of the time? Rarely?" If no, "Why not?" "Do you and your partners use any other protection against STI?" "Do you or your partner use PrEP? "Are you interested in starting PrEP?"
Past history of STI	• Explore patient STI history as a risk factor for future STI	"Have you ever been tested for HIV or other STIs?" "Have you ever been diagnosed with an STI?" If yes, "When were you diagnosed? How were you treated?" "Would you like to be tested? And which parts of your body should we check?" "Has your current or any former partners ever been diagnosed with an STI?" If yes, "Have you been tested for the same STI?"
Pleasure/pain	• Recognize the importance of pleasure in sexual intimacy and well-being	"Are you satisfied with your sexual life?" "Do you have any pain with sex?" "Do you have any problems with erection, lubrication, ejaculation, or orgasm?"
Prevention/planning of pregnancy	• Evaluate desire for/risk of pregnancy	"Are you concerned about getting pregnant or getting your partner pregnant?" "Are you using contraception or practicing any form of birth control?" "Do you need any information on birth control?"

*For more information, please see, "Sexual Health and the LGBTQ+ Community," by Taylor NM, King CK.. *Prim Care Clin Office Pract.* 2021;48:271-282.
†For patients who report one or fewer partners in the last 12 mo, ask whether they have any concerns about STI.
BDSM, Bondage and discipline, dominance and submission, sadism and masochism; HIV, human immunodeficiency virus; PrEP, preexposure prophylaxis.
From Suarez S, Lupez E, Siegel J, Streed Jr C. The annual examination for lesbian, gay, and bisexual patients. *Prim Care Clin Office Pract.* 2021;48:191–212, Table 2.

out of their homes. GLB young people are overrepresented among homeless and runaway populations across the United States, which can expose them to drugs, sexual abuse, and other health risks.

RECOMMENDATIONS FOR CARE

Evaluation

The goal of GLB pediatric care is physical health, social and emotional well-being, and healthy development. Physicians should provide nonjudgmental care to all adolescents, including those who are GLB or questioning (see Chapter 153, Table 153.1, and Table 154.1). They should receive the age-appropriate history, examination, and anticipatory guidance recommended for adolescents in general. The physical examination and laboratory evaluation of GLB and questioning adolescents are the same as for any teenager. However, providers should appropriately screen for special potential medical and psychosocial threats to GLB teenagers' health.

A nonjudgmental healthcare environment is important, with open communication and a positive relationship with youth and families. In the waiting room, written material about sexual orientation, support groups, and community resources will signal openness to discussing sexuality. Registration forms recognizing the possibility of same-gender parents signal a safe setting (e.g., forms can list parent/guardian #1, parent/guardian #2). Sexual history questions should avoid heterosexual assumptions (e.g., ask "Are you dating someone?" vs "Do you have a boyfriend/girlfriend?"). This is important at all ages. For example, asking a 6-year-old male if he has a girlfriend may convey an unsupportive message if he discovers later that he would like a boyfriend. Explaining confidentiality and incorporating into each adolescent visit private time with no parent in the room (see Chapter 137) may facilitate discussing sexual orientation, as may use of appropriate health history forms such as the American Medical Association's Guidelines for Adolescent Prevention Services Questionnaire.

Clinicians should remember that any youth might be GLB whether or not they are identified or perceived as such, so clinicians should not presuppose a particular orientation (see Table 154.1). Competency in conveying sensitivity, acceptance, and respectfulness; effective communication skills; and appropriate attention to privacy and confidentiality (including practices related to billing and record requests) are fundamental to providing high-quality care. While remaining attuned to youth's preferences, explicit or implied, for discussing sexual orientation, providers can tactfully take the lead, if necessary, regarding any pressing areas of clinical concern.

Medical and Sexual Health

STIs are covered in Chapter 163, but issues specific to GLB youth are included here. Use of latex condoms for fellatio, and dental dams and cut-open latex condoms for anilingus and cunnilingus, should be discussed with adolescents. Recommendations also include use of latex condoms for sexual appliances. In addition, it is important to emphasize that people who have been using alcohol or other drugs are at increased likelihood for engaging in riskier sexual activity. It is important not to assume that a gay male or female who does not identify as bisexual has not had sex with someone of a different sex or gender; lesbians can still have an unplanned pregnancy. Therefore prevention counseling about unintended pregnancy is relevant to all adolescents. Similarly, youth who identify as heterosexual and whose attractions are not to those of the same sex or gender may still have sexual activity with a partner of the same sex or gender.

Although vaccination against hepatitis A and B is recommended for all children, it is particularly recommended that nonvaccinated adolescent males who are having (or are likely to have) sex with males receive catch-up vaccines. The same recommendation applies to the human papillomavirus (HPV) vaccine for males. The Centers for Disease Control and Prevention (CDC) recommends that males who are engaging in sexual activity with males have annual testing for HIV, hepatitis A, hepatitis B, syphilis, urethral gonorrhea, and chlamydia (if engaging in insertive oral or anal intercourse), oral gonorrhea (if engaging in receptive oral intercourse), and rectal gonorrhea and chlamydia (if engaging in receptive anal intercourse). The CDC also recommends HIV pre-exposure prophylaxis (PrEP) for adolescents who are engaging in or plan to engage in sexual behavior placing them at "substantial ongoing risk of HIV exposure and acquisition."

Mental Health

Awareness of mental health and social problems is important when caring for GLB youth, as for all youth. Clinicians should monitor for depression, suicidality, anxiety, and substance abuse and know their community's mental health resources. Minor psychosocial problems might be handled by referral to a support group for patients (e.g., a school gay-straight or genders-sexualities alliance, other community support group) or for parents and others (e.g., Parents, Families and Friends of Lesbians and Gays). In some communities, agencies and organizations serving the GLB community can help with social, educational, vocational, housing, and other needs.

Individuals or families who harbor negative attitudes may inquire about mental health treatment to avert or change a gay or bisexual orientation (conversion therapy). However, a GLB orientation is not an illness, and all leading health organizations have concluded that such change is neither possible nor warranted. Conversion therapy is illegal in 18 states; 22 states have no law or policy.

It is important to distinguish between a GLB orientation, which is not a mental illness, and mental health problems (e.g., depression) for which GLB youth are at elevated risk. While understanding different families' values, clinicians must recognize the morbidity and mortality associated with stigma and attempt to foster physical and emotional health. Individual or family therapy might be indicated.

Clinicians should also monitor for specific stressors, such as bullying and other homophobic victimization, family nonacceptance, and abuse. Failure to confront harassment constitutes tacit assent. Anticipatory guidance, referral, and substance abuse treatment should be considered for the subset of GLB youth who use alcohol, drugs, or tobacco, some of whom may be using these to manage painful feelings related to conflicts over their sexuality.

Adolescents with serious psychiatric symptoms, such as suicidality, depression, and substance abuse, should be referred to mental health specialists with competency in treating GLB adolescents (see Chapter 40).

Chapter 155

The Epidemiology of Adolescent Health Problems

Samantha V. Hill and Tamera Coyne-Beasley

Adolescence is the first period of life where the major determinants of morbidity and mortality are *behavioral* rather than congenital or infectious. As adolescents make the transition from childhood to adulthood, they establish behaviors that affect both their current and future health. Adolescence is a time of immense biologic, psychologic, and social change (see Chapter 150). Many of the psychologic changes have a biologic substrate in the development and eventual maturation of the central nervous system, particularly the frontal lobe areas responsible for executive functioning (Fig. 155.1). In addition to cognitive development, there are both risk and protective factors for adverse adolescent health behaviors that are dependent on the social environment and the mental health of an adolescent (Table 155.1).

Many adolescents continually confront the task of making healthy choices while struggling with impulsivity that can lead to unintentional consequences, such as injuries, sexually transmitted infections (STIs), or drug overdoses. Adolescents are also challenged with adopting behaviors that will affect their future adult health, such as eating nutritiously; engaging in physical activity; and choosing not to use tobacco (including vapes and e-cigarettes), alcohol, cannabis, or illicit substances. Environmental factors and social determinants of health in and among an individual's family, peers, school, and community also contribute to adolescents' health and risk behaviors. The U.S. Centers for Disease Control and Prevention (CDC) **Youth Risk Behavior Surveillance Survey**, a school-based survey of a nationally representative sample of U.S. high school students, demonstrates that youth begin engaging in behaviors that place their health at risk during adolescence (Fig. 155.2).

Although according to the 2018 CDC National Health Interview Survey (https://www.cdc.gov/nchs/nhis/shs/tables.htm), a probability sample survey conducted annually, an estimated 83% of 12- to 17-year-olds report excellent or very good health, 11% reported limitation in usual activities because of one or more chronic conditions, 10% missed 6-10 school days in the past year, 6% are uninsured, 5% have no usual place of healthcare, 10% have asthma, 12% have respiratory allergies, 10% have a learning disability, 13% have attention-deficit/hyperactivity disorder, and 18% take prescription medications routinely. In 2018 the mortality rate among adolescents 15-19 years of age was 49 deaths per 100,000 population. Although varying by gender, the leading causes of death overall among adolescents 15-19 years of age are (1) unintentional injuries, (2) suicide, and (3) homicide (Table 155.2).

Within the adolescent population, **disparities in health** occur. Adolescent health outcomes and behaviors vary among populations that can be defined by being Black, ethnicity, gender, education, income, disability, geographic location (e.g., rural or urban), or sexual orientation. Health disparities result from multiple factors affecting social determinates of health, including poverty, environmental threats, inadequate access to healthcare, individual and behavioral factors, racism and other systemic biases, and educational and other inequalities (Table 155.3).

ACCESS TO HEALTHCARE

Adolescents in the United States make fewer visits to physicians for ambulatory office visits than any other age-group; school-age children and adolescents are more likely than younger children to have unmet health needs and delayed medical care. Adolescents who actually receive preventive care may still not have access to time alone with their provider to discuss confidential health issues such as STIs, HIV, or pregnancy prevention. Less than half (22% of 13- to 14-year-olds and 43% of 15- to 18-year-olds) of adolescents have time alone with their healthcare provider during a preventive healthcare visit; sexually experienced teens report sexual health discussions more often than nonsexually experienced teens, but the frequency is still low at 81% and 65% for sexually experienced young women and men, respectively.

The 2010 Patient Protection and Affordable Care Act (ACA) has improved access to care for young adults 18 to 24 years old. The ACA permits children to receive benefits from their parents' health plans through age 26 years. Although accomplishments have been made in improving adolescent health, *Healthy People* provides science-based, 10-year national objectives for measuring and improving the health of all Americans by establishing benchmarks and monitoring progress over time. The ***Healthy People 2030*** agenda includes 24 adolescent-specific objectives with a goal of improving the healthy development, health, safety, and well-being of adolescents and young adults over the next 10 years (Table 155.4). This science-based initiative is centered around a framework for public health prevention priorities and actions to improve the health status of U.S. youth.

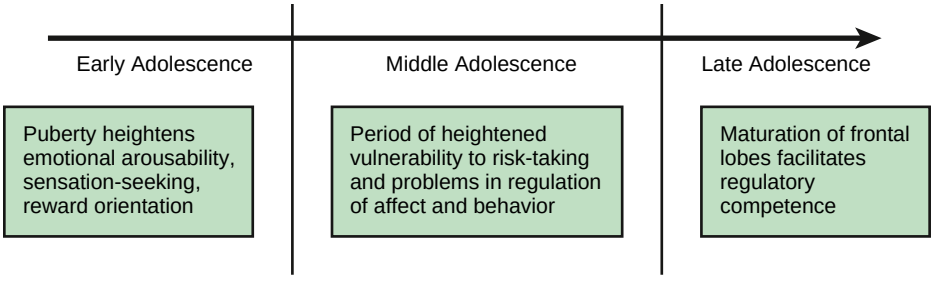

Fig. 155.1 It has been speculated that the impact of puberty on arousal and motivation occurs before the maturation of the frontal lobes is complete. This gap may create a period of heightened vulnerability to problems in the regulation of affect and behavior, which might help to explain the increased potential in adolescence for risk-taking, recklessness, and the onset of emotional and behavioral problems. *(From Steinberg L. Cognitive and affective development in adolescence. Trends Cogn Sci. 2005;9:69–74.)*

Table 155.1 Identified Risk and Protective Factors for Adolescent Health Behaviors

BEHAVIOR	RISK FACTORS	PROTECTIVE FACTORS
Smoking	Depression and other mental health problems, alcohol use, disconnectedness from school or family, difficulty talking with parents, minority ethnicity, low school achievement, peer smoking	Family connectedness, perceived healthiness, higher parental expectations, low prevalence of smoking in school
Alcohol and drug misuse	Depression and other mental health problems, low self-esteem, easy family access to alcohol, working outside school, difficulty talking with parents, risk factors for transition from occasional to regular substance misuse (smoking, availability of substances, peer use, other risk behaviors)	Connectedness with school and family, religious affiliation
Teenage pregnancy	Deprivation, city residence, low educational expectations, sexual intercourse, lack of access to sexual health services, drug and alcohol use	Connectedness with school and family, religious affiliation
Sexually transmitted infections	Mental health problems, substance misuse, exploration of sexuality and sexual identity (sexual activity)	Connectedness with school and family, religious affiliation

Table 155.4 *Healthy People 2030* Adolescent Health (AH) Objectives

- **AH-01:** Increase the proportion of adolescents who had a preventive healthcare visit in the past year.
- **AH-02:** Increase the proportion of adolescents who speak privately with a provider at a preventive medical visit.
- **AH-03:** Increase the proportion of adolescents who have an adult they can talk to about serious problems.
- **AH-04**: Increase the proportion of students participating in the School Breakfast Program.
- **AH-05:** Increase the proportion of 4th-graders with reading skills at or above the proficient level.
- **AH-06:** Increase the proportion of 4th-graders with math skills at or above the proficient level.
- **AH-07:** Reduce chronic school absence among early adolescents.
- **AH-08:** Increase the proportion of high school students who graduate in 4 years.
- **AH-09:** Reduce the proportion of adolescents and young adults who are not in school or working.
- **AH-10:** Reduce the rate of minors and young adults committing violent crimes.
- **AH-D01:** Increase the proportion of trauma-informed early childcare settings and elementary and secondary schools.
- **AH-D02:** Increase the proportion of children and adolescents with symptoms of trauma who get treatment.
- **AH-D03**: Reduce the proportion of public schools with a serious violent incident.
- **AH-R01:** Increase the proportion of adolescents who get support for their transition to adult healthcare.
- **AH-R02:** Increase the proportion of adolescents in foster care who show signs of being ready for adulthood.
- **AH-R03:** Increase the proportion of eligible students participating in the Summer Food Service Program.
- **AH-R04:** Increase the proportion of 8th-graders with reading skills at or above the proficient level.
- **AH-R0:** Increase the proportion of 8th-graders with math skills at or above the proficient level.
- **AH-R06:** Increase the proportion of schools requiring students to take at least two health education courses from 6 to 12.
- **AH-R07:** Increase the proportion of secondary schools with a start time of 8:30 AM or later.
- **AH-R08:** Increase the proportion of secondary schools with a full-time registered nurse.
- **AH-R09**: Increase the proportion of public schools with a counselor, social worker, and psychologist.
- **AH-R10:** Increase the proportion of students served under the Individuals with Disabilities Education Act who earn a high school diploma.
- **AH-R11:** Reduce the rate of adolescents and young adult victimization from violent crimes.

Chapter 156

Violent Behavior

Michael N. Levas and Marlene D. Melzer-Lange

Violence is recognized by the World Health Organization (WHO) as a leading worldwide public health problem. The WHO defines violence as "the *intentional* use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of resulting in *injury*, death, psychologic harm, maldevelopment or deprivation" (see Chapter 15). Youths may be perpetrators, victims, or observers of violence (or any combination of the three roles, wherein the roles are unclear), with varying severity of impact on the individual, family, and larger community. Risk factors for youth violence include poverty, socially disorganized communities, war and other regional conflicts, substance misuse (in the child or family), behavioral health disorders (attention-deficit, hyperactivity, conduct disorder), poor school performance, social isolation, child trafficking, runaway youth, criminal or gang involvement (child or family), bullying, and low parental involvement.

EPIDEMIOLOGY

In 2019 (and 2021), **homicide** in the United States was the third leading cause of death for 10- to 24-year-olds, totaling 4,965 deaths, which were largely males (85%) killed by a handgun (79%). The 2019 homicide rate for teens age 12-17 years was 3.43/100,000 youth, down 63% from 8.4/100,000 youth in 1993. The WHO reports that other than the United States, where the youth and young adult homicide rate was 11/100,000, most countries with homicide rates above 10/100,000 are developing nations or countries with socioeconomic instability. In the United States the prevalence of behaviors that contribute to violence has not decreased, as fighting, weapon carrying, and cyberbullying remain prevalent among youth. Furthermore, the rate of homicide in youth had been declining since the peak in the 1990s but showed an increase in 2017 that has continued (Fig. 156.1). Adolescent reports of **physical fighting** have decreased from 42% in 1991 to 22% in 2019.

Violence at U.S. schools remains a significant problem, with 8.1% of students reporting being in a physical fight on school property one or more times in the preceding 12 months in 2019. The 2019 Youth Risk Behavior Surveillance System reported 13.1% of youths overall carried a weapon such as a gun, knife, or club in the last 30 days; 2.8% carried the weapon to school; and 7.4% reported being threatened or injured with a type of weapon on school property. Males are more likely than females to carry a gun or weapon and therefore may need more support and engagement at home and at school. These **violence-related behaviors** at school affect the general students' perception of safety. More than 8.7% of students did not go to school on one or more days in the preceding 30 days because they felt it was unsafe. School-based prevention programs initiated at the elementary school level have been found to decrease violent behaviors in students. Increased surveillance of students is warranted both on and around school property to improve student safety.

Adolescent relationship abuse (dating violence/reproductive coercion) occurs between two people in a close relationship and can be physical (punching, kicking, hitting, shoving), emotional (shaming, bullying, controlling, stalking), or sexual (forcing a partner to engage in a sexual act when he or she does not consent to it). Incidents of adolescent relationship abuse are not uncommon, with 22.4% of females and 15% of males experiencing some type of partner violence between the ages of 11 and 17 years. It may start with teasing, name calling, or shaming but often progresses electronically, with frequent calls, texting, or posting sexual pictures of a partner on social media. Risk factors for being a victim of adolescent relationship abuse include those who use alcohol, believe violence is acceptable, have a lack of adult supervision, or have a peer who is in a violent relationship. Most teens do not report the behaviors because of fear of retaliation from the partner. Teens who are victims of adolescent relationship abuse are more likely to experience decreased school performance, have thoughts about suicide, use drugs and alcohol, develop an eating disorder, experience depression, and are more likely to be victimized during college and into adulthood. School-based prevention programs that address attitudes and behaviors linked with adolescent relationship abuse, such as **Safe Dates** and **Dating Matters**, offer training experiences to change social norms among teens.

ETIOLOGY

The WHO places youth violence in a model within the context of three larger types of violence: self-inflicted, interpersonal, and collective. **Interpersonal violence** is subdivided into violence largely between family members or partners and includes child abuse. **Community violence** occurs between individuals who are unrelated. **Collective violence** incorporates violence by people who are members of an identified group

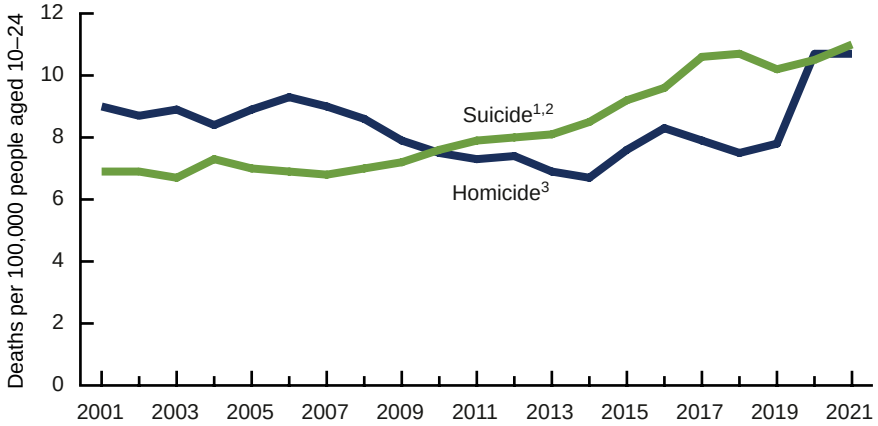

Fig. 156.1 Suicide and homicide death rates among people aged 10–24, United States, 2001–2021. [1]No statistically significant trend from 2001–2007, then significant increasing trend from 2007–2021 ($p < 0.05$). [2]Rate significantly lower than the rates for homicide from 2001–2009 and significantly higher from 2011–2019 ($p < 0.05$). [3]No statistically significant trend for homicides from 2001–2006, then significant decreasing trend from 2006–2014, and a significant increasing trend from 2014–2021 ($p < 0.05$). The rate in 2021 was not significantly different than the rate in 2020 ($p < 0.05$). NOTES: Suicides are identified with International Classification of Diseases, 10th Revision codes U03, X60–X84, and Y87.0, and homicides with codes U01–U02, X85–Y09, and Y87.1. Access data table at: https://www.cdc.gov/nchs/data/databriefs/db471-tables.pdf#1. SOURCE: National Center for Health Statistics, National Vital Statistics System, Mortality data file. *(From Curtin SC, Garnett MF. Suicide and Homicide Death Rates Among Youth and Young Adults Aged 10–24: United States, 2001–2021. NCHS Data Brief. 2023 Jun;(471):1–8. Fig 1.)*

against another group of individuals with social, political, or economic motivation. The types of violence in this model have behavioral links, such that child abuse victims are more likely to experience violent and aggressive interpersonal behavior as adolescents and adults. Overlapping risk factors for the types of violence include firearm availability, alcohol use, and socioeconomic inequalities. The benefit to identifying common risk factors for the types of violence lies in the potential for intervening with prevention efforts and gaining positive outcomes for more than one type of violent behavior. The model further acknowledges four categories that explore the potential nature of violence as involving physical, sexual, or psychologic force and deprivation.

The social-ecologic model of public health focuses on both population-level and individual-level determinants of health and their respective interventions. On the individual level, there may be two types of antisocial youth: life course persistent and limited. **Life course–limited offenders** have no childhood aberrant behaviors and are more likely to commit *status* offenses such as vandalism, running away, and other behaviors symbolic of their struggle for autonomy from parents. **Life course–persistent offenders** exhibit aberrant behavior in childhood, such as problems with temperament, behavioral development, and cognition; as adolescents they participate in more *victim-oriented* crimes. The existence of **adverse childhood experiences** foretells future health issues and subsequent violence. This hypothesis proposes that precursors such as child abuse and neglect, a child witnessing violence, adolescent sexual and physical abuse, and adolescent exposure to violence and violent assaults predispose youths to outcomes of violent behavior, violent crime, delinquency, violent assaults, suicide, or premature death. This public health model also emphasizes the community environment and resiliency of the individual and family. An additional common paradigm for high-risk violence behavior poses a balance of risk and protective factors at the individual, family, and community levels.

CLINICAL MANIFESTATIONS

The identified risk factors for youth violence include poverty, association with delinquent peers, poor school performance or low education status, disconnection from adult role models or mentors, prior history of violence or victimization, poor family functioning, childhood abuse, substance misuse, and certain mental health disorders. The most common disorders associated with **aggressive behavior** in adolescents are intellectual disabilities, learning disabilities, moderately severe language disorders, and mental health disorders such as attention-deficit/hyperactivity disorder (ADHD) and mood disturbances. In general, youth with mental health disorders are not violent. However, the link between severe mental illness and violent behaviors is strongest for those with coexisting alcohol or substance abuse or dependence.

Inability to master prosocial skills such as the establishment and maintenance of positive family/peer relations and poor resolution of conflict may put adolescents at higher risk of physical violence and other risky behaviors. The single, most protective factor is the existence of one or more significant adult mentors in the child's life. **Conduct disorder** and **oppositional defiant disorder** are specific psychiatric diagnoses whose definitions are associated with violent behavior (Table 156.1). They occur with other disorders such as ADHD (see Chapter 50) and increase an adolescent's vulnerability for juvenile delinquency, substance use or abuse, sexual promiscuity, adult criminal behavior, incarceration, and antisocial personality disorder. Other co-occurring risk factors for youth violence include use of anabolic steroids, gang tattoos, belief in one's premature death (inability to see oneself as surviving to adulthood), preteen alcohol use, and placement in a juvenile detention center.

DIAGNOSIS

The assessment of an adolescent at risk or with a history of violent behavior or victimization should be a part of the health maintenance visit of all adolescents. The answers to questions about recent history of involvement in a physical fight, carrying a weapon, or firearms in the household, as well as concerns that the adolescent may have about personal safety, may suggest a problem requiring a more in-depth evaluation. The **FISTS** mnemonic provides guidance for structuring the assessment (Table 156.2). Another screening tool, **Violence Injury Protection and Risk Screen (VIPRS)**, has been validated to predict *future* violence among youth in the primary care setting (Table 156.3). The additional factors of physical or sexual abuse, serious problems at school, poor school performance and attendance, multiple incidents of trauma, substance use, and symptoms associated with behavioral disorders are indications for evaluation by a behavioral health professional. In a situation of acute trauma, assault victims are not always forthcoming about the circumstances of their injuries for fear of retaliation or police involvement. Stabilization of the injury or the gathering of forensic evidence in sexual assault is the treatment priority; however, once this is achieved, addressing a more comprehensive set of issues surrounding the assault is appropriate.

Table 156.1 Oppositional Defiant Disorder and Conduct Disorder

OPPOSITIONAL DEFIANT DISORDER	CONDUCT DISORDER
• Often being angry or losing one's temper • Often arguing with adults or refusing to comply with adults' rules or requests • Often resentful or spiteful • Deliberately annoying others or becoming annoyed with others • Often blaming other people for one's own mistakes or misbehavior	• Breaking serious rules, such as running away, staying out at night when told not to, or skipping school • Being aggressive in a way that causes harm, such as bullying, fighting, or being cruel to animals • Lying, stealing, or damaging other people's property on purpose

TREATMENT

In the patient with acute injury secondary to violent assault, the treatment plan should follow standard protocols, which include the stabilization of the injury, evaluation and treatment of the injury, evaluation of the assault circumstance, psychologic evaluation and support, social service evaluation of the circumstances surrounding the assault, and a treatment plan on discharge that is designed to protect the adolescent from subsequent injury episodes, prevent retaliation, and minimize the development of psychologic disability. Victims and *witnesses* of violence are at risk for posttraumatic stress disorder and future aggressive or violent behavior. Using a **trauma-informed care** approach enables providers to help these victims and witnesses so that they can develop linkages to recovery and resilience. **Hospital-based violence intervention programs** have shown success by supporting violently injured youth and their families in the emergency department, hospital, or community. Credible messenger and violence interrupter programs have shown promise in decreasing the cycle of violence and retaliation in the community after violent events.

Table 156.3 Violence Injury and Perpetration Risk Screen (VIPRS Scale): Percent and Odds of Future Violence Perpetration by Question Type

PROTECTIVE FACTORS	%	ODDS OF ASSOCIATION WITH VIOLENCE PERPETRATION IF PROTECTIVE FACTOR NOT PRESENT OR (95% CI)
1. Do your parents expect you to do well at school?		6.1 (1.1-33.83)

Table 156.4 Preventing Youth Violence (CDC)

STRATEGY	APPROACH
Promote family environments that support healthy development	Early childhood home visitation Parenting skill and family relationship programs
Provide quality education early in life	Preschool enrichment with family engagement
Strengthen youth skills	Universal school-based programs
Connect youth to caring adults and activities	Mentoring programs After-school programs
Create protective community environments	Modify the physical and social environment Reduce exposure to community-level risks Street outreach and community norm change
Intervene to lessen harms and prevent future risk	Treatment to lessen the harms of violence exposures Treatment to prevent problem behavior and further involvement in violence Hospital-community partnerships

From David-Ferdon, C, Vivolo-Kantor AM, Dahlberg LL, et al. *A Comprehensive Technical Package for the Prevention of Youth Violence and Associated Risk Behaviors*. Atlanta, GA: National Center for Injury Prevention and Control, Centers for Disease Control and Prevention; 2016.

Table 156.5 Prevention of Youth Violence (WHO)

Promising prevention programs include:
- Life skills and social development programs designed to help children and adolescents manage anger, resolve conflict, and develop the necessary social skills to solve problems
- Whole-school approaches to violence prevention in educational facilities
- Programs that support parents and teach positive parenting skills
- Preschool programs that provide children with academic and social skills at an early age
- Therapeutic approaches for youths at high risk of being involved in violence
- Reducing access to alcohol
- Interventions to reduce the harmful use of drugs
- Restrictive firearm licensing
- Community and problem-oriented policing
- Interventions to reduce concentrated poverty and to upgrade urban environments

Preventing youth violence requires a comprehensive approach that addresses the social determinants of violence, such as income inequality, rapid demographic and social change, and low levels of social protection.
Courtesy World Health Organization: Youth Violence. https://www.who.int/news-room/fact-sheets/detail/youth-violence, accessed August 11, 2022.

Multiple treatment modalities are used simultaneously in managing adolescents with persistent violent and aggressive behavior and range from cognitive-behavioral therapy involving the individual and family to specific family interventions (parent management training, multisystemic treatment) and pharmacotherapy. Treatment of comorbid conditions, such as ADHD, depression, anxiety, and substance abuse, appears to reduce aggressive behavior.

PREVENTION

The WHO recognizes a multifactorial approach to prevention: parenting and early childhood development strategies, school-based academic and social skills development strategies, strategies for young people at higher risk of or already involved in violence, and community- and society-level strategies (Tables 156.4 and 156.5). **Parenting and early childhood development approaches** concentrate on working with families to provide nonviolent parenting through home visitation and parent groups as well as teaching coping strategies and nonviolent conflict resolution for all children and families. **School-based social skills development strategies** focus on students' families and peer relationships, especially those with the potential to trigger aggressive or violent responses. Solutions include improving coping or problem-solving skills, anti-bullying campaigns, peer mediation, adolescent relationship abuse prevention, and after-school programs. **Strategies for young people at higher risk of, or already involved in, violence** include therapeutic behavioral health approaches, crime victim services, vocational training, mentoring, and gang intervention. These youth are at highest risk for repeat injury or incarceration. **Community- and societal-level approaches** include broader advocacy and legislative actions and changing the cultural norm toward violent behaviors.

A specific prevention strategy can incorporate several approaches, such as the handgun/firearm prevention recommendations that include gun-lock safety, public education, and legislative advocacy. Other efforts are directed toward establishing a national database to track and define the problem of youth violence. The **National Violent Death Reporting System** collects and analyzes violent death data from all 50 states, the District of Columbia, and Puerto Rico and aims to improve surveillance of current trends, to share information state to state, to build partnerships among state and community organizations, and to develop and implement prevention and intervention programs. The Centers for Disease Control and Prevention characterizes specific successful prevention programs, including Striving to Reduce Youth Violence Everywhere (STRYVE), and summarizes program content on its website (www.cdc.gov).

Chapter 157
Substance Use Disorder

Cora Collette Breuner

Many adolescents engage in the use of a wide range of substances, including alcohol, tobacco products, natural marijuana and synthetic cannabinoids, opiates, psychoactive agents (amphetamine, cocaine, MDMA, 3,4-methylenedioxymethamphetamine), hallucinogens, inhaled products (glue, organic solvents, nitrous oxide), and stimulants. Their reactions to and the consequences of these exposures are influenced by a complex interaction among biologic and psychosocial development, environmental messages, legality, and societal attitudes. The potential for adverse outcome with occasional use, such as motor vehicle crashes, violence, and other injuries, is sufficient justification to consider any substance use in adolescents a considerable risk.

Individuals who initiate substance use at an early age are at a greater risk for developing a **substance use disorder** than those who begin using substances in early adulthood. Substance use disorder is diagnosed when the recurrent use of the substance causes clinically significant impairment, including health problems, disability, and failure to meet major responsibilities at work, school, or home. Substance use in younger adolescents may act as a substitute for developing age-appropriate coping strategies and enhance vulnerability to poor decision-making. Most (88%) people report that their age of first alcohol use was <21 years old, the legal drinking age in the United States. Inhalants have been identified as a popular first substance for youth in eighth grade (age 13-14 years).

Substance use disorder is a pervasive phenomenon and infiltrates every socioeconomic and cultural segment of the population. It is one of the costliest and most challenging public health problems facing all societies and cultures. The challenge to the clinician is to identify youth at risk for substance use disorder and offer early intervention. The challenge to the community and society is to create norms that decrease the likelihood of adverse health outcomes for adolescents and promote and facilitate opportunities for adolescents to choose healthier and safer options. Recognizing those substances with the greatest harm, and at times focusing on harm reduction with or without abstinence, is essential in the approach to the adolescent with substance use disorder (Fig. 157.1).

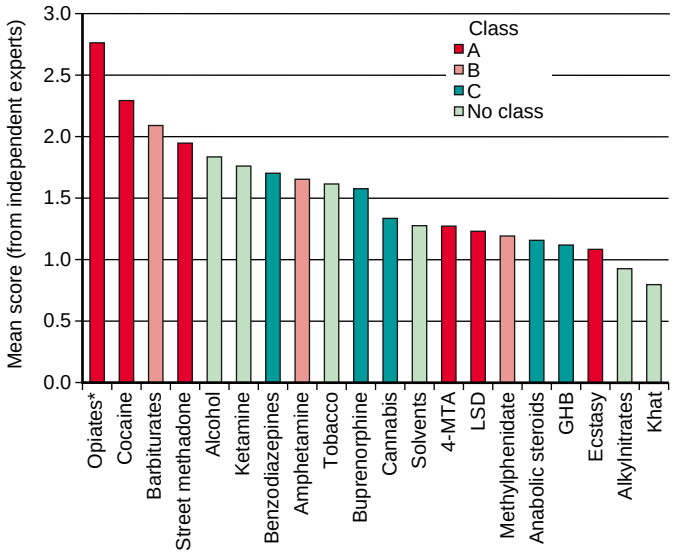

Fig. 157.1 Mean harm scores for 20 substances as determined by an expert panel based on three criteria: physical harm to user, potential for dependence, and effect on family, community, and society. Classification under the Misuse of Substances Act, when appropriate, is shown by the color of each bar. Class A substances are deemed potentially most dangerous; class C least dangerous. *Heroin, fentanyl, fentanyl derivatives. *(From Nutt D, King LA, Saulsbury W, et al. Development of a rational scale to access the harm of substances of potential misuse. Lancet 2007;369:1047–1053.)*

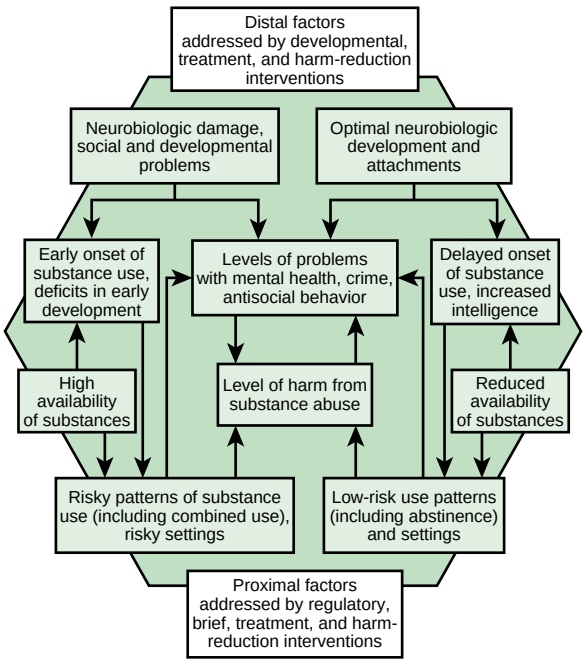

Fig. 157.2 Protection and risk model for distal and proximal determinants of risky substance use disorder and related harms. *(From Toumbourou JW, Stockwell T, Neighbors C, et al. Interventions to reduce harm associated with adolescent substance use. Lancet 2007;369:1391–1571.)*

ETIOLOGY

Substance use disorder has multifactorial origins (Fig. 157.2). Social determinants of health, including economic stability, education, health and healthcare, neighborhood environment, and social and community context, all have an impact on adolescents and can lead to substance use disorder and use. Biologic factors, including genetic predisposition, are established contributors. Behaviors such as ineffective self-control, poor school performance, involvement with the juvenile justice system, and emotional trends such as low self-esteem are frequently associated with or predate the onset of substance use. Psychiatric disorders often coexist with adolescent substance use. Conduct disorders and antisocial personality disorders are the most common diagnoses coexisting with substance use, particularly in males. Teens with depression (see Chapter 39.1), attention-deficit disorder (Chapter 50), anxiety (Chapter 38), and eating disorders (Chapter 41) have high rates of substance use. The determinants of adolescent substance use disorder and substance use are explained using numerous theoretical models and include factors at the individual level, the level of significant relationships with others, and the level of the setting or environment. These models include a balance of risk and protective or coping factors contributing to individual differences among adolescents with similar risk factors who escape adverse outcomes.

Risk factors for adolescent *substance use disorder* may differ from those associated with adolescent substance use. Adolescent substance use is more commonly related to social and peer factors, whereas *use disorder* is more often a function of psychologic and biologic factors. The likelihood that an otherwise normal adolescent would experiment with substances may depend on the availability of the substance to the adolescent, the perceived positive or otherwise functional value to the adolescent, the perceived risk associated with use, and the presence or absence of restraints, as determined by the adolescent's cultural or other important value systems.

Specific historical questions can assist in determining the severity of the substance problem through a rating system (Table 157.1). The type of substance used (marijuana vs cocaine), the circumstances of use (alone or in a group setting), the frequency and timing of use (daily before school vs occasionally on a weekend), current mental health status, and general functional status, including sleep habits and screen use, should all be considered in evaluating any adolescent found to be using a substance. The stage of substance use should also be considered (Table 157.2). A teen may spend months or years in the experimentation phase trying a variety of illicit substances, including the most common substances: alcohol, tobacco products, and marijuana. Often it is not until regular use of substances results in negative consequences (problem use) that the adolescent is identified as having a problem, either by parents, friends, teachers, or a healthcare provider. Having emotionally supportive parents with open communication styles, involvement in organized school activities, having mentors or role models outside the home, and recognition of the importance of academic achievement are examples of important protective factors against developing problematic use.

EPIDEMIOLOGY

Alcohol, tobacco products, and marijuana are the most commonly reported substances used among U.S. teens (Table 157.3). The prevalence of substance use and associated risky behaviors vary by age, gender, race/ethnicity, and other sociodemographic factors. Younger teenagers tend to report less use of substances than do older teenagers, except for inhalants (in 2016, 4.4% in 8th grade, 2.8% in 10th grade, 1.0% in 12th grade). In 2019, a total of 50.1% of U.S. high school students had ever used electronic vapor products, and 24.1% had ever tried cigarette smoking. Current electronic vapor product use was 32.7%, current cigarette smoking was 6.0%, current cigar smoking was 5.7%, and current smokeless tobacco use was 3.8%. Approximately 36.5% of students were current users of any tobacco product, and 8.2% were current users of two or more tobacco products. Males have higher rates of substances use than females, with greatest differences seen in their higher rates of use of tobacco products including vaping, chewing and cigarettes/cigars, and anabolic steroids.

Fewer students engaged in some high-risk substance use–related behaviors from 2009 through 2019. However, approximately one in seven students are still reporting lifetime use of any illicit drug or misuse of prescription medicine.

Marijuana use has been trending down over the past several years among adolescents, though there is variation in the extent and rate of use in different racial/ethnic groups. Use also depends on grade level, urban vs rural location, class size, and state laws regarding legalization of recreational or medical marijuana. The magnitude of the increase was greater in states with legal medical or recreational marijuana. Synthetic cannabinoids have significant psychotropic effects and addictive potential. Severe neuropsychiatric toxicity is often different from and more severe than marijuana.

The number of 12th graders who report using any of the **prescription psychotherapeutic** substances, including amphetamines, sedatives (barbiturates), tranquilizers, and narcotics other than heroin, decreased in 2019. Prevalence was 14% for ever used and 7.0% for 30-day use, indicating that a substantial portion of adolescents still misuse prescription substances including opioids. Rural adolescents are also more likely than urban adolescents to misuse prescription substances. In a large-scale study of 16,209 adolescent exposures to prescription substances, 52.4% were females, and the mean age was 16.6 years. The five most frequently misused substances were hydrocodone (32%),

Table 157.2 Stages of Adolescent Substance Use

STAGE	DESCRIPTION
1	Potential for use • Decreased impulse control • Need for immediate gratification • Available substances, alcohol, inhalants • Need for peer acceptance
2	Experimentation: learning the euphoria • Use of inhalants, tobacco, marijuana, and alcohol with friends • Few, if any, consequences • Use may increase to weekends regularly • Little change in behavior
3	Regular use: seeking the euphoria • Use of other substances (e.g., stimulants, LSD, sedatives) • Behavioral changes and some consequences • Increased frequency of use; use disorder alone • Buying or stealing substances
4	Regular use: preoccupation with the "high" • Daily use of substances • Loss of control • Multiple consequences and risk taking • Estrangement from family and "straight" friends
5	Burnout: use of substances to feel normal • Polysubstance use/cross-addiction • Guilt, withdrawal, shame, remorse, depression • Physical and mental deterioration • Increased risk taking, self-destructive, suicidal

Table 157.1 Assessing the Seriousness of Adolescent Substance Use

VARIABLE	0	+1	+2
Age (yr)	>15	<15	
Sex	Male	Female	
Family history of substance use		Yes	
Setting of substance use	In group		Alone
Affect before substance use	Happy	Always poor	Sad
School performance	Good, improving		Recently poor
Use disorder before driving	None		Yes
History of accidents	None		Yes
Time of week	Weekend	Weekdays	
Time of day		After school	Before or during school
Type of substance	Marijuana, beer, wine	Hallucinogens, amphetamines	Whiskey, opiates, cocaine, barbiturates

Total score: 0-3, less worrisome; 3-8, serious; 8-18, very serious.

[a]The proportional change is the percent by which the most recent year deviates from the peak year (or the low year) for the drug in question. So, if a drug was at 20% prevalence in the peak year and declined to 10% prevalence in the most recent year, that would reflect a proportional decline of 50%.

[b]Question was discontinued among 8th and 10th graders in 2012.

[c]In 2013, for the questions on the use of amphetamines, the text was changed on two of the questionnaire forms for 8th and 10th graders and four of the questionnaire forms for 12th graders. This change also affected the any illicit drug indices. Data presented here include only the changed forms beginning in 2013.

[d]In 2014, the text was changed on one of the questionnaire forms for 8th, 10th, and 12th graders to include "molly" in the description. The remaining forms were changed in 2015. Data for both versions of the question are presented here.

[e]Drug prevalence results in 2019 combine results from paper-and-pencil surveys with those completed using electronic tablets. In 2019, students in a randomly selected half of schools completed MTF surveys on paper-and-pencil and students in the other half completed the surveys using electronic tablets. Analysis of this randomized controlled trial demonstrated that these results did not significantly differ across survey mode (Miech RA, Couper MP, Heeringa SG, et al. The impact of survey mode on US national estimates of adolescent drug prevalence: results from a randomized controlled study, *Addiction*). Results for student attitudes and beliefs in 2019 are based on answers from paper-and-pencil surveys only because these appear more susceptible to survey mode effects.

Notes: – indicates data not available. ‡ indicates a change in the question text. When a question change occurs, peak levels after that change are used to calculate the peak year to current year difference. Values in bold equal peak levels since 1991. Values in *italics* equal peak level before wording change. Level of significance of difference between classes: s = 0.05, ss = 0.01, sss = 0.001. Any apparent inconsistency between the change estimate and the prevalence estimates for the two most recent years is the result of rounding.

Modified from Miech RA, Johnston LD, O'Malley PM, et al. *Monitoring the Future National Survey Results on Drug Use, 1975–2021: Volume I, Secondary School Students.* Ann Arbor, MI: Institute for Social Research, The University of Michigan; 2022. Available https://monitoringthefuture.org/wp-content/uploads/2022/12/mtf2022.pdf

amphetamines (18%), oxycodone (15%), methylphenidate (14%), and tramadol (11%). Many of these substances can be found in the home of friends; some are over-the-counter (OTC) substances (dextromethorphan, pseudoephedrine), whereas others are purchased from substance dealers at schools and colleges. Adolescents often combine opioids with marijuana, alcohol, cocaine, and tranquilizers, putting them at risk for serious complications and overdose.

CLINICAL MANIFESTATIONS

Although manifestations vary by the specific substance of use, adolescents who use substances often present in an office setting with no obvious physical findings. Substance use disorder is more frequently detected in adolescents who experience trauma such as motor vehicle crashes, bicycle injuries, or violence. Eliciting appropriate historical information regarding substance use, followed by blood alcohol and urine substance screens, is recommended in emergency settings. Although waning in popularity, the illicit substances known as "club drugs" still need to be considered in the differential diagnosis of a teen with an altered sensorium. An adolescent presenting to an emergency setting with an impaired sensorium should be evaluated for substance use as a part of the differential diagnosis (Table 157.4). Screening for substance use is recommended for patients with psychiatric and behavioral diagnoses. Other clinical manifestations of substance use are associated with the route of use; intravenous substance use is associated with venous "tracks" and needle marks, and nasal mucosal injuries are associated with nasal insufflation of substances. Seizures can be a direct effect of substances such as cocaine, synthetic marijuana, and amphetamines or an effect of substance withdrawal in the case of barbiturates or tranquilizers.

SCREENING FOR SUBSTANCE USE DISORDERS

In a primary care setting the annual health maintenance examination provides an opportunity for identifying adolescents with substance use disorder. The direct questions and the assessment of school performance, family relationships, and peer activities may necessitate a more in-depth interview if there are suggestions of difficulties in those areas. Several self-report screening questionnaires also are available, with varying degrees of standardization, length, and reliability. The **CRAFFT mnemonic** is specifically designed to screen for adolescents' substance use in the primary care setting (Table 157.5). Privacy and confidentiality must be established when asking the teen about specifics of their substance experimentation or use. Interviewing the parents can provide additional perspective on early warning signs that go unnoticed or disregarded by the teen. Examples of early warning signs of teen substance use disorder are change in mood, appetite, or sleep pattern; decreased interest in school or school performance; loss of weight; secretive behavior about social plans; or valuables such as money or jewelry missing from the home. The use of urine substance screening is recommended when select circumstances are present: (1) psychiatric symptoms to rule out comorbidity or dual diagnoses, (2) significant changes in school performance or other daily behaviors, (3) frequently occurring accidents, (4) frequently occurring episodes of respiratory problems, (5) evaluation of serious motor vehicular or other injuries, and (6) as a monitoring procedure for a recovery program. Most initial screening uses an immunoassay method, such as the enzyme-multiplied immunoassay technique, followed by a confirmatory test using highly sensitive, highly specific gas chromatography–mass spectrometry. The substances that can cause false-positive results should be considered, especially when there is a discrepancy between

Table 157.4 Most Common Toxic Syndromes

ANTICHOLINERGIC SYNDROMES	
Common signs	Delirium with mumbling speech, tachycardia, dry, flushed skin, dilated pupils, myoclonus, slightly elevated temperature, urinary retention, and decreased bowel sounds. Seizures and dysrhythmias may occur in severe cases.
Common causes	Antihistamines, antiparkinsonian medication, atropine, scopolamine, amantadine, antipsychotic agents, antidepressant agents, antispasmodic agents, mydriatic agents, skeletal muscle relaxants, and many plants (notably jimsonweed and *Amanita muscaria*).
SYMPATHOMIMETIC SYNDROMES	
Common signs	Delusions, paranoia, tachycardia (or bradycardia if the substance is a pure α-adrenergic agonist), hypertension, hyperpyrexia, diaphoresis, piloerection, mydriasis, and hyperreflexia. Seizures, hypotension, and dysrhythmias may occur in severe cases.
Common causes	Cocaine, amphetamine, methamphetamine (and its derivatives 3,4-methylenedioxyamphetamine, 3,4-methylenedioxymethamphetamine, 3,4-methylenedioxyethamphetamine, and 2,5-dimethoxy-4-bromoamphetamine), some synthetic marijuana, and OTC decongestants (phenylpropanolamine, ephedrine, and pseudoephedrine). In caffeine and theophylline overdoses, similar findings, except for the organic psychiatric signs, result from catecholamine release.
OPIATE, SEDATIVE, OR ETHANOL INTOXICATION	
Common signs	Coma, respiratory depression, miosis, hypotension, bradycardia, hypothermia, pulmonary edema, decreased bowel sounds, hyporeflexia, and needle marks. Seizures may occur after overdoses of some narcotics, notably propoxyphene.
Common causes	Narcotics, barbiturates, benzodiazepines, ethchlorvynol, glutethimide, methyprylon, methaqualone, meprobamate, ethanol, clonidine, and guanabenz.
CHOLINERGIC SYNDROMES	
Common signs	Confusion, central nervous system depression, weakness, salivation, lacrimation, urinary and fecal incontinence, gastrointestinal cramping, emesis, diaphoresis, muscle fasciculations, pulmonary edema, miosis, bradycardia or tachycardia, and seizures.
Common causes	Organophosphate and carbamate insecticides, physostigmine, edrophonium, and some mushrooms.

From Kulig K. Initial management of ingestions of toxic substances. *N Engl J Med* 1992;326:1677–1681.

Table 157.5 CRAFFT Mnemonic Tool

- Have you ever ridden in a **C**ar driven by someone (including yourself) who was high or had been using alcohol or substances?
- Do you ever use alcohol or substances to **R**elax, feel better about yourself, or fit in?
- Do you ever use alcohol or substances while you are by yourself (**A**lone)?
- Do you ever **F**orget things you did while using alcohol or substances?
- Do your **F**amily or **F**riends ever tell you that you should cut down on your drinking or substance use?
- Have you ever gotten into **T**rouble while you were using alcohol or substances?

From the Center for Adolescent Substance Use Research (CeASAR). *The CRAFFT Screening Interview.* (Copyright John R. Knight, MD, Boston Children's Hospital, 2015.)

the physical findings and the urine substance screen result. Current guidelines strongly discourage routine home-based or school-based testing.

DIAGNOSIS

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) no longer identifies substance use disorder as those of *abuse* or of *dependence*. A substance use disorder is defined by a cluster of cognitive, behavioral, and physiologic symptoms that indicate that an adolescent is using a substance even though there is evidence that the substance is harming the adolescent. Even after detoxification, a substance use disorder may leave persistent changes in brain circuits with resulting behavioral changes. There are 11 criteria that describe a pathologic pattern of behaviors related to use of the substance, falling into four categories: impaired control, social impairment, increased risk, and pharmacologic criteria. The first category, **impaired control**, describes an individual taking increasing amounts of the substance who expresses a persistent desire to decrease use, with unsuccessful efforts. The individual may spend a great deal of time obtaining the substance, using the substance, or recovering from its effects and expresses an intense desire for the substance, usually in settings where the substance had been available, such as a specific type of social situation. The second cluster of criteria (5-7) reflects **social impairment,** including the inability to perform as expected in school, at home, or at a job; increasing social problems; and withdrawing from the family. The third cluster addresses **increased risk** associated with use of the substance, and the fourth cluster addresses **pharmacologic responses** (tolerance and/or withdrawal). The total number of criteria present is associated with a determination of a *mild, moderate,* or *severe* disorder.

These criteria may have limitations with adolescents because of differing patterns of use, developmental implications, and other age-related consequences. Adolescents who meet diagnostic criteria should be referred to a program for substance use disorder treatment unless the primary care physician has additional training in addiction medicine.

COMPLICATIONS

Substance use disorder in adolescence is associated with significant comorbidities and acts of juvenile delinquency. Youth may engage in other high-risk behaviors such as robbery, burglary, substance dealing, or prostitution for the purpose of acquiring the money necessary to buy substances. Regular use of any substance eventually diminishes judgment and is associated with unprotected sexual activity with its consequences of pregnancy and sexually transmitted infections, including HIV, as well as physical violence. Substance use disorder is closely associated with trauma in the adolescent population. Several studies of adolescent trauma victims have identified cannabinoids and cocaine in blood and urine samples in significant proportions (40%), in addition to the more common identification of alcohol. Any use of injected substances involves the risk of hepatitis B and C viruses and HIV (see Chapter 322).

TREATMENT

Adolescent substance use disorder is a complex condition requiring a multidisciplinary approach that attends to the needs of the individual, not just substance use. Fundamental principles for treatment include accessibility to treatment, using a multidisciplinary approach, employing individual or group counseling, offering mental health services, monitoring of substance use while in treatment, and understanding that recovery from substance use/addiction may involve multiple relapses. For most patients, remaining in treatment for a minimum period of 3 months may result in a significant improvement.

PROGNOSIS

For adolescent substance users who have been referred to a substance treatment program, positive outcomes are directly related to regular attendance in posttreatment groups. Outcomes are worse for males with learning problems or conduct disorder than for those without such disorders. Peer use patterns and parental use have a major influence on outcome for males. The chronicity of a substance use disorder makes **relapse** an issue that must always be considered when managing patients after treatment, and appropriate assistance from a healthcare professional qualified in substance use disorder treatment should be obtained.

Table 157.6 Domains of Risk and Protective Factors for Substance Use Prevention

RISK FACTORS	DOMAIN	PROTECTIVE FACTORS
Early aggressive behavior	Individual	Self-control
Lack of parental supervision	Family	Parental monitoring
Substance use	Peer	Academic competence
Substance availability	School	Anti–substance use disorder policies
Poverty	Community	Strong neighborhood attachment

From National Institute on Substance Use. Preventing Substance Use Disorder Among Children and Adolescents: A Research-Based Guide for Parents, Educators, and Community Leaders, NIH Pub No 04-4212(B), 2nd ed. Bethesda, MD: NIDA; 2003.

PREVENTION

Preventing substance use disorder among adolescents requires prevention efforts aimed at the individual, family, school, and community levels. The National Institute on Drug Abuse (NIDA) of the U.S. National Institutes of Health has identified essential principles of successful prevention programs. Programs should enhance *protective factors* (parent support) and reduce *risk factors* (poor self-control), should address all forms of substance use (legal and illegal), should address the specific type(s) of substance use within an identified community, and should be culturally competent to improve effectiveness (Table 157.6). Prevention programs need to target emotionally and socially intense times such as life/school transitions for adolescents to adequately anticipate potential substance use disorder. Examples of effective research-based substance use prevention programs featuring a variety of strategies are listed on the NIDA website (www.drugabuse.gov) and on the Center for Substance Abuse Prevention website (www.prevention.samhsa.gov).

157.1 Alcohol

Cora Collette Breuner

Alcohol is the most widely used substance of abuse among America's youth, and a higher proportion use alcohol than use tobacco or other substances, but the numbers are trending down. According to the 2020 *Monitoring the Future (MTF)* study, by the end of high school, 61.5% of students had reported ever using alcohol and 26% of eighth graders had reported ever using alcohol. Early initiation of alcohol use increases the risk for a variety of developmental problems during adolescence and is frequently an indicator of future substance use. Drinking by children, adolescents, and young adults has serious negative consequences for the individuals, their families, their communities, and society as a whole. Underage drinking contributes to a wide range of costly health and social problems, including motor vehicle crashes (the greatest single mortality risk for underage drinkers); suicide; interpersonal violence (e.g., homicides, assaults, rapes); unintentional injuries such as burns, falls, and drowning; brain impairment; alcohol dependence; risky sexual activity; academic problems; and alcohol and other drug poisoning.

Multiple factors can affect a young teen's risk of developing a drinking problem at an early age (Table 157.7). One third of high school seniors admit to combining drinking behaviors with other risky behaviors, such as driving or taking additional substances. **Binge drinking**

Table 157.7 Risk Factors for a Teen Developing a Drinking Problem

FAMILY RISK FACTORS

- Low parental supervision
- Poor parent to teen communication
- Family conflicts
- Severe or inconsistent family discipline
- Having a parent with an alcohol or substance problem

INDIVIDUAL RISK FACTORS

- Poor impulse control
- Emotional instability
- Thrill-seeking behaviors
- Behavioral problems
- Perceived risk of drinking is low
- Begins drinking before age 14 yr

remains especially problematic among older teens and young adults; 31% of high school seniors report having five or more drinks in a row in the last 30 days. Higher rates of alcohol use disorder are seen in males (23.8%) than in females (19.8%). Teens with binge-drinking patterns are more likely to be assaulted, engage in high-risk sexual behaviors, have academic problems, and be injured than those teens without binge-drinking patterns.

Alcohol contributes to more deaths in young individuals in the United States than all the illicit substances combined. Among studies of adolescent trauma victims, alcohol is reported to be present in 32–45% of hospital admissions. Motor vehicle crashes are the most frequent type of event associated with alcohol use, but the injuries span several types, including self-inflicted wounds.

Alcohol is often mixed with energy drinks (caffeine, taurine, sugars), which can result in a spectrum of alcohol-related negative behaviors. Caffeine may counter the sedative effects of alcohol, resulting in more alcohol consumption and a perception of not being intoxicated, thus leading to risk-taking behavior such as driving while intoxicated. In addition, aggressive behavior, including sexual assaults and motor vehicle or other injuries, has been reported. Both alcohol and caffeine overdoses have also been reported.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Alcohol (ethyl alcohol or ethanol) is rapidly absorbed in the stomach and is transported to the liver and metabolized by two pathways. The primary metabolic pathway contributes to the excess synthesis of triglycerides, a phenomenon that is responsible for producing a **fatty liver**, even in those who are well nourished. Engorgement of hepatocytes with fat causes necrosis, triggering an inflammatory process **(alcoholic hepatitis)**, later followed by fibrosis, the hallmark of **cirrhosis**. Early hepatic involvement may result in elevation in γ-glutamyltransferase (GGT) and serum glutamic-pyruvic transaminase (alanine transaminase). The second metabolic pathway, which is used at high serum alcohol levels, involves the microsomal enzyme system of the liver, in which the cofactor is reduced to nicotinamide-adenine dinucleotide phosphate. The net effect of activation of this pathway is to decrease metabolism of substances that share this system and to allow for their accumulation, enhanced effect, and possible toxicity.

CLINICAL MANIFESTATIONS

Alcohol acts primarily as a central nervous system (CNS) depressant. It produces euphoria, grogginess, talkativeness, impaired short-term memory, and an increased pain threshold. Alcohol's ability to produce vasodilation and hypothermia is also centrally mediated. At very high serum levels, respiratory depression occurs. Its inhibitory effect on pituitary antidiuretic hormone release is responsible for its diuretic effect. The gastrointestinal (GI) complications of alcohol use can occur from a single large ingestion. The most common is acute **erosive gastritis**, manifesting as epigastric pain, anorexia, vomiting, and heme-positive stools. Less frequently, vomiting and mid-abdominal pain may be caused by acute alcoholic **pancreatitis**; the diagnosis is confirmed by the finding of elevated serum amylase and lipase levels.

DIAGNOSIS

Primary care settings provide the opportunity to screen teens for alcohol use disorder or problem behaviors. Brief alcohol screening instruments such as CRAFFT (see Table 157.5) perform well in a clinical setting as techniques to identify alcohol use disorders A score of 2 or higher is a positive screen, indicating a need for additional assessment.

Teenagers in the early phases of alcohol use exhibit few physical findings. Recent use of alcohol may be reflected in elevated GGT and aspartate transaminase levels.

In acute care settings the **alcohol overdose syndrome** should be suspected in any teenager who appears disoriented, lethargic, or comatose. Although the distinctive aroma of alcohol may assist in diagnosis, confirmation by analysis of blood is recommended. At levels >200 mg/dL, the adolescent is at risk of death, and levels >500 mg/dL (median lethal dose) are usually associated with a fatal outcome. *When the level of obtundation appears excessive for the reported blood alcohol level, head trauma, hypoglycemia, or ingestion of other substances should be considered as possible confounding factors.*

TREATMENT

The usual mechanism of death from alcohol overdose syndrome is **respiratory depression**; artificial ventilatory support must be provided until the liver can eliminate sufficient amounts of alcohol from the body. In a patient *without* chronic alcohol use, it generally takes 20 hours to reduce the blood level of alcohol from 400 mg/dL to zero. Dialysis should be considered when the blood level is >400 mg/dL. As a follow-up to acute treatment, referral for treatment of the alcohol use disorder is indicated. Group counseling, individualized counseling, and multifamily educational intervention have proved to be effective interventions for teens.

157.2 Tobacco, E-Cigarettes, and Other Tobacco Products

Brian P. Jenssen

CIGARETTES

Tobacco use and addiction often start in childhood or adolescence, a period when the brain has heightened susceptibility to nicotine addiction. Nearly 90% of adult cigarette smokers began smoking before age 18. Factors associated with youth tobacco use include exposure to smokers (friends, parents), tobacco availability, low socioeconomic status, poor school performance, low self-esteem, lack of perceived risk of use, and lack of skills to resist influences to use tobacco.

The landscape of tobacco product use among youth has shifted dramatically over the past decade. Various sources are used to capture data on tobacco use. Similar trends have been observed across cross-sectional surveys with data on youth use, including, for example, the National Youth Tobacco Survey, Monitoring the Future, and the Youth Risk Behavior Surveillance system.

Based on 2022 data, current use of any tobacco product was reported by 11.3% (3.08 million) of all students, including 16.5% (2.51 million) of high school and 4.5% (530,000) of middle school students. E-cigarettes were the most used tobacco product among high school (14.1%; 21.4 million) and middle school (3.3%; 380,000) students. Among high school students, 5.2% reported current use of any combustible tobacco product. By product, current use among high school students was highest for e-cigarettes (14.1%), followed by cigars (2.8%), cigarettes (2.0%), smokeless tobacco (1.6%), hookahs (1.5%), nicotine pouches (1.4%), heated tobacco products (1.1%), and pipe tobacco (0.7%). Among middle school students, 1.6% reported current use of any combustible tobacco product. By type of product, current use among middle school students

was highest for e-cigarettes (3.3%), followed by cigarettes (1.0%), smokeless tobacco (0.7%), heated tobacco products (0.7%), cigars (0.6%), hookahs (0.5%), nicotine pouches (0.5%), and pipe tobacco (0.3%).

Tobacco use tends to be higher among males compared to females and by those identifying as lesbian, gay, or bisexual compared to heterosexual or uncertain sexual identity. Tobacco is used by teens in all regions of the world, although the form of tobacco used differs. In the Americas and Europe, cigarette smoking is the predominant form of tobacco use, followed by cigars and smokeless tobacco; in the Eastern Mediterranean, hookah use is prevalent; in Southeast Asia, smokeless tobacco products are used; in the Western Pacific, betel nut is chewed with tobacco; and pipe, snuff, and rolled tobacco leaves are used in Africa. Cigarette use by teens in low- and middle-income nations is increasing.

PHARMACOLOGY

Nicotine, the primary active ingredient in cigarettes, is addictive. Nicotine is absorbed by multiple sites in the body, including the lungs, skin, GI tract, and buccal and nasal mucosa. The action of nicotine is mediated through nicotinic acetylcholine receptors located on noncholinergic presynaptic and postsynaptic sites in the brain and causes increased levels of dopamine. Nicotine also stimulates the adrenal glands to release epinephrine, causing an immediate elevation in blood pressure, respiration, and heart rate. The dose of nicotine delivered to the user in a cigarette depends on a variety of factors, including puffing characteristics. A smoker typically takes 10 puffs within the span of 5 minutes and absorbs 1-2 mg of nicotine (range: 0.5-3 mg). The Food and Drug Administration (FDA) is planning to reduce the permissible amount of nicotine in cigarettes. **Cotinine**, the major metabolite of nicotine, has a biologic half-life of 19-24 hours and can be detected in urine, serum, and saliva.

CLINICAL MANIFESTATIONS

Cigarettes are addictive by design and result in life-shortening diseases in half of their long-term users. Each year, approximately 480,000 deaths are attributable to smoking, responsible for 1 of every 5 deaths and 1 of every 3 cancer deaths in the United States. Cigarette smoking has severe adverse health consequences for youth and young adults, including increased prevalence of chronic cough, sputum production, wheezing, and worsening asthma. Smoking during pregnancy increases prenatal and perinatal morbidity and mortality, either causing or exacerbating the risks of preterm birth, low birthweight, congenital malformations, stillbirth, and sudden infant death syndrome (SIDS) and sudden unexplained infant death (SUID). **Withdrawal** symptoms, including irritability, decreased concentration, increased appetite, and strong cravings for tobacco, can occur when adolescents try to quit.

ELECTRONIC CIGARETTES (E-CIGARETTES)

E-cigarettes are handheld devices that produce an aerosol created from a solution of nicotine, flavoring chemicals, humectants such as propylene glycol, and often other constituents unknown and unadvertised to the consumer. There is wide variability in terminology, product design, and engineering of these products, with alternative names including e-cigs, electronic cigars, electronic hookah, e-hookah, and vaping devices. The tobacco industry continues to develop new products that contain nicotine but may not be recognized as a tobacco product by teens. The unique flavors offered in e-cigarette solutions, the majority of which are confectionary in nature and appealing to children, have been shown to encourage youth experimentation, regular use, and addiction.

Known harmful toxicants and carcinogens have been found in e-cigarette solutions, in device emissions, and within the bodies of adolescent users. Multiple systematic reviews and meta-analyses have found e-cigarette use is associated with an increased risk of subsequent cigarette smoking initiation and current cigarette smoking in young people. There is a critical need for e-cigarette regulation, legislative action, and counter-promotion to prevent children, adolescents, and young adults from transitioning from e-cigarettes to traditional cigarettes and minimize the potential public health harm from e-cigarette use. The FDA should regulate all tobacco and nicotine products to protect public health.

HOOKAH

Hookah (water pipe) smoking uses specially treated tobacco that comes in a variety of flavors. Many teens believe incorrectly that hookah does not contain nicotine. Emerging evidence indicates that hookah may involve comparable health risks to cigarettes, including nicotine dependence. Both human and machine simulation studies of hookah use consistently find that smoke content and user toxicant exposure, including carbon monoxide, tar, and nicotine, are at least comparable to that of cigarettes. Secondhand smoke from hookahs can be a health risk for nonsmokers exposed to harmful toxicants.

TREATMENT

The 2020 U.S. Surgeon Report on smoking cessation emphasizes that smoking cessation is beneficial at any age, reducing the risk of premature death, adding as much as a decade to life expectancy, while also reducing the risk of many adverse health effects. More than half of adolescents who use tobacco products report that they want to quit, and more than half report making at least one quit attempt in the past year. Thus for adolescents who want to stop tobacco or e-cigarette use, it is reasonable to consider referral to behavioral cessation supports. Behavioral interventions for adults have significant evidence supporting their effectiveness, and many youth and young adult supports are modeled off of these programs.

Little research has been conducted assessing the effectiveness of pharmacologic therapies for combustible tobacco use among adolescents. The 2020 U.S. Preventive Services Task Force recommendation concluded there was inadequate evidence on the benefits and harms of medications for tobacco cessation in children and adolescents. Nonetheless, consensus panels recommend that for adolescents who want to stop tobacco or e-cigarette use with moderate to severe tobacco dependence, it is reasonable to consider pharmacotherapy, especially nicotine replacement therapy (NRT). Cessation medications are not approved by the FDA for use with children or adolescents, and NRT cannot be purchased OTC by persons younger than 18 years of age. However, cessation medications can be prescribed for and used by youth under the supervision of a physician. NRT is also available as a patch, gum, inhaler, nasal spray, lozenge, or microtab (Table 157.8). Tobacco dependence treatment for youth should be tailored to the patient's level of nicotine dependence and readiness for change. Given the very high rates of nonadherence during therapy and relapse after discontinuation of therapy among adolescents in the trials of these medications, close follow-up is recommended.

Pediatric clinicians can connect patients to effective behavioral interventions, including telephone, text message, smartphone app, internet, and community-based resources. Free telephone-based treatment (800-QUIT-NOW) has been shown to improve smoking cessation rates. Smoke-free TXT, offered by the National Cancer Institute, engages teens to quit smoking using free, daily text messaging. Teens can sign up online (teen.smokefree.gov) or text QUIT to iQUIT (47848). A smartphone-based app, quitSTART, helps teens track cravings, monitor moods, use cessation tips, and follow quitting attempts. Truth Initiative has an evidence-based program, This Is Quitting, which is targeted to teens who want to stop using e-cigarettes (https://truthinitiative.org/thisisquitting). The American Academy of Pediatrics offers a brief, practical guide that is designed to support pediatric health clinicians in providing behavioral and pharmacologic support to help youth quit (https://services.aap.org/en/patient-care/tobacco-control-and-prevention/youth-tobacco-cessation/).

Table 157.8 Smoking Cessation Pharmacotherapy Available in the United States*

THERAPY BRAND	NAME	STRENGTHS	FDA-APPROVED ADULT DOSING	AVAILABILITY†	STUDIED IN ADOLESCENTS
NICOTINE REPLACEMENT THERAPY					
Gum‡	Nicorette	2 mg, 4 mg	The 4-mg strength should be used by patients who smoke ≥25 cigarettes a day; otherwise, 2-mg strength should be used. Wk 1-6: 1 piece every 1-2 hr Wk 7-9: 1 piece every 2-4 hr Wk 10-12: 1 piece every 4-8 hr	OTC*	Yes
Inhaler	Nicotrol Inhaler	4 mg	6-16 cartridges a day for up to 12 wk	Rx	No
Lozenge	Commit, Nicorette mini	2 mg, 4 mg	The 4-mg strength should be used by patients who smoke their first cigarette within 30 min of waking; otherwise, 2-mg strength should be used. Wk 1-6: 1 lozenge every 1-2 hr Wk 7-9: 1 lozenge every 2-4 hr Wk 10-12: 1 lozenge every 4-8 hr	OTC	No
Nasal spray	Nicotrol NS	0.5 mg/spray	1-2 sprays/hr up to a maximum of 80 sprays per day	Rx	Yes
Transdermal patch‡	NicoDerm CQ	7, 14, 21 mg/24 hr	For patients who smoke >10 cigarettes daily: Step 1: one 21-mg patch daily for wk 1-6 Step 2: one 14-mg patch daily for wk 7-8 Step 3: one 7-mg patch daily for wk 9-10 For patients who smoke <10 cigarettes daily: Begin with 14-mg patch daily for 6 wk, followed by 7-mg patch for 2 wk.	OTC	Yes
NONNICOTINE THERAPY					
Bupropion SR‡	Zyban	150-mg sustained-release tablets	150 mg PO in morning for 3 days, then increase to 150 mg PO bid	Rx	Yes
Varenicline	Chantix	0.5-, 1-mg tablets	0.5 mg PO in morning for 3 days; increase to 0.5 mg PO bid for 4 days, then increase to 1 mg PO bid	Rx	Yes

*None are FDA approved for use in patients younger than 18 years of age.
†OTC, Over the counter; Rx, prescription product; PO, by mouth (orally); bid, twice daily.
‡Generics are available.

157.3 Marijuana

Cora Collette Breuner

Marijuana (cannabis, pot, weed, hash, grass), derived from the *Cannabis sativa* hemp plant, is the most commonly used illicit substance. The main active chemical, tetrahydrocannabinol (**THC**), is responsible for its hallucinogenic properties. THC is absorbed rapidly by the nasal or oral routes, producing a peak of subjective effect at 10 min and 1 hour, respectively. Marijuana is generally smoked as a cigarette (reefer, joint), in a pipe, or ingested (edibles). Although there is much variation in content, each cigarette contains 8–10% THC. Another popular form that is smoked, a "blunt," is a hollowed-out small cigar (tobacco leaf) refilled with marijuana, and thus also contains nicotine. Marijuana products (hash oil or leaf) can also be used in some vaping devices or hookah pens. **Hashish** is the concentrated THC resin in a sticky black liquid or oil. Although marijuana use by U.S. teens has declined in the last decade, ~25% of high school students have used marijuana at least once during the previous 30 days. About 8% of students report having tried marijuana before age 13, with a range of 4.3–18.5% across various states, indicating the need for early prevention efforts. Adolescents living in states where medical marijuana is legal report a higher use of cannabis edibles. It is important to recognize that as perceived harm drops, marijuana use increases. (Fig. 157.3). In addition, the potency of cannabis has increased substantially in part to marketing and legal sales.

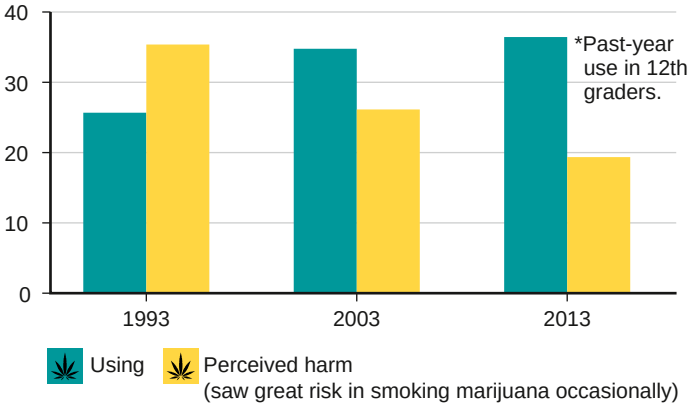

Fig. 157.3 As the perceived harm of marijuana drops, use disorder goes up. The 36.4% using in 2013 equates to about 11 students in the average class. *(From NIH National Institute on Substance Use.)*

Table 157.9 Acute and Chronic Adverse Effects of Cannabis Use

ACUTE ADVERSE EFFECTS

- Anxiety and panic, especially in naïve users
- Psychotic symptoms (at high doses)
- Road crashes if a person drives while intoxicated
- Cannabis hyperemesis syndrome

CHRONIC ADVERSE EFFECTS

- Cannabis dependence syndrome (in about 1 in 10 users)
- Chronic bronchitis and impaired respiratory function in regular smokers
- Psychotic symptoms and disorders in heavy users, especially those with a history of psychotic symptoms or a family history of these disorders
- Impaired educational attainment in adolescents who are regular users
- Subtle cognitive impairment in those who are daily users for 10 yr or more
- Impaired tasks of sequencing ability, cognitive processing speed, inhibition, and sustained attention

Modified from Hall W, Degenhardt L. Adverse health effects of non-medical cannabis use. *Lancet*. 2009;374:1383–1390.

Table 157.10 Rome IV Criteria for CHS Diagnosis

CATEGORY	FEATURES
Essential	Stereotypical episodic vomiting resembling CVS in terms of onset, duration, and frequency Presentation after prolonged, excessive cannabis use Relief of vomiting episodes by sustained cessation of cannabis use
Supportive remarks	May be associated with pathologic bathing behavior (prolonged hot baths or showers)

CHS, Cannabinoid hyperemesis syndrome; CVS, cyclic vomiting syndrome.
From Zhu JW, Gonsalves CL, Issenman RM, Kam AJ. Diagnosis and acute management of adolescent cannabinoid hyperemesis syndrome: a systematic review. *J Adolesc Health*. 2021;68:246–254, Table 1, p. 248.

CLINICAL MANIFESTATIONS

In addition to the desired effects of elation and euphoria, marijuana may cause impairment of short-term memory, poor performance of tasks requiring divided attention (e.g., those involved in driving), loss of critical judgment, decreased coordination, and distortion of time perception (Table 157.9). Visual hallucinations and perceived body distortions occur rarely, but "flashbacks" or recall of frightening hallucinations experienced under marijuana's influence may occur, usually during stress or with fever.

Smoking marijuana for a minimum of 4 days/week for 6 months appears to result in dose-related suppression of plasma testosterone levels and spermatogenesis, prompting concern about the potential deleterious effect of smoking marijuana before completion of pubertal growth and development. There is an antiemetic effect of oral THC or smoked marijuana, often followed by appetite stimulation, which is the basis of the substance's use in patients receiving cancer chemotherapy.

An **amotivational syndrome** has been described in long-term marijuana users who lose interest in age-appropriate behavior; proof of the causative relationship remains equivocal. Chronic use is associated with increased anxiety and depression, learning problems, poor job performance, hyperemesis, and respiratory problems such as pharyngitis, sinusitis, bronchitis, and asthma (see Table 157.9).

Cannabinoid hyperemesis syndrome (CHS) is characterized by recurrent episodes of vomiting associated with abdominal pain and nausea; patients often find relief by taking a hot shower or bath (Table 157.10). Cannabis use typically has been chronic (>1-2 year) and frequent (multiple times per week). There is considerable similarities between CHS and cyclic vomiting syndrome (see Chapter 390). Treatment of CHS includes stopping marijuana use, antiemetics, and topical capsaicin.

The increased THC content of marijuana of 5- to 15-fold compared to that of the 1970s is related to the observation of a **withdrawal syndrome** occurring 24-48 hours after discontinuing the substance. Heavy users experience malaise, irritability, agitation, insomnia, substance craving, shakiness, diaphoresis, night sweats, and GI disturbance. The symptoms peak by the fourth day and resolve in 10-14 days. Certain substances may interact with marijuana to potentiate sedation (alcohol, diazepam) and stimulation (cocaine, amphetamines) or may be antagonistic (propranolol, phenytoin).

Behavioral interventions, including **cognitive-behavioral therapy (CBT)** and motivational incentives, have shown to be effective in treating marijuana dependency.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

157.4 Inhalants

Cora Collette Breuner

Inhalants, found in many common household products, comprise a diverse group of volatile substances whose vapors can be inhaled to produce psychoactive effects. The practice of inhalation is popular among younger adolescents and decreases with increasing age. Young adolescents are attracted to these substances because of their rapid action, easy availability, and low cost. Products that are abused as inhalants include *volatile solvents* (paint thinners, glue, e-cigarette solvents known as "dripping," toluene, acetone, refrigerants, gasoline, cleaning fluids, correction fluids), *aerosols* (spray paint, nitrous oxide, hair spray), *gases* (propane tanks, lighter fluid), *nitrites* ("poppers" or "video head cleaner"), and *propellants* used in whipped cream dispensers. The most popular inhalants among young adolescents are glue, shoe polish, and spray paint. The various products contain a wide range of chemicals with serious adverse health effects (Table 157.11). **Huffing**, the practice of inhaling fumes, can be accomplished using a paper bag containing a chemical-soaked cloth; spraying aerosols directly into the nose/mouth; or using a balloon, plastic bag, or soda can filled with fumes. The percentage of adolescents using inhalants has remained stable, with 5.8% of high school students reporting having ever used inhalants. Eighth and ninth graders report highest use, suggesting targeted prevention strategies for this age-group.

CLINICAL MANIFESTATIONS

The major effects of inhalants are psychoactive (Table 157.12). The intoxication lasts only a few minutes, so a typical user will huff repeatedly over an extended period (hours) to maintain the high. The immediate effects of inhalants are similar to alcohol: euphoria, slurred speech, decreased coordination, and dizziness. **Toluene**, the main ingredient in model airplane glue and some rubber cements, causes relaxation and pleasant hallucinations for up to 2 hours. Euphoria is followed by violent excitement; coma may result from prolonged or rapid inhalation. **Volatile nitrites**, such as amyl nitrite, butyl nitrite, and related compounds marketed as room deodorizers, are used as euphoriants, enhancers of musical appreciation, and sexual enhancements among older adolescents and young adults. They may result in headaches, syncope, and lightheadedness; profound hypotension and cutaneous flushing followed by vasoconstriction and tachycardia; transiently inverted T waves and depressed ST segments on electrocardiography; methemoglobinemia; increased bronchial irritation;

Table 157.11 Hazards of Chemicals Found in Commonly Used Inhalants

Amyl nitrite, butyl nitrite ("poppers," "video head cleaner"): sudden sniffing death syndrome, suppressed immunologic function, injury to red blood cells (interfering with oxygen supply to vital tissues)

Benzene (found in gasoline): bone marrow injury, impaired immunologic function, increased risk of leukemia, reproductive system toxicity

Butane, propane (found in lighter fluid, hair and paint sprays): sudden sniffing death syndrome via cardiac effects, serious burn injuries (because of flammability)

Freon (used as a refrigerant and aerosol propellant): sudden sniffing death syndrome, respiratory obstruction and death (from sudden cooling/cold injury to airways), liver damage

Methylene chloride (found in paint thinners and removers, degreasers): reduction of oxygen-carrying of blood, changes to the heart muscle and heartbeat

Nitrous oxide ("laughing gas, Whippits, i.e., whipped cream dispensers), **hexane**: death from lack of oxygen to the brain, altered perception and motor coordination, loss of sensation, limb spasms, blackouts caused by blood pressure changes, depression of heart muscle functioning; vitamin B_{12} deficiency

Toluene (found in gasoline, paint thinners and removers, correction fluid): brain damage (loss of brain tissue mass, impaired cognition, gait disturbance, loss of coordination, loss of equilibrium, limb spasms, hearing and vision loss), liver and kidney damage

Trichloroethylene (found in spot removers, degreasers): sudden sniffing death syndrome, cirrhosis of the liver, reproductive complications, hearing and vision damage

Table 157.12 Stages in Symptom Development After Use of Inhalants

STAGE	SYMPTOMS
1: Excitatory	Euphoria, excitation, exhilaration, dizziness, hallucinations, sneezing, coughing, excess salivation, intolerance to light, nausea and vomiting, flushed skin and bizarre behavior
2: Early CNS depression	Confusion, disorientation, dullness, loss of self-control, ringing or buzzing in the head, blurred or double vision, cramps, headache, insensitivity to pain, and pallor or paleness
3: Medium CNS depression	Drowsiness, muscular incoordination, slurred speech, depressed reflexes, and nystagmus or rapid involuntary oscillation of the eyeballs
4: Late CNS depression	Unconsciousness that may be accompanied by bizarre dreams, epileptiform seizures, and EEG changes

CNS, Central nervous system; EEG, electroencephalogram.
From Harris D. Volatile substance use. *Arch Dis Child Educ Pract Ed.* 2006;91:ep93–ep100.

Table 157.13 Documented Clinical Presentations of Acute and Chronic Volatile Substance Use

Ventricular fibrillation	Muscle weakness
Asystolic cardiac arrest	Abdominal pain
Myocardial infarction	Cough
Ataxia	Aspiration pneumonia
Agitation	Chemical pneumonitis
Limb and trunk incoordination	Coma
Tremor	Visual and auditory hallucinations
Visual loss	Acute delusions
Tinnitus	Nausea and vomiting
Dysarthria	Pulmonary edema
Vertigo	Photophobia
Hyperreflexia	Rash
Acute confusional state	Jaundice
Conjunctivitis	Anorexia
Acute paranoia	Slurred speech
Depression	Diarrhea
Oral and nasal mucosal ulceration	Weight loss
Halitosis	Epistaxis
Convulsions/fits	Rhinitis
Headache	Cerebral edema
Peripheral neuropathy	Visual loss
Methemoglobinemia	Burns
Acute trauma	Renal tubular acidosis

and increased intraocular pressure. There may be dermatologic findings, including perianal/perioral dermatitis ("huffer rash"), frostbite, and contact dermatitis, as well as epistaxis, nasal ulcers, and conjunctivitis.

COMPLICATIONS

Model airplane glue is responsible for a wide range of complications related to chemical toxicity, to the method of administration (in plastic bags, with resultant suffocation), and to the dangerous setting in which the inhalation occurs (roof tops). Common neuromuscular changes reported in chronic inhalant users include difficulty coordinating movement, gait disorders, muscle tremors, and spasticity, particularly in the legs (Table 157.13). Chronic use may cause pulmonary hypertension, restrictive lung defects or reduced diffusion capacity, peripheral neuropathy, hematuria, tubular acidosis, and possibly cerebral and cerebellar atrophy. Chronic inhalant use has long been linked to widespread brain damage and cognitive abnormalities that can range from mild impairment (poor memory, decreased learning ability) to severe dementia. High-frequency inhalant users were significantly more likely than moderate- and low-frequency users to experience adverse consequences of inhalant intoxication, such as behavioral, language, and memory problems. Certain risky behaviors and consequences, such as engaging in unprotected sex or fighting while high on inhalants, were dramatically more common among high-frequency than low-frequency inhalant users. Death in the acute phase may result from cerebral or pulmonary edema or myocardial involvement (see Table 157.13).

DIAGNOSIS

Diagnosis of inhalant abuse is difficult because of the ubiquitous nature of the products and decreased parental awareness of the dangers. In the primary care setting, providers need to ask parents if they have witnessed any unusual behaviors in their teen; noticed high-risk products in the teen's bedroom; seen paint on the teen's hands, nose, or mouth; or found paint- or chemical-coated rags. Complete blood count, coagulation studies, and hepatic and renal function studies may identify the complications. In extreme intoxication, a user may manifest symptoms of restlessness, general muscle weakness, dysarthria, nystagmus, disruptive behavior, and occasionally hallucinations. Toluene is excreted rapidly in the urine as hippuric acid, with the residual detectable in the serum by gas chromatography.

TREATMENT

Treatment is generally supportive and directed toward control of arrhythmia and stabilization of respirations and circulation. Withdrawal symptoms do not usually occur.

See Chapter 450.

157.6 Hallucinogens

Cora Collette Breuner

Several naturally occurring and synthetic substances are used by adolescents for their hallucinogenic properties. They have chemical structures similar to neurotransmitters such as serotonin, but their exact mechanism of action remains unclear. Lysergic acid diethylamide **(LSD)**, methylenedioxymethamphetamine **(ecstasy**, **MDMA)**, and hallucinogenic magic mushrooms **(psilocybins)** are the most commonly reported hallucinogens used. Peyote **(mescaline)** derived from a cactus flower is chemically related to MDMA. **Ayahuasca** is another plant-derived hallucinogen found in South America whose active agents are N,N-dimethyltryptamine **(DMT)** and harmala alkaloids, which act as a monoamine oxidase inhibitor. Another hallucinatory agent is derived from a poisonous toad *(Bufo alvarius),* native to the Sonoran Desert, which produces **5-MeO-DMT** in its venom gland. 251-NBOMe **(N-Bomb)** is a designer substance that interacts with the 5HT-2a receptor and has sympathomimetic and hallucinogenic properties (Table 157.14).

LYSERGIC ACID DIETHYLAMIDE

LSD (acid, big "d," blotters) is a very potent hallucinogen that is made from lysergic acid found in ergot, a fungus that grows on rye and other grains. Its high potency allows effective doses to be applied to absorbent paper, or it can be taken as a liquid or a tablet. The onset of action can be 30-60 minutes, and it peaks at 2-4 hours. By 10-12 hours, individuals return to the preingestion state. Among U.S. 12th graders, 4% report trying LSD at least once.

Clinical Manifestations

The effects of LSD can be divided into three categories: somatic (physical effects), perceptual (altered changes in vision and hearing), and psychic (changes in sensorium). The common somatic symptoms are dizziness, dilated pupils, nausea, flushing, elevated temperature, and tachycardia. The sensation of *synesthesia,* or "seeing" smells and "hearing" colors, as well as major distortions of time and self, have been reported with high doses of LSD. Delusional ideation, body distortion, and suspiciousness to the point of toxic psychosis are the more serious of the psychic symptoms. LSD is not considered to be an addictive substance because it does not typically produce substance-seeking behavior.

Treatment

An individual is considered to have a "bad trip" when the sensory experiences cause the user to become terrified or panicked. These episodes should be treated by removing the individual from the aggravating situation and placing them in a quiet room with a calming friend. In situations of extreme agitation or seizures, use of benzodiazepines may be warranted. "Flashbacks," or LSD-induced states after the drug has worn off, and tolerance to the effects of the drug are additional complications of its use.

METHYLENEDIOXYMETHAMPHETAMINE

MDMA ("X," ecstasy, Molly), a phenylisopropylamine hallucinogen, is a synthetic compound similar to hallucinogenic cactus-derived mescaline and the stimulant methamphetamine. Like other hallucinogens, this substance is proposed to interact with serotoninergic neurons in the CNS. It is the preferred substance at "raves," all-night dance parties, and is also known as one of the "club substances" along with γ-hydroxybutyrate (GHB) and ketamine. Nationwide, the prevalence of having ever used MDMA was 8.4% of college students; 12th-grade lifetime use was 2.8% in 2021.

Clinical Manifestations

Euphoria, a heightened sensual awareness, and increased psychic and emotional energy are acute effects. Compared to other hallucinogens, MDMA is less likely to produce emotional lability, depersonalization, and disturbances of thought. Nausea, jaw clenching, teeth grinding, and blurred vision are somatic symptoms, whereas anxiety, panic attacks, and psychosis are the adverse psychiatric outcomes. A few deaths have been reported after ingestion of the substance. In high doses, MDMA can interfere with the body's ability to regulate temperature. The resultant hyperthermia in association with vigorous dancing at a "rave" has resulted in severe liver, kidney, and cardiovascular system failure and death. No specific treatments are recommended for acute toxicity.

Chronic MDMA use can lead to changes in brain function, affecting cognitive tasks and memory. These symptoms may occur because of MDMA's effects on neurons that secrete serotonin as a neurotransmitter. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain. A high rate of dependence has been found among MDMA users. MDMA exposure may be associated with long-term neurotoxicity and damage to serotonin-containing neurons. In nonhuman primates, exposure to MDMA for only 4 days caused damage to serotonin nerve terminals that was evident 6-7 years later. There are no specific pharmacologic treatments for MDMA addiction. Substance use recovery groups are recommended.

PHENCYCLIDINE

Phencyclidine **(PCP)** (Sernyl, angel dust, hog, peace pill, sheets) is an arylcyclohexalamine whose popularity is related in part to its ease of synthesis in home laboratories. One of the by-products of home synthesis can cause cramps, diarrhea, and hematemesis. It is a "dissociative substance" that produces feelings of detachment from the surrounding environment and self. The substance is thought to potentiate adrenergic effects by inhibiting neuronal reuptake of catecholamines. PCP is available as a tablet, liquid, or powder, which may be used alone or sprinkled on cigarettes (joints). The powders and tablets generally contain 2-6 mg of PCP, whereas joints average 1 mg for every 150 mg of tobacco leaves, or approximately 30-50 mg per joint. The prevalence of PCP use (a hallucinogenic substance) among U.S. 12th graders is approximately 1%.

Clinical Manifestations

The clinical manifestations are dose related and produce alterations of perception, behavior, and autonomic functions. Euphoria, nystagmus, ataxia, and emotional lability occur within 2-3 minutes after smoking 1-5 mg and last for 4-6 hours. At these low doses the user is likely to experience shallow breathing, flushing, generalized numbness of extremities, and loss of motor coordination. Hallucinations may involve bizarre distortions of body image that often precipitate panic reactions. With doses of 5-15 mg, a toxic psychosis may occur, with disorientation, hypersalivation, and abusive language lasting for >1 hour. Hypotension, generalized seizures, and cardiac arrhythmias typically occur with plasma concentrations of 40-200 mg/dL. Death has been reported during psychotic delirium from hypertension, hypotension, hypothermia, seizures, and trauma. The coma of PCP may be distinguished from that of the opiates by the absence of respiratory depression; the presence of muscle rigidity, hyperreflexia, and nystagmus; and lack of response to naloxone. PCP psychosis may be difficult to distinguish from schizophrenia. In the absence of a history of use, the diagnosis depends on urinalysis.

Treatment

Management of the PCP-intoxicated patient includes placement in a darkened, quiet room on a floor pad, safe from injury. Acute alcohol intoxication may also be present. For recent oral ingestion, gastric absorption is poor, and induction of emesis or gastric lavage is useful. Diazepam, in a dose of 5-10 mg orally or 2-5 mg intravenously, may

be helpful if the patient is agitated and not comatose. Rapid excretion of the substance is promoted by acidification of the urine. Supportive therapy of the comatose patient is indicated with particular attention to hydration, which may be compromised by PCP-induced diuresis. Inpatient and/or behavioral treatments can be helpful for chronic PCP users.

157.7 Cocaine

Cora Collette Breuner

Cocaine, an alkaloid extracted from the leaves of the South American *Erythroxylum coca*, is supplied as the hydrochloride salt in crystalline form. With **snorting**, it is rapidly absorbed into the bloodstream from the nasal mucosa, detoxified by the liver, and excreted in the urine as benzoylecgonine. Smoking the cocaine alkaloid **(freebasing)** involves inhaling the cocaine vapors in pipes or cigarettes mixed with tobacco

or marijuana. Accidental burns are potential complications of this practice. With **crack** cocaine, the crystallized rock form, the smoker feels "high" in <10 seconds. The risk of addiction with this method is higher and more rapidly progressive than from snorting cocaine. Tolerance develops, and the user must increase the dose or change the route of administration, or both, to achieve the same effect. To sustain the high, cocaine users repeatedly use cocaine in short periods known as "binges." Substance dealers often place cocaine in plastic bags or condoms and swallow these containers during transport. Rupture of a container produces a sympathomimetic crisis (see Table 157.4). Cocaine use disorder among U.S. high school students has decreased in the last decade, with 2.5% of 12th graders having tried the substance (any route) at least once.

CLINICAL MANIFESTATIONS

Cocaine is a strong CNS stimulant that increases dopamine levels by preventing reuptake. Cocaine produces euphoria, increased motor activity, decreased fatigability, and mental alertness. Its sympathomimetic properties are responsible for pupillary dilation, tachycardia, hypertension, and hyperthermia. Snorting cocaine chronically results in loss of sense of smell, nosebleeds, and chronic rhinorrhea. Injecting cocaine increases risk for HIV infection. Chronic users experience anxiety, irritability, and sometimes paranoid psychosis. Lethal effects are possible, especially when cocaine is used in combination with other substances, such as heroin, in an injectable form known as a "speedball." When taken with alcohol, cocaine is metabolized by the liver to produce cocaethylene, a substance that enhances the euphoria and is associated with a greater risk of sudden death than with cocaine alone. Pregnant adolescents who use cocaine place their fetus at risk of premature delivery, complications of low birthweight, and possibly developmental disorders.

TREATMENT

There are no FDA-approved medications for treatment of cocaine addiction. CBT has been shown to be effective when provided in combination with additional services and social support. Oral sustained-release dexamphetamine has been shown to be partially effective in adults with cocaine dependence.

157.8 Amphetamines

Cora Collette Breuner

Methamphetamine, commonly known as **meth**, is a nervous system stimulant and Schedule II substance with a high potential for abuse. Most of the methamphetamine currently used is produced in illegal laboratories. It is a white, odorless, bitter-tasting powder that is particularly popular among adolescents and young adults because of its potency and ease of absorption. It can be ingested orally, smoked, needle-injected, or absorbed across mucous membranes. Amphetamines have multiple CNS effects, including release of neurotransmitters and an indirect catecholamine agonist effect. Approximately 0.6% of 12th graders reported using methamphetamine at least once.

CLINICAL MANIFESTATIONS

Methamphetamine rapidly increases the release and blocks the reuptake of dopamine, a powerful "feel good" neurotransmitter (Table 157.15). The effects of amphetamines can be dose related. In small amounts, amphetamine effects resemble other stimulants: increased physical activity, rapid and/or irregular heart rate, increased blood pressure, and decreased appetite. High doses produce slowing of cardiac conduction in the face of ventricular irritability. Hypertensive and hyperpyrexic episodes can occur, as can seizures (see Table 157.4). Binging may result in the development of psychotic ideation with the potential for sudden violence. Cerebrovascular damage, psychosis, severe receding of the gums with tooth decay, and infection with HIV and hepatitides B and C can result from long-term use. A withdrawal syndrome is associated with amphetamine use, with early, intermediate, and late phases (see Table 157.15). The early phase is characterized as a "crash" phase with depression, agitation, fatigue, and desire for more of the substance. Loss of physical and mental energy, limited interest in the environment, and anhedonia mark the intermediate phase. In the final phase, substance craving returns, often triggered by particular situations or objects.

TREATMENT

Acute agitation and delusional behaviors can be treated with haloperidol or droperidol. Phenothiazines are contraindicated and may cause

Table 157.15 Signs and Symptoms of Intoxication and Withdrawal

	OPIATES	AMPHETAMINES/COCAINE	BENZODIAZEPINES
INTOXICATION			
Behavior	Apathy and sedation; disinhibition; psychomotor retardation; impaired attention and judgment	Euphoria and sensation of increased energy; hypervigilance; grandiosity, aggression, argumentative; labile mood; repetitive stereotyped behaviors; hallucinations, usually with intact orientation; paranoid ideation; interference with personal functioning	Euphoria; apathy and sedation; abusiveness or aggression; labile mood; impaired attention; anterograde amnesia; impaired psychomotor performance; interference with personal functioning
Signs	Drowsiness; slurred speech; pupillary constriction (except anoxia from severe overdose—dilation); decreased level of consciousness	Dilated pupils; tachycardia (occasionally bradycardia, cardiac arrhythmias); hypertension; nausea/vomiting; sweating and chills; evidence of weight loss; dilated pupils; chest pain; convulsions	Unsteady gait; difficulty in standing; slurred speech; nystagmus; decreased level consciousness; erythematous skin lesions or blisters
Overdose	Respiratory depression; hypothermia	Sympathomimetic symptoms	Hypotension; hyperthermia; depression of gag reflex; coma
Withdrawal	Craving to use; lacrimation; yawning; rhinorrhea/sneezing; muscle aches or cramps; abdominal cramps; nausea/vomiting/diarrhea; sweating; dilated pupils; anorexia; irritability; tremor; piloerection/chills; restlessness; disturbed sleep	Dysphoric mood (sadness/anhedonia); lethargy and fatigue; psychomotor retardation or agitation; craving; increased appetite; insomnia or hypersomnia; bizarre or unpleasant dreams	Tremor of tongue, eyelids, or outstretched hands; nausea or vomiting; tachycardia; postural hypotension; psychomotor agitation; headache; insomnia; malaise or weakness; transient visual, tactile, or auditory hallucinations or illusions; paranoid ideation; grand mal convulsions

From Haber PS, Demirkol A, Lange K, et al. Management of injecting substance users admitted to hospital. *Lancet.* 2009;374:1284–1292.

a rapid drop in blood pressure or seizure activity. Other supportive treatment consists of a cooling blanket for hyperthermia and treatment of the hypertension and arrhythmias, which may respond to sedation with lorazepam or diazepam. For the chronic user, comprehensive CBT interventions have been demonstrated as effective treatment options.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

157.9 Stimulant Use and Diversion

Cora Collette Breuner

In MTF 2021, 4.6% of 12th graders reported using OTC diet pills in their lifetime and 1.1% in the past 30 days. These include nonprescription stimulants of two general types: pseudoamphetamines, usually sold by internet/mail order, and OTC stimulants, primarily diet and "stay-awake" pills. These substances usually contain caffeine, ephedrine, and/or phenylpropanolamine.

The *misuse* of a stimulant medication, defined as taking a stimulant not prescribed by a healthcare provider and not in accordance with healthcare provider guidance, has been growing over the past two decades, with an increase in prevalence rates of nonprescription stimulant use among both adolescents and young adults in the past 10 years. Nonprescription use of methylphenidate **(MPH)** in 2000 was 1.2%, increasing to 2% for MPH and 7.5% for nonprescription mixed amphetamine salts **(AMPs)** in 2015.

The majority of nonprescription stimulant users reported obtaining the substances by **diversion**, a process for obtaining the substance from peers. Diversion occurs quite often and can begin in childhood, adolescence, or young adulthood. Lifetime rates of diversion ranged from 16–29% of students with stimulant prescriptions. One survey reported that 23.3% of middle and high school students taking prescribed stimulants had been solicited to divert their medication to others at a rate that increased from middle to high school. It has been shown that 54% of college students prescribed stimulants for attention-deficit/hyperactivity disorder (ADHD) had been approached to divert their medication.

In U.S. college students, nonprescription use of stimulants is more prevalent among particular subgroups (males; members of fraternities/sororities; with lower grade point averages; more likely to use alcohol, cigarettes, marijuana, MDMA, or cocaine) and types of colleges (northeastern region, with more competitive admission standards). Lifetime prevalence of nonprescription stimulant use was 6.9% and past-month prevalence 2.1%. According to a survey of 334 ADHD-diagnosed college students taking prescription stimulants, 25% misused their own prescription medications. Scholastic pressures, including the need to succeed academically, and persistent social and financial demands place many students at an increased risk for misuse of various substances, especially at the end of school terms. A web-based survey of medical and health profession students found that the most common reason for nonprescription stimulant use was to focus and concentrate during studying.

CLINICAL MANIFESTATIONS

Misuse of stimulants is associated with psychosis, seizures, dysrhythmias, myocardial infarction, cardiomyopathy, and even sudden death. Intentional misuse of MPH or AMPs in combination with other substances leads to adverse medical consequences. Importantly, 14% of the emergency department (ED) visits for stimulant use were associated with cardiovascular (CV) events. Psychosis includes visual hallucinations, delusions, anorexia, flattening of affect, and insomnia mediated by dopaminergic excess. The CV effects include hypertension, arrhythmias, tachycardia, cardiomyopathy, cardiac dysrhythmias, necrotizing vasculitis, and CV accidents. Case reports include serious CV adverse drug reactions (ADRs), sudden death, and psychiatric disorders. Many patients report sleep difficulties (72%), irritability (62%), dizziness and lightheadedness (35%), headaches (33%), stomachaches (33%), and sadness (25%). Other health risks include loss of appetite, weight loss, and nervousness. Many users are involved in heavy episodic alcohol use while using MPH or AMPs. Most users of MPH or AMPs are unaware of these adverse effects and predominantly "feel good" about taking these medications.

Despite reports that MPH misuse is a healthcare issue, >82% of primary care physicians did not suspect misuse of prescribed ADHD medication in one report, and <1% thought that their patients were diverting prescribed ADHD medication. Improved monitoring for malingering and patient misuse may assist stopping diversion of these medications. An ADHD diagnosis should be confirmed in those requesting ADHD medication, and they should be screened for use of other substances.

TREATMENT

Treatment for nonprescription stimulant overdose is similar as that for amphetamine overdose. Haloperidol or droperidol is recommended for acute agitation and delusional behaviors. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Hyperthermia may require use of a cooling blanket, and sedation with a benzodiazepine is recommended for treatment of the hypertension and arrhythmias. In those with chronic use, inpatient or outpatient substance use interventions using CBT have been shown to be the most effective treatment option.

Monitoring of the diversion and misuse of pharmaceutical stimulants must be a priority. More data need to be obtained on the prevalence, patterns, and harmful effects in adolescents and young adults.

157.10 Opiates/Opioids

Cora Collette Breuner

Opiates refers to natural derived drugs (morphine, codeine, opium), whereas opioids refers to natural, semisynthetic, and synthetic agents. **Heroin** is a highly addictive synthetic opiate substance made from a naturally occurring substance **(morphine)** in the opium poppy plant. It is a white or brown powder that can be injected (intravenously or subcutaneously), snorted/sniffed, or smoked. Intravenous (IV) injection produces an immediate effect, whereas effects from the subcutaneous route occur in minutes, and from snorting, in 30 minutes. After injection, heroin crosses the blood-brain barrier, is converted to morphine, and binds to opiate receptors. Tolerance develops to the euphoric effect, and the chronic user must take more heroin to achieve the same intense effect. Heroin use among U.S. teens peaked in the mid-1990s but is resurgent in some suburban communities, as is the use of **prescription opioids** found in the home. Nationwide, 2.9% of high school students report having tried heroin at least once. **Fentanyl** is a more potent opiate and is responsible for many opiate overdoses. Other opioid drugs are noted in Table 157.16. Synthetic opioid fentanyl-derived analogues or nitrazene drugs (novel potent opioids:NPO) are much more potent than fentanyl and require higher and multiple doses of naloxone to reverse an overdose. NPOs include brorphine, isotonitazene, metonitazene, and N-piperidinyl etonitazene. Fentanyl is often illicitly manufactured and may be mixed with other substances, including xylazine, a nonopioid sedative. Xylazine, also known as *tranq*, is a veterinary drug that in humans produces central nervous system and respiratory depression, as well as bradycardia and hypotension. Xylazine also produces poorly healing cutaneous ulcerations at the site of injection and at distal sites. In 2022, fentanyl-xylazine combinations have been responsible for a significant number of overdose deaths; there is no antidote for xylazine.

CLINICAL MANIFESTATIONS

The clinical manifestations are determined by the purity of the heroin or its adulterants, combined with the route of administration (oral vs injection). The immediate effects include euphoria, diminution in pain, flushing of the skin, and pinpoint pupils (see Table 157.15). An effect on the hypothalamus is suggested by the lowering of body temperature. The most common dermatologic lesions are the "tracks," the hypertrophic linear scars that follow the course of large veins. Smaller, discrete peripheral scars, resembling healed insect bites, may be easily overlooked. The adolescent who injects heroin subcutaneously may have fat necrosis, lipodystrophy, and atrophy over portions

Table 157.16 Types and Actions of the Most Commonly Prescribed and Used Opioids

	TYPE OF OPIOID	ACTION ON OPIOID RECEPTOR
Alfentanil	Fully synthetic	Agonist of μ-receptors
Buprenorphine	Semisynthetic	Partial agonist of μ-receptors and NOP receptors; antagonist of κ-receptors
Codeine	Natural	Weak agonist of μ-receptors
Diamorphine (heroin)	Semisynthetic	Agonist of μ-receptors, δ-receptors, and κ-receptors; predominant binding to μ-receptors
Dihydrocodeine	Semisynthetic	Agonist of μ-receptors
Fentanyl	Fully synthetic	Agonist of μ-receptors, δ-receptors, and κ-receptors; predominant binding to μ-receptors
Hydromorphone	Semisynthetic	Agonist of μ-receptors and κ-receptors; predominant binding to μ-receptors
Methadone	Fully synthetic	Agonist of μ-receptors
Morphine	Natural	Agonist of μ-receptors, δ-receptors, and κ-receptors; predominant binding to μ-receptors
Oxycodone	Semisynthetic	Weak agonist of μ-receptors, δ-receptors, and κ-receptors; predominant binding to μ-receptors
Pentazocine	Fully synthetic	Partial agonist of δ-receptors and κ-receptors; antagonist of μ-receptors
Pethidine (meperidine)	Fully synthetic	Agonist of κ-receptors
Tramadol	Fully synthetic	Weak agonist of μ-receptors

Information presented is from the DrugBank and PubChem databases.
NOP, Nociceptin opioid peptide.

of the extremities. Attempts to conceal these stigmata may include amateur tattoos in unusual sites. Skin abscesses secondary to unsterile techniques of substance administration are usually found. There is a loss of libido; the mechanism is unknown. The chronic heroin user may resort to prostitution to support the habit, thus increasing the risk of sexually transmitted diseases (including HIV), pregnancy, and other infectious diseases. Constipation results from decreased smooth muscle propulsive contractions and increased anal sphincter tone. The absence of sterile technique in injection may lead to cerebral microabscesses or endocarditis, usually caused by *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Abnormal serologic reactions are also common, including false-positive Venereal Disease Research Laboratories and latex fixation tests. Infectious complications are usually not seen with oral prescription opioid use unless the pills are dissolved and injected.

WITHDRAWAL

After ≥8 hours without heroin, the addicted individual undergoes a series of physiologic disturbances over 24-36 hours, referred to collectively as "withdrawal" or **abstinence syndrome** (see Table 157.15). The earliest sign is yawning, followed by lacrimation, mydriasis, restlessness, insomnia, "goose flesh," cramping of the voluntary musculature, bone pain, hyperactive bowel sounds and diarrhea, tachycardia, and systolic hypertension. Although the administration of **methadone** is the most common method of detoxification, **buprenorphine**, an opiate agonist-antagonist, is available for detoxification and maintenance treatment of heroin and other opiates. Buprenorphine has the advantage of offering less risk of addiction, overdose, and withdrawal effects and can be dispensed in the privacy of a physician's office. Combined with behavioral interventions, it has a greater success rate of detoxification. A combination substance, buprenorphine plus naloxone, has been formulated to minimize use during detoxification. Clonidine and tramadol have also been used to manage opioid withdrawal.

Substances used to treat **opioid use disorder**, a chronic relapsing problem, traditionally include methadone maintenance and buprenorphine. Use-deterrent opioid pill formulations (when pain control requires an opioid) include pills resistant to crushing that form a viscous gel when dissolved or pills with a sequestered opioid antagonist (naltrexone).

OVERDOSE SYNDROME

Overdose syndrome is an acute reaction after administration of an opiate. It is the leading cause of death among substance users. Many opiate overdoses are complicated by polydrug use (Fig. 157.4). The clinical signs include stupor or coma, seizures, miotic pupils (unless severe anoxia has occurred), respiratory depression, cyanosis, and pulmonary edema. The differential diagnosis includes CNS trauma, diabetic coma, hepatic (and other) encephalopathy, Reye syndrome, and overdose of alcohol, barbiturates, PCP, or methadone. Diagnosis of opiate toxicity is facilitated by IV administration of naloxone 0.1 mg/kg, not to exceed 2 mg, which causes dilation of pupils constricted by the opiate. Diagnosis is confirmed by the finding of opiates in the urine and/or serum.

TREATMENT

Treatment of acute heroin overdose consists of maintaining adequate oxygenation and continued administration of **naloxone**, a pure opioid antagonist (see Chapter 94). It may be given intravenously, intramuscularly, subcutaneously, as a nasal spray, or by endotracheal tube. Naloxone has an ultra-rapid onset of action (1 minute) and duration of action of 20-60 minutes. Naloxone is often available in the field, carried by first responders. Take-home naloxone may also be given to substance users, their family, or friends; such programs have been effective in treating overdoses. If there is no response, other etiologies for the respiratory depression must be explored. Naloxone may have to be repeated if given by nasal route or continued for 24 hours if methadone, rather than shorter-acting heroin, has been taken. Higher and prolonged naloxone dosing is required for novel potent opioid overdoses. Admission to the intensive care unit is indicated for patients who require continuous naloxone infusions (rebound coma, respiratory depression) and for those with life-threatening arrhythmias, shock, and seizures.

157.11 Synthetic Cannabinoids

Cora Collette Breuner

Bath salts refers to a group of previously OTC, but now illicit, often home synthesized, substances containing one or more chemicals similar to **cathinone**, an amphetamine-like stimulant found in the khat

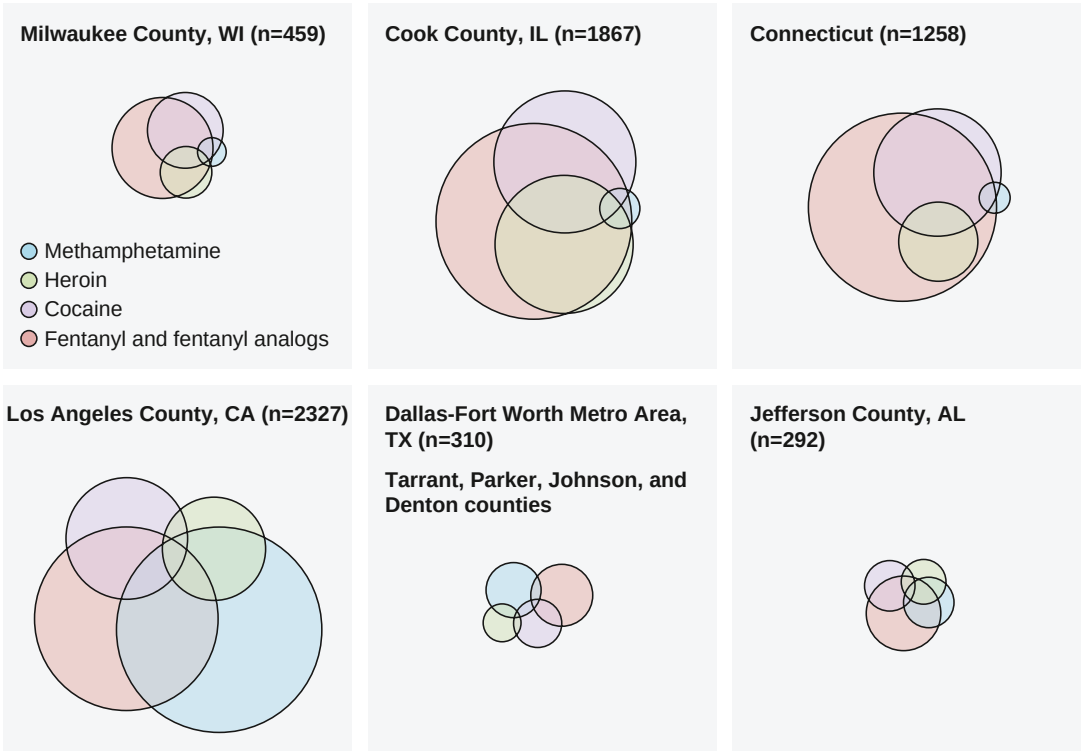

Fig. 157.4 Proportional drug combinations involved in fatal overdoses in U.S. jurisdictions with detailed medical examiner data available, 2020. Based on death investigations that were completed at the time of data request. Official counts by jurisdictions may differ as all investigations are completed. These areas were chosen to provide a country-wide view. *(From Humphreys K, Shover CL, Andrews CM, et al. Responding to the opioid crisis in North America and beyond: recommendations of the Stanford-Lancet commission. Lancet. 2022;399:555–604, Fig. 5.)*

plant. The bath salts, marketed under ever-changing brand names (e.g., Lunar Wave, Cloud Nine, Vanilla Sky), are sold online or in substance paraphernalia stores as a white or brown crystalline powder and can be ingested, inhaled, or injected. The most current information about teen use of bath salts is from the 2016 MTF survey of 8th, 10th, and 12th graders, who report use of 0.9%, 0.8%, and 0.8%, respectively. The synthetic cathinones found in bath salts include methylone, mephedrone, and 3,4-methylenedioxypyrovalerone (MDPV), all of which are chemically similar to amphetamines and MDMA (ecstasy).

CLINICAL MANIFESTATIONS

The chemicals in bath salts raise brain dopamine levels, causing the user to feel a surge of euphoria, with increased sociability and sex drive. In addition, the user may experience a surge in norepinephrine, causing reactions such as an elevated heart rate, chest pain, vasoconstriction, diaphoresis, hyperthermia, dilated pupils, seizures, arrhythmias, and high blood pressure. Users also experience psychiatric symptoms such as aggressive behavior, panic attacks, paranoia, psychosis, delirium, self-mutilation, and hallucinations caused by elevated serotonin levels. Intoxication from bath salts may cause **excited delirium syndrome**, which includes dehydration, rhabdomyolysis, and kidney failure.

TREATMENT

Treatment of overdose should be directed at specific complications but often includes benzodiazepines or propofol for agitation and other neuropsychiatric manifestations. The synthetic cathinones in bath salts are highly addictive, triggering intense cravings in those who consume them frequently. This may result in dependence, tolerance, and strong withdrawal symptoms, as seen in other highly addictive substances. The sale of two of the synthetic cathinones, mephedrone and MDPV, is illegal in the United States.

SYNTHETIC CANNABINOIDS (MARIJUANA)

Spice, K2, crazy clown, aroma, black mamba, blaze, dream, and funky monkey are some of the common street names for synthetic marijuana, which is a mixture of herbs or plant materials that have been sprayed with artificial chemicals similar to THC, the psychoactive ingredient in marijuana. One active group of chemicals is the **carboxamides**, which *are not detected* by standard assays to detect THC. In the United States the chemicals in "spice" are designated a Schedule I controlled substance (as is marijuana) by the Drug Enforcement Administration (DEA), thereby making it illegal to sell, buy, or possess them. Nonetheless, synthetic marijuana is the second most common illicit substance used by high school seniors. More than 10% of high school seniors used synthetic marijuana in the last year.

Synthetic marijuana is mainly used by smoking, or mixed with marijuana, or brewed as a tea for drinking. The chemicals in synthetic marijuana affect the same receptors as THC and produce similar effects as seen in cannabis use, such as relaxation, elevated mood, and altered perception. In addition, sympathomimetic symptoms are quite common and are the cause of significant toxicity. Symptoms of **intoxication** depend on the individual compounds in the community and include vomiting, tachycardia, hypertension, hyperthermia, confusion, extreme anxiety, profuse sweating, agitation, aggression, dysphoria, hallucinations, seizures, rhabdomyolysis, dystonia, unresponsiveness, confusion, catatonia, "zombie-like" behaviors, psychosis, coma, and myocardial ischemia. Some of the neuropsychiatric manifestations may last for 1-4 weeks and at times resemble autoimmune encephalitis syndromes. Patients often require psychopharmacology for agitation or frank psychosis. In response to legislation to ban the chemicals in OTC synthetic marijuana products, manufacturers alter and substitute the chemicals in the product, keeping it on the legal market and leaving teens particularly vulnerable to potential health effects.

Synthetic marijuana is not detected by standard toxicology screening but can be identified in specialized laboratories.

Chapter 158

The Breast

Cynthia M. Holland-Hall

Breast development is often the first visible sign of puberty in the adolescent female. Pediatric practitioners must be able to distinguish normal breast development, including normal variants, from pathologic breast disorders. Visual inspection of the breast tissue should routinely be a component of the adolescent's general physical examination. Breast development during puberty is described using the **Sexual Maturity Rating (SMR)** scale, progressing from SMR 1 to SMR 5 as the breast becomes more mature (see Chapter 150, Fig. 150.2).

FEMALE DISORDERS

See Chapter 588.

MALE DISORDERS

Pubertal gynecomastia, benign glandular proliferation in the male breast, occurs in up to 65% of healthy adolescent males (see Chapter 625). The incidence of gynecomastia has increased over the past 20 years, suggesting that changes in the endogenous or exogenous sex-steroid environment have occurred. It is thought that an imbalance of estrogen and androgen concentrations contributes, at least in part, to the development of gynecomastia. Elevations of insulin-like growth factor (IGF)-1 have also been demonstrated. The onset of physiologic gynecomastia typically is between 10 and 13 years, peaking at SMR 3-4. Careful physical examination is essential to distinguish between **true gynecomastia**, characterized by a discrete disk of palpable glandular tissue under the nipple-areolar complex, and **pseudogynecomastia**, characterized by more diffuse, bilateral adiposity of the anterior chest wall. Physiologic gynecomastia regresses spontaneously in up to 90% of adolescents within 18-24 months but may transition into lipomastia. Reassurance and continued observation are recommended in most patients; surgery may be indicated in severe or persistent cases. No medical therapies for gynecomastia have been approved for use in adolescents by the U.S. Food and Drug Administration. Small, noncontrolled trials of antiestrogens, such as tamoxifen, appear promising, but more evidence is needed. Conditions associated with nonphysiologic gynecomastia include endocrine disorders, liver disease, neoplasms, chronic disease, and trauma. It can also be seen as a late effect in childhood cancer survivors. Although dozens of medications are implicated as possible causes of gynecomastia, convincing evidence exists only for a few, including several antiandrogens and other exogenous hormones, isoniazid, antiretrovirals, and histamine-2 receptor blockers. Calcium channel blockers, isotretinoin, statins, certain antipsychotics, proton pump inhibitors, lavender, and tea tree oil may be causative. Among drugs of misuse, alcohol, opioids, and anabolic steroids may be associated with gynecomastia, but minimal evidence supports an association with marijuana or amphetamines.

Other breast pathology in males is uncommon. Benign masses such as neurofibromas, lipomas, and dermoid cysts have been reported in the male breast. Males with Klinefelter syndrome have an elevated risk of breast cancer (see Chapter 623), but this malignancy is otherwise exceedingly rare in adolescents.

Chapter 159

Menstruation-Related Disorders

Fareeda Haamid and Gina S. Sucato

See also Chapter 587.

At least 400 lifetime episodes of menstruation are predicted in those who menstruate, yet many adolescents consistently report stigma, inadequate health education, and hesitance to discuss their menses with trusted adults. Clinicians should normalize menstruation and avoid unnecessarily medicalizing this natural process. Menstrual disturbances, including delayed onset, irregularity, heavy flow, and pain, occur in 75% of adolescent females. For adolescents with minor variations from normal (Table 159.1), an explanation of symptoms and reassurance may be all that is needed. Severe dysmenorrhea or prolonged menstrual bleeding can be not only frightening but a cause of persistent morbidity requiring more intensive management, potentially including referral to a specialist in adolescent gynecology.

NORMAL MENSTRUATION

The average age of **menarche**, or first menses, was thought to vary according to ethnic origin and socioeconomic status (SES). A prospective U.S. study of nearly 1,100 diverse females demonstrated no correlation between SES and menarche yet a statistically significant correlation with SES and thelarche; lower SES was associated with earlier pubertal onset. There is often a close concordance of the age at menarche between mother and daughter, which suggests genetic factors are determinants in addition to individual factors such as weight, exercise level, and chronic medical conditions. The age of menarche has declined in countries and populations experiencing improved nutritional standards and other living conditions. In U.S. females, the average age of menarche, 12.5 years, has been relatively stable over the last few decades. Higher body mass index (BMI) is associated with earlier onset of menarche.

The onset of breast budding **(thelarche)** is the first sign of puberty in most females, though it has decreased worldwide by a mean of roughly 3 months per decade from 1977 to 2013. Menarche typically occurs within 2-3 years of thelarche during breast **sexual maturity rating** (**SMR**; i.e., Tanner stage) 4. Longer cycle lengths ranging between 21 and 45 days occur initially then periods gradually become more regular. However, for most adolescents, by 3 years postmenarche, menstrual cycle patterns are similar to adults, occurring every 21-35 days.

MENSTRUAL IRREGULARITIES

In young adolescents, many menstrual variations are explained by **anovulation** caused by immaturity of the hypothalamic-pituitary-ovarian

Table 159.1 Characteristics of Normal Menses*

Cycle length**	21-35 days 21-45 days during first 3 yr after menarche
Duration of menses	7 or fewer days
Blood flow	6 or fewer soaked menstrual products per day Infrequent overflow of menstrual cups

*Adolescents with two or more cycles outside this range or who skip their period for 3 consecutive months warrant evaluation.

**A cycle begins with the first day of one period and extends to the first day of the next.

axis governing the menstrual cycle. Significant deviations from normal should prompt a search for organic pathology in a logical and cost-effective manner. An accurate menstrual history is an important, but often lacking, first step toward a diagnosis. At menarche, all patients should be encouraged to track their periods.

A range of terms has previously been used to describe abnormal menstrual bleeding. Terms such as "menorrhagia and metrorrhagia" are imprecise, confusing, and not linked to any specific underlying pathology. **Abnormal uterine bleeding (AUB)** is the preferred term for uterine bleeding that is abnormal in regularity, volume, frequency, or duration. AUB is further specified by adding descriptive terms such as *heavy menstrual* bleeding or *intermenstrual* bleeding. A qualifier is added to categorize the etiology of abnormal bleeding. Of the nine categories, the three most relevant to adolescents are **ovulatory dysfunction** (AUB-**O**), previously referred to as *dysfunctional uterine bleeding* and discussed in Chapter 159.2; **coagulopathy** (AUB-**C**); and **not otherwise classified** (AUB-**N**).

In addition to a standard medical history noting hospitalizations, chronic illness, and medication and supplement use, a complete history for evaluating a patient with menstrual irregularity should include the timing of pubertal milestones, such as onset of pubic and axillary hair and breast development; a detailed patient menstrual history; age of menarche and overall menstrual pattern of mother and sisters; and a family history of gynecologic problems. The complete review of systems should elicit any changes in headache pattern or vision; the presence of galactorrhea; and any changes in skin, hair, or bowel patterns. Changes in diet, level of exercise, and sports participation are also important factors when generating a differential diagnosis. The patient should be interviewed alone, and the confidential history should assess substance use, consensual sexual activity, forced sexual behavior, abuse, and other psychosocial stressors.

Assessment of basic growth parameters should include weight, height, and BMI and a thorough review of the growth chart. Physical examination should document heart rate, blood pressure, SMR, signs of androgen excess, such as hirsutism or severe acne, and signs suggestive of an eating disorder (see Chapter 41), such as bradycardia, cachexia, lanugo, or knuckle calluses. A careful external genital examination should be performed. An internal pelvic examination is rarely necessary in the absence of sexual activity. Any internal exam being considered for young adolescents should be performed with proper equipment and technique by a clinician with expertise in this age-group. Transabdominal pelvic ultrasound can be a useful adjunct for evaluating anatomic abnormalities in the adolescent; when indicated, MRI can provide greater detail of pelvic anatomy.

Table 159.2 Causes of Primary or Secondary Amenorrhea

Pregnancy (regardless of history can cause primary or secondary amenorrhea)
Functional hypothalamic states (stress, weight loss, undernutrition, high levels of exercise, energy deficit even at normal weight)
Relative energy deficiency in sport (RED-S) (inadequate energy intake causing impaired physiologic function, including amenorrhea, bradycardia, and low bone density)
Eating disorders
Premature ovarian insufficiency (autoimmune, idiopathic, galactosemia, or secondary to radiation or chemotherapy)
Hypothalamic and/or pituitary damage (e.g., irradiation, tumor, traumatic brain injury, surgery, hemochromatosis, midline central nervous system defects such as septooptic dysplasia, autoimmune pituitary hypophysitis)
Thyroid disease (hyper- or hypo-; hypothyroidism more likely to be associated with increased bleeding)
Prolactinoma
Systemic disease (e.g., inflammatory bowel disease, cyanotic congenital heart disease, sickle cell disease, cystic fibrosis, celiac disease)
Hyperandrogenism (polycystic ovary syndrome, nonclassic congenital adrenal hyperplasia, adrenal tumor or dysfunction)
Drugs and medications (e.g., illicit drugs, atypical antipsychotics, hormones)
Turner syndrome (including mosaicism)

Table 159.3 Additional Causes of Primary Amenorrhea

Physiologic/constitutional delay
Anatomic abnormalities
Müllerian agenesis
Imperforate hymen
Transverse vaginal septum
Genetic disorders
46,XY disorders of sexual development (e.g., androgen insensitivity syndrome, 5α-reductase deficiency, 17α-hydroxylase deficiency)
Mixed gonadal dysgenesis (associated with various chromosome patterns)
Turner syndrome (resulting from 45,X or a variety of mosaic or other abnormal karyotypes)
Genetic hypogonadotropic hypogonadism (e.g., X-linked Kallmann syndrome)

159.1 Amenorrhea

Fareeda Haamid and Gina S. Sucato

Amenorrhea, the absence of menstruation, generally requires evaluation at age 15 years, or if there has been no menstruation within 3 years of the onset of puberty **(primary amenorrhea)**, or if there has been no menstruation for the length of three previous cycles in a postmenarchal patient **(secondary amenorrhea)**. However, the following caveats exist: lack of any pubertal signs by age 13 years in a female should prompt evaluation for pubertal delay; in sexually active patients, or those with other symptoms suggesting pathology, evaluation should be initiated without waiting for three missed cycles; in patients whose breast development started between age 8 and 9 years, observation for >3 years may be warranted in some cases, given data suggesting that the age of thelarche has decreased but the age of menarche has not. Conversely, expectant management with close follow-up can be considered in a patient whose history, physical examination showing some pubertal development, and family history suggest constitutional delay of puberty.

The differential diagnosis of amenorrhea is broad (Table 159.2) and requires a careful history and physical exam to guide any necessary diagnostic studies. Understanding the timing and tempo of the patient's pubertal milestones is key to the evaluation. The first step in the amenorrhea evaluation is to ascertain whether the patient has ever had any menstrual bleeding. Conditions that can interrupt the menstrual cycle can also prevent menarche; therefore some aspects of the evaluation of primary and secondary amenorrhea are identical. In females with primary amenorrhea, genetic and anatomic conditions must also be considered (Table 159.3).

HISTORY AND PHYSICAL EXAMINATION

Important historical elements include dietary intake, exercise level, and a thorough review of any ongoing symptoms, including fever, headache, vision changes, chronic respiratory or gastrointestinal (GI) complaints, bowel habit changes, galactorrhea, changes in hair or nails, excessive body hair, severe acne, unexplained musculoskeletal complaints, and changes in

vaginal discharge, which may decrease in females who are hypoestrogenic. Any underlying medical conditions and the adequacy of their control should be noted, as well as the presence of any renal or skeletal anomalies, some of which may have associated reproductive system anomalies. Clinicians should document medications, particularly those for psychiatric conditions. Family history of menarcheal age, eating disorders (see Chapter 41), and **polycystic ovary syndrome (PCOS**; see Chapter 589) should be elicited. A thorough social history is necessary, especially concerning the presence or absence of sexual activity or abuse (see Chapter 16.1).

Physical examination should begin with careful attention to growth chart trajectories. In addition to a search for undiagnosed systemic disease, clues to an eating disorder, thyroid disease, or hyperandrogenism should be sought. The exam should assess for BMI, orthostatic pulses, blood pressure, abnormal dentition, anosmia or hyposmia (suggestive of Kallmann syndrome; see Chapter 623.2), parotid enlargement, thyroid gland palpation, hepatosplenomegaly, abdominal mass, lymphadenopathy, and SMR (see Chapter 150). Skin examination should note any lanugo, dry or doughy skin, loss of hair from scalp or eyebrows, striae, acanthosis nigricans, or acne. Clinicians should assess for glandular breast tissue via palpation in patients with primary amenorrhea. The external genital exam should note SMR and appearance of the vagina, which should be pink and moist; thin, dry, reddened mucosa suggests estrogen deficiency. The clitoral width should be <1 cm. In the patient with primary amenorrhea, vaginal patency can be painlessly assessed using a slender saline-moistened swab and careful avoidance of the hymen. If physical assessment of the cervix and uterus is not tolerated, a transabdominal pelvic ultrasound is advisable in patients with primary amenorrhea, followed by MRI if more detail is needed.

LABORATORY STUDIES

A urine pregnancy test, serum prolactin levels, thyroid-stimulating hormone, and follicle-stimulating hormone (FSH) are reasonable to measure in all patients presenting with amenorrhea (Fig. 159.1). Elevation of FSH (>30 mIU/mL) in an amenorrheic female suggests ovarian insufficiency, and if confirmed with repeat testing, should be followed with a pelvic ultrasound, karyotype, and specialist referral. Diagnostic tests in the patient presenting with amenorrhea should be tailored to the history and physical exam.

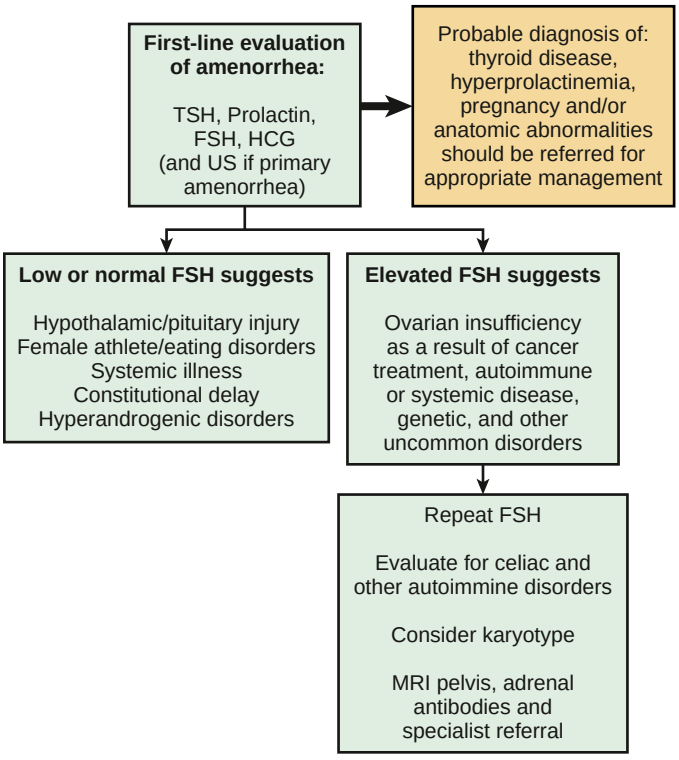

Fig. 159.1 Initial diagnostic testing algorithm to evaluate amenorrhea. FSH, Follicle-stimulating hormone; HCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; US, ultrasound.

In patients with signs of androgen excess (e.g., severe acne or hirsutism) or other physical stigmata associated with PCOS (rapid pubertal weight gain, acanthosis nigricans) consider measuring levels of 17-hydroxyprogesterone (17-OHP), free and total testosterone, dehydroepiandrosterone sulfate (DHEAS), and androstenedione; all preferably collected in the morning. PCOS affects up to 15% of females; diagnostic criteria for adolescents are controversial but include variations of menstrual irregularity (ranging from amenorrhea to AUB) and clinical or biochemical hyperandrogenism. The interpretation of polycystic ovarian morphology identified on ultrasound in adolescents can be challenging, and an ultrasound is not necessary for diagnosis in adolescents.

With the exceptions of pregnancy, constitutional delay, and imperforate hymen, conditions causing primary amenorrhea are associated with reduced fertility; thus their diagnosis may cause profound emotional responses in patients and families. Therefore before ordering studies to confirm these diagnoses (e.g., karyotype, MRI of reproductive anatomy), the clinician should carefully consider the implications and be prepared to refer to specialists with experience managing the long-term treatment of such diagnoses.

In patients presumed to have hypothalamic amenorrhea, based on prepubertal luteinizing hormone (LH) and low FSH levels using an ultrasensitive assay and consistent history and physical exam, MRI of the brain is not necessary in all patients. However, MRI should be considered for patients presenting with a headache history that has changed from baseline; persistent emesis; change in thirst, urination, or vision; elevated prolactin or galactorrhea; or other neurologic symptoms.

TREATMENT

Treatment for amenorrhea widely varies depending on the underlying cause. Many diagnoses require referral to clinicians in specialties such as endocrinology, adolescent medicine, and gynecology; often, collaboration with other disciplines such as psychology or nutrition is indicated. The mainstay of PCOS treatment is suppression of ovarian androgens, typically with **combined hormonal contraception** (i.e., estrogen and progestin) and **lifestyle modifications** to decrease obesity and insulin resistance. Patients with abnormal glucose tolerance may benefit from the addition of **metformin**. **Spironolactone**, an androgen receptor blocker, can also be used to reduce androgen effects, including hirsutism. **Metabolic syndrome** is highly prevalent in PCOS; thus clinicians should evaluate for comorbid diabetes and hyperlipidemia with periodic lipid and hemoglobin A_{1c} screening. It is crucial to normalize weight and improve nutritional status for patients with eating disorders or other hypoestrogenic conditions of energy imbalance. It is not routinely recommended to initiate hormonal therapy in these patients. However, short-term use of **transdermal estrogen therapy** (E2) to protect bone health may be considered for those who remain amenorrheic after a trial of nutritional and activity modification. For females with amenorrhea due to partial or total ovarian insufficiency, exogenous hormones are required for all pubertal development. Experts recommend starting at age 10-12 years with low-dose transdermal estrogen, progressing to increased doses of estrogen and cyclic progestin. Continued maintenance therapy can be accomplished with higher-dose combination products, as found in typical combined hormonal contraceptive pills, patches, and vaginal rings.

In the absence of a clear indication such as PCOS, hormonal medications (e.g., combined hormonal methods) to produce monthly bleeding are not recommended for patients with **secondary amenorrhea** because it will mask the patient's subsequent menstrual pattern. However, in patients with normal postpubertal estrogen levels, progesterone can be useful to periodically (every 4-12 weeks) induce shedding of the endometrial lining to avoid buildup and subsequent heavy menses. One commonly used regimen is **medroxyprogesterone** 10 mg PO daily for the first 7-14 days of the month.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

159.2 Abnormal Uterine Bleeding

Fareeda Haamid and Gina S. Sucato

Abnormal uterine bleeding (AUB) is a broad term used to describe any menstrual bleeding pattern that deviates from physiologic patterns. Clinicians are encouraged to categorize the abnormal pattern based on the patient's complaint, which is typically irregular (AUB/**IMB: intermenstrual bleeding**) or heavy (AUB/**HMB: heavy menstrual bleeding**).

IRREGULAR MENSTRUAL BLEEDING

Menstrual status should be treated as a *vital sign;* at every preventative care or comprehensive visit clinicians should document the first day of the last menstrual period and the menstrual pattern. Although menses are frequently irregular in the early postmenarcheal years, further evaluation is necessary when menstrual patterns vary too widely from what is normal for age. Even in the first postmenarcheal year, menses are usually not less frequent than every 45 days. Menses become increasingly regular with age, and by 3 years after menarche typically occur every 21-35 days, lasting 3-7 days. Personal cycle duration is usually established by age 19 or 20 years.

In the early postmenarcheal years, the most common cause of AUB in adolescents is anovulation caused by immaturity of the hypothalamic-pituitary-ovarian axis. In the absence of a mid-cycle LH surge to stimulate ovulation, there is no corpus luteum production of progesterone. Without the stabilizing effects of progesterone on the endometrial lining, there is increased risk of irregular bleeding. **AUB caused by ovulatory dysfunction (AUB-O**; previously termed *dysfunctional uterine bleeding*), describes irregular bleeding in the absence of specific anatomic, systemic, or endocrinologic disease. Although it is the most common cause of abnormal menstrual bleeding in adolescents, AUB-O is a diagnosis of exclusion. It is important to remember that most conditions that cause amenorrhea can first cause anovulation, which is a key risk for heavy irregular bleeding. Table 159.4 lists the causes of AUB and vaginal bleeding. Adolescents rarely present with complaints of unusually short or light menses. However, short, light, or infrequent menstrual patterns that have changed from a previously established pattern may need to be evaluated similarly to secondary amenorrhea.

Unscheduled bleeding during the use of hormonal contraception frequently occurs, particularly with progestin-only methods. Common causes include medication nonadherence, interactions with prescribed or over-the-counter medications, and smoking. Patients should be reassured such bleeding is benign and not an indication to stop an otherwise satisfactory contraceptive method.

HEAVY AND PROLONGED MENSTRUAL BLEEDING

Irregular bleeding, particularly from anovulation, can be long and heavy (see Table 159.4). However, a hematologic cause **(AUB-C)** should be strongly considered in patients with regular, cyclic menses that are long and/or heavy, especially if heavy menses occurs at the onset of menarche and bleeding disorder symptoms are present. **von Willebrand disease** and other coagulation disorders are found in up to 13% and 20%, respectively, of patients with heavy menstrual bleeding. Other symptoms suggestive of bleeding disorders include changing

Table 159.4 Causes of Vaginal Bleeding in Adolescence

CAUSES OF VAGINAL BLEEDING	EXAMPLES	FEATURES
Immature hypothalamic-pituitary-ovarian axis (AUB-O)	Patient within 2 yr of menarche	Patient responds to hormonal treatment.
Weight changes, disordered eating, or excessive exercise	Anorexia nervosa, bulimia, weight gain or loss of more than 10 pounds from any etiology	Weight loss more frequently results in lighter, less frequent menses.
Endocrinologic causes	Thyroid disease, polycystic ovary syndrome (PCOS)	Bleeding typically increases with hypothyroidism and decreases with PCOS and hyperthyroidism.
Pregnancy complication	Threatened abortion, postpartum or postabortal endometritis	History of sexual activity and/or pregnancy
Infection	Cervicitis, condyloma, pelvic inflammatory disease	Bleeding is usually not heavy and may occur during or after sexual intercourse.
Trauma	Sexual assault, straddle injuries	History will be evident in patients of menstruating age unless there is cognitive disability.
Vaginal foreign body	Toilet paper, broken condoms, tampons	Associated with odor and vaginal discharge, but usually not heavy bleeding.
Hematologic causes (AUB-C)	Type 1, 2, 3 von Willebrand disease, platelet function disorders, thrombocytopenia (idiopathic thrombocytopenic purpura, drug induced), symptomatic hemophilia carrier, clotting factor deficiency, leukemia, aplastic anemia	Bleeding is heavy and/or long and frequently regular, may present at menarche, and may be accompanied by a suggestive personal or family history (hysterectomy, uterine ablation, cautery for epistaxis) or physical exam (ecchymoses, petechiae).
Medications	Estrogens and progestins in combined hormonal contraception Androgens Drugs that affect prolactin (estrogens, phenothiazines, tricyclic antidepressants, metoclopramide) Anticoagulants (heparin, warfarin, aspirin, NSAIDs) SSRIs	Affect the hypothalamic-pituitary-ovarian axis, endometrial lining, platelets, or coagulation pathway.
Anatomic	Partial obstruction of vagina or uterus causing asynchronous bleeding; cervical or endometrial polyps or myomas; hemangioma; uterine vascular malformation; genital/reproductive tract cancer	Most of these entities are extremely rare, especially reproductive tract cancers.
Systemic disease	Celiac disease, rheumatoid arthritis, Ehlers-Danlos syndrome and other connective tissue disorders	Accompanied by other condition-specific signs.

a pad or tampon more than hourly, passing clots larger than 1 inch in diameter, iron deficiency, menses longer than 7 days, a history of hemorrhagic ovarian cysts, excessive bleeding from wounds or postoperatively, mucosal bleeding (epistaxis or GI tract), and first-degree relatives with heavy menses or epistaxis requiring medical treatment. Inherited collagen disorders such as Ehlers-Danlos syndrome are associated with vascular collagen abnormalities; thus patients with heavy menses and manifestations of joint hyperflexibility may require a hematology referral.

LABORATORY FINDINGS

Table 159.5 lists laboratory tests to consider in patients with long, heavy bleeding. Females with persistent heavy bleeding despite negative first-line testing should be referred to a hematologist for testing for platelet function disorders, factor deficiencies, and other less common disorders. In the initial evaluation, rapidity of blood loss in conjunction with the hemoglobin establishes the **bleeding severity**: **mild** (hemoglobin 10-11 g/dL), **moderate** (hemoglobin 7-10 g/dL), or **severe** (hemoglobin <7 g/dL). Iron deficiency is defined as serum ferritin of <15 µg/mL.

TREATMENT

In bleeding that has resulted in **mild** anemia, the patient should keep a menstrual calendar to follow the subsequent flow patterns. **Nonsteroidal antiinflammatory drugs** (NSAIDs; e.g., naproxen) are more effective than placebo in treating heavy bleeding and can also treat concurrent dysmenorrhea. Clinicians may need to educate patients and families about the noncontraceptive medical indications for hormonal contraception given the unnecessary stigma commonly associated with these medications. Active bleeding typically responds well to cycling with any **combined hormonal contraceptive method** containing estrogen and progestin starting with once-daily dosing; up to twice-daily dosing may be considered until bleeding stops. Patients with estrogen contraindications such as migraine with aura, uncontrolled hypertension, or thrombotic risks can be treated with progestins alone, such as medroxyprogesterone 10 mg orally daily or norethindrone acetate 5-10 mg PO daily, either continuously or for 10-14 days per month. The latter regimen will be followed by monthly bleeding.

Iron deficiency with or without anemia should be treated with **65 mg elemental oral iron** once daily until serum ferritin >30 µg/mL. Dosing more frequently than daily has not been shown to be beneficial. Ferritin and hemoglobin should be repeated 4 weeks after treatment is initiated. Once anemia is corrected, iron should be continued once daily for 3 months to replenish iron stores. A referral to hematology may be warranted for insufficient response or intolerance of oral iron for consideration of **intravenous (IV) iron therapy**.

With **moderate** anemia, any of the hormonal regimens noted earlier can be used. However, it may be necessary in patients with more brisk bleeding to start with three to four **combined oral contraceptive (COC) pills** (or three to four doses of **medroxyprogesterone** 10 mg) per day, with additional medication to control nausea. The dose can usually be tapered to daily dosing over the next 2 weeks. Patients with ongoing rapid bleeding, syncope or lightheadedness, hemodynamic instability, or hemoglobin of <7 g/dL should be treated in the hospital.

Patients with **severe** anemia should be treated with one of the hormone tapers described earlier, in addition to **IV fluid or blood products** as indicated; it is advisable to draw necessary hematologic laboratory studies before transfusion. Patients with emesis or other significant symptoms may be initially treated with **conjugated estrogens** 25 mg IV every 4-6 hours for 1-2 days. A COC or progestin regimen should be added within 24-48 hours because progestin is needed to stabilize the endometrial lining and can be used as maintenance therapy after hospital discharge. In the exceptionally rare case of a patient whose bleeding cannot be controlled hormonally, options for gynecologic interventions include **intrauterine Foley balloon placement** or **uterine packing** to tamponade the uterus mechanically. Dilation and curettage, performed frequently in adults, is almost never indicated in adolescents and can increase blood loss in patients with bleeding disorders.

Hormonal AUB treatment should continue for at least 3-6 months, depending on the patient's age, prior menstrual history, and severity of presentation, before reassessing the need for ongoing therapy. Additional options for maintenance therapy include **combined hormonal transdermal patches and vaginal rings**; **depot medroxyprogesterone acetate** 150 mg intramuscularly (IM) or 104 mg subcutaneously (SC) every 3 months; and placement of a **levonorgestrel intrauterine device** (IUD), depending on the patient's preference and/or concurrent need for long-term contraception. For patients who need or choose to avoid hormonal therapy, **antifibrinolytics such as tranexamic acid** 1,300 mgPO 3 times daily can be used for up to 5 days during monthly menstruation in patients who do not have an increased risk of thrombosis.

Females with a known bleeding disorder may be up to 5 times more likely to develop heavy menstrual bleeding. Therefore it can be helpful while the patient is premenarcheal to devise a proactive plan in collaboration with the patient's hematology team in the event of acute heavy menstrual bleeding, which can occur at menarche.

Table 159.5 Laboratory Tests to Evaluate Patients with Abnormal Uterine Bleeding

Complete blood count with platelets
Ferritin
Urine pregnancy test (regardless of history)
Thyroid function studies
Total and free testosterone*
Liver and kidney function studies
Nucleic acid amplification test (NAAT) or equivalent testing for *Chlamydia trachomatis, Neisseria gonorrhoeae*, and *Trichomonas vaginalis*
Prothrombin time and partial thromboplastin time
von Willebrand factor antigen, vWF activity (such as ristocetin cofactor), and factor VIII† activity
Pelvic ultrasound (if palpable mass or bleeding persists despite treatment)

*In patients with signs or symptoms suggestive of polycystic ovary syndrome, such as acne, hirsutism, obesity, acanthosis nigricans, and a history of infrequent menses.
†Any abnormalities should be referred to a hematologist. False-negative von Willebrand tests and false-positive platelet function studies have been observed in the setting of anemia. It is preferable to obtain tests before estrogen treatment is started to minimize false-negative results. Repeat testing is common in patients for whom there is a high pretest suspicion.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

159.3 Dysmenorrhea

Fareeda Haamid and Gina S. Sucato

Dysmenorrhea, painful uterine cramps that precede and accompany menses, occur in up to 90% of 17- to 24-year-olds. Although dysmenorrhea is frequently severe enough to interfere with school and other activities, many adolescents undertreat their symptoms, and fewer seek medical care.

Dysmenorrhea may be primary or secondary. **Primary dysmenorrhea**, characterized by the absence of any specific pelvic pathologic condition, is the more commonly occurring form, accounting for approximately 90% of cases. After ovulation, withdrawal of progesterone results in synthesis of prostaglandins by the endometrium, which stimulates local vasoconstriction, uterine ischemia and pain, and smooth muscle contraction, explaining uterine and GI symptoms.

Secondary dysmenorrhea results from underlying pathology, such as anatomic abnormality, or infection, such as pelvic inflammatory disease. However, the most common cause of secondary dysmenorrhea in adolescents is **endometriosis**, a condition in which implants of endometrial tissue are found outside the uterus, usually near the fallopian tubes and ovaries. Often, other family members have endometriosis. Severe menstrual pain is characteristic of endometriosis; however, adolescents may also have noncyclic pain. Although primary dysmenorrhea is almost always the cause, a careful history and physical examination are required for adolescents who present with **pelvic pain**. An internal pelvic exam is not required in females who are not sexually experienced and whose presentation is consistent with primary dysmenorrhea. Constipation can vary cyclically in many females, especially those with irritable bowel syndrome, and often significantly contributes to the pain. **Mittelschmerz**, brief severe pain with ovulation, occurs at mid-cycle. Table 159.6 lists the differential diagnosis and "red flags" for secondary dysmenorrhea. Ovarian cysts, a frequent concern of families, are usually transient and painless.

Treatment for primary dysmenorrhea is aimed at preventing or decreasing prostaglandin production. The mainstay of first-line treatment is prostaglandin synthetase inhibition with **NSAIDs** (Table 159.7) beginning at,

Table 159.6 Differential Diagnosis of Dysmenorrhea in Adolescents*

	PRESENTATION	DIAGNOSIS
Primary	Crampy pelvic pain may be accompanied by aching/heaviness in lower back and upper thighs, nausea, emesis, diarrhea, headache, mastalgia, fatigue, and dizziness; symptoms begin at or shortly before menstrual flow onset and last 1-3 days.	Normal physical exam; internal exam only for sexually active adolescents. Ultrasound can be reserved for patients with atypical presentations (e.g., onset at menarche) or pain despite NSAIDs and hormonal therapy.
Endometriosis and adenomyosis†	**Increasingly severe dysmenorrhea despite adequate therapy**; pain exacerbated during menses or noncyclical pain.	Increased risk in patients with obstructive anomalies and possibly bleeding disorders; however, most adolescents with endometriosis have normal anatomy and bleeding indices; visual diagnosis is made during surgery and confirmed by tissue sample.
Müllerian anomalies with partial outflow obstruction	**Pain begins at or shortly after menarche** and occurs with bleeding; presence of **known renal tract anomaly** (often coexists with müllerian anomaly).	Pelvic ultrasound will demonstrate uterine anomalies (e.g., rudimentary uterine horn); MRI may be required to identify some lesions (e.g., obstructed hemivagina).
Pelvic inflammatory disease	Abrupt onset of dysmenorrhea more severe than baseline in a sexually active adolescent; presentation can range from mild discomfort to acute abdomen.	Clinical diagnosis made by finding **lower abdominal tenderness plus cervical motion tenderness, uterine or adnexal tenderness** on bimanual pelvic examination (see Chapter 146); supporting features include dysuria, dyspareunia, **vaginal discharge**, fever, and increased white blood cell count.
Pregnancy complication	Coincident pain and bleeding may be misdiagnosed as dysmenorrhea.	Urine test positive for human chorionic gonadotropin.

*__Bold__ entries indicate "red flags" for diagnosis.
†Adenomyosis is the presence of endometrial tissue within the uterine myometrium.

Table 159.7 Treatment for Dysmenorrhea

	MEDICATION	REGIMEN	COMMENTS
NSAIDs (for up to 5 days)	Ibuprofen 200 mg	2 tablets PO q4-6h	Over-the-counter
	Naproxen sodium 275 mg	550 mg loading dose, then 275 mg PO q6h	Patients may prefer the equivalent 550 mg PO q12h dosing regimen.
	Celecoxib (cyclooxygenase [COX]-2 inhibitor)*	400 mg loading dose, then 200 mg PO q12h prn pain	Can be used for patients with bleeding disorders.
Hormonal contraception	Combined hormonal contraceptive	Continuous hormone regimens vs standard 21 hormone days followed by 7 placebo days may offer better relief but may increase the risk of unscheduled intermenstrual bleeding.	Treatment can be based on patient preference.
	Progestin-only methods	DMPA 150 mg IM or 104 mg SC q3mo; levonorgestrel intrauterine device for up to 8 yr; etonogestrel implant	DMPA has potential side effects of weight gain, interference with expected bone density increase during adolescence, and higher discontinuation rates than LARC methods.
Gonadotropin-releasing hormone agonist	Depot leuprolide	11.25 mg IM q3mo	Consider for presumed endometriosis unresponsive to hormonal methods; add-back hormones advised to prevent bone loss.

*This medication may cause serious cardiovascular and gastrointestinal events. Use with caution in patients with impaired renal or liver dysfunction, heart failure, or a history of GI bleeding or ulcer. Full prescribing information can be found at https://www.accessdata.fda.gov/drugsatfda_docs/label/2018/020998s050lbl.pdf
DMPA, Depot medroxyprogesterone acetate; LARC, long-acting reversible contraceptive; NSAIDs, nonsteroidal antiinflammatory drugs.

Table 159.8 Criteria for Premenstrual Dysphoric Disorder

A. In the majority of menstrual cycles, at least five symptoms must be present in the final week before the onset of menses, start to *improve* with a few days after the onset of menses, and become *minimal* or absent in the week post menses.
B. One (or more) of the following symptoms must be present:
   1. Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
   2. Marked irritability or anger or increased interpersonal conflicts.
   3. Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
   4. Marked anxiety, tension, and/or feelings of being keyed up or on edge.
C. One (or more) of the following symptoms must additionally be present, to reach a total of five symptoms when combined with symptoms from criterion B.
   1. Decreased interest in usual activities (e.g., work, school, friends, and hobbies).
   2. Subjective difficulty in concentration.
   3. Lethargy, easy fatigability, or marked lack of energy.
   4. Marked change in appetite, overeating, or specific food cravings.
   5. Hypersomnia or insomnia.
   6. A sense of being overwhelmed or out of control.
   7. Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of "bloating," or weight gain.

Note: The symptoms in criteria A-C must have been met for most menstrual cycles that occurred in the preceding year.

D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).
E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).
F. Criterion A should be confirmed by prospective daily ratings during at least two symptomatic cycles. (*Note:* The diagnosis may be made provisionally prior to this confirmation.)
G. The symptoms are not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed., pp. 171–172. Copyright 2013. American Psychiatric Association.

or preferably the day before, menstruation. High doses of around-the-clock treatment are rarely needed for more than the first 2 days. More data are needed to make specific treatment recommendations regarding exercise, but females should be reassured that participation in usual sports and extracurricular activities is not only permissible but a benchmark of adequate treatment.

For those adolescents whose pain does not optimally respond to dosed NSAIDs, or who also require contraception, the currently available forms of **hormonal contraception** will improve dysmenorrhea. Up to three cycles may be required to appreciate the full benefit. Methods and regimens that eliminate a placebo interval may provide better relief. Despite various studies of adjuvant treatments including heat, aromatherapy, acupressure, acupuncture, transcutaneous nerve stimulation, herbal remedies, yoga, and dietary supplements, hormonal medications are the mainstay of second-line treatment. Females whose pain persists despite more than 3 months of adequate hormonal therapy require further evaluation and treatment and referral to a specialist, as endometriosis has been found in up to 69% of adolescents who underwent laparoscopy for persistent pelvic pain.

159.4 Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Fareeda Haamid and Gina S. Sucato

Premenstrual syndrome (PMS), which occurs in up to 30% of adolescents, is marked by symptoms such as mood changes, bloating, and breast tenderness that begin in the luteal phase of the menstrual cycle (i.e., the time between ovulation and the first day of bleeding) and improve within a few days after the onset of menses. Adolescents are often reassured by education about the relationship of symptoms to the menstrual cycle. Lifestyle interventions such as exercise and stress reduction sometimes provide adequate relief. For more severe symptoms, cognitive-behavioral therapy may be useful. Current data do not support routine recommendations for any vitamin, mineral, or other dietary supplements in the absence of documented deficiency. There is not strong evidence supporting the effectiveness of combined hormonal contraceptive methods for PMS. However, some experts suggest this treatment option for adolescents who also have dysmenorrhea, acne, or contraceptive needs.

Premenstrual dysphoric disorder (PMDD) is distinguished from other depressive disorders by its timing; mood symptoms are precipitated by ovulation, recur in the luteal phase, and disappear at the end of menstruation. It is distinguished from PMS by the severity and consequences of the affective symptoms. PMDD causes significant distress and functional impairment and may be accompanied by physical and behavioral symptoms (Table 159.8). It is a distinct, treatment-responsive depressive disorder. PMDD occurs in 2–6% of menstruating females worldwide. Accurate diagnosis requires use of a menstrual calendar to prospectively document cyclic symptoms. Other mental health conditions such as depression and anxiety disorders may be exacerbated before or during menses, but symptoms will occur throughout the cycle.

Selective serotonin reuptake inhibitors (SSRIs) are first-line therapy for PMDD and severe PMS. In contrast to the treatment of depression, SSRIs can be rapidly effective for premenstrual symptoms and thus can be prescribed either continuously or intermittently, beginning at ovulation (or whenever in the luteal phase symptoms begin) and ending when symptoms resolve. Adolescents can be prescribed the standard regimens used for adults, such as fluoxetine 20 mg PO daily. For adolescents who also need contraception, the drospirenone 3 mg and ethinyl estradiol 0.02 mg combination pill delivered for 24 days followed by 4 inactive days has been approved by the Food and Drug Administration for PMDD.

Chapter 160
Contraception

Mary E. Romano and Elizabeth M. Alderman

The consequences of sexual activity, including unintended pregnancy (see Chapter 161) and sexually transmitted infections (STIs; Chapter 163), occur in adolescents at higher rates than in adults. Significant barriers, including access to confidential care, may delay an adolescent's ability to access reproductive healthcare until after initiation of sexual activity, and many may become pregnant and/or acquire an STI during this interval. Early and appropriate counseling and education with adolescents, including direct discussion of the risks of unintended pregnancy and STI prevention, can help to mitigate these risks; adolescents who plan sexual initiation are 75% more likely to use contraception at sexual debut. Therefore appropriate patient-centered counseling and provision of contraception as warranted are an essential component of comprehensive healthcare for adolescents. *Female* refers to cisfemale but theoretically would include all those with a uterus engaging in sexual behaviors that put them at risk for pregnancy.

CONTRACEPTIVE EFFECTIVENESS

To decrease rates of unintended pregnancy, the American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists (ACOG) recommend that healthcare providers counsel about and ensure access to all contraceptive methods for their adolescent patients. Comparing typical effectiveness of contraceptive methods, Figure 160.1 illustrates a tiered system of contraceptive methods ranging from more effective to least effective. These tiers are categorized by **typical-use failure rates**, which reflect the effectiveness of a method for the average person who may not always use the method consistently or correctly (Table 160.1). For example, for oral contraceptive pills, the typical-use failure rate is 7%, whereas the *perfect-use* failure rate is <1%. **Tier 1** methods, the most effective, include those with failure rates of <1 pregnancy per 100 women in a year of typical use, and reversible Tier 1 methods include intrauterine devices (IUDs) and implants. **Tier 2** methods have failure rates of 4-7 pregnancies per 100 women in a year of typical use and include injectable contraception, oral contraceptive pills, contraceptive patches, and the vaginal ring. **Tier 3** methods have failure rates of >13 pregnancies per 100 women per year of typical use and include the male and female condom, the diaphragm, withdrawal, the sponge, fertility awareness–based methods, and spermicides.

160.1 Contraceptive Use

Mary E. Romano and Elizabeth M. Alderman

SEXUAL ACTIVITY

According to the 2021 Youth Risk Behavior Surveillance System, 30% of U.S. high school students had ever had sexual intercourse and approximately 22% reported being currently sexually active. These numbers have been decreasing since 2015. However, significant decreases noted from 2019 to 2021 may be attributable to the effect of the COVID pandemic on behaviors.

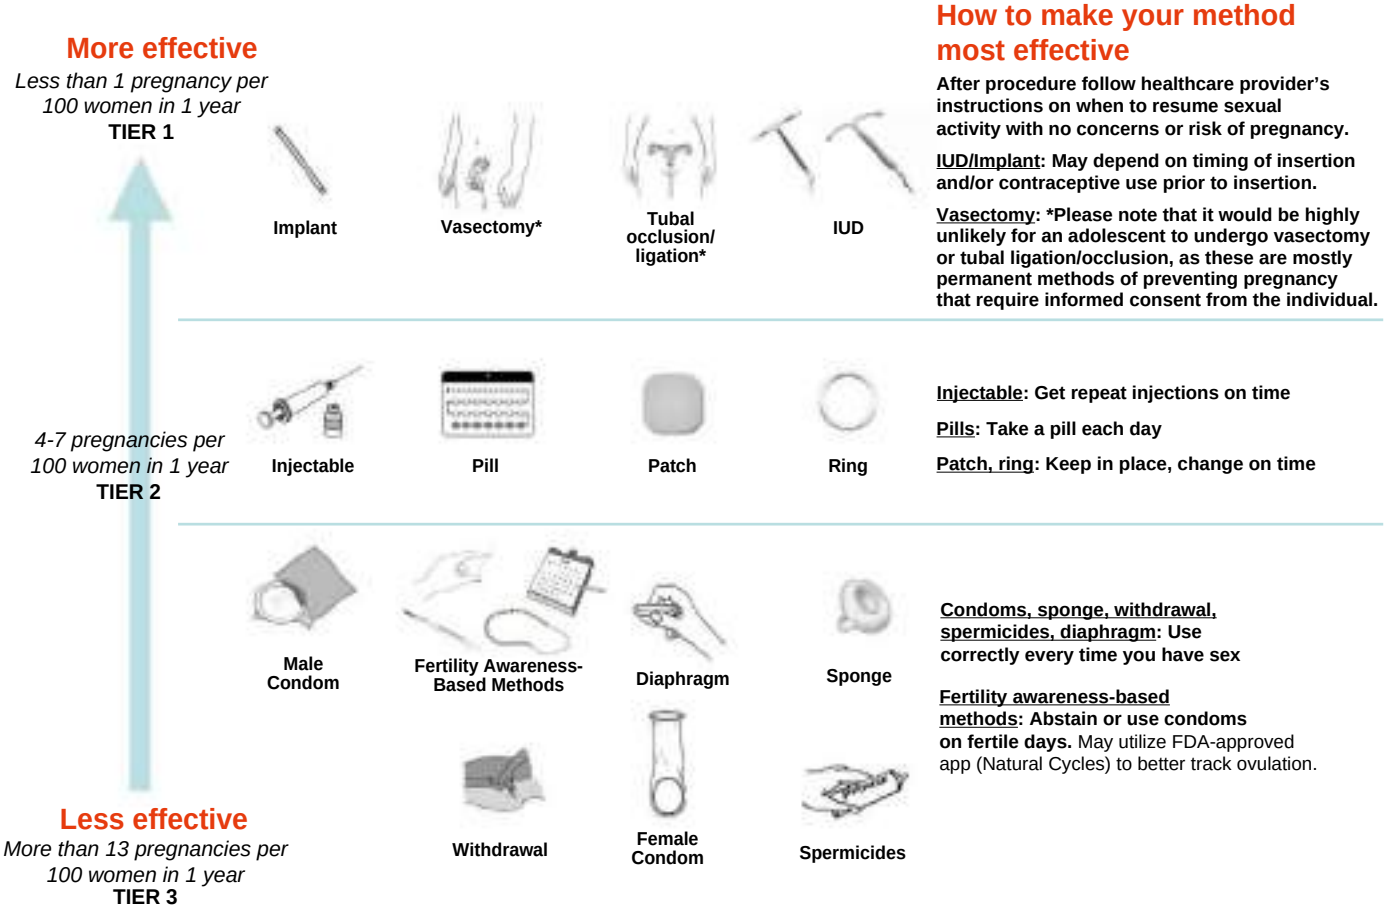

Fig. 160.1 Effectiveness of contraceptive methods. (*Modified from Trussell J, Aiken ARA, Micks E, Guthrie K. Contraceptive efficacy, safety, and personal considerations. In: Hatcher RA, Nelson AL, Trussell J, et al., eds. Contraceptive Technology, 21st ed. New York: Ayer Company Publishers; 2018:102.*)

Table 160.1 Efficacy of Contraceptives

METHOD	FAILURE RATE (%)* TYPICAL USE	PERFECT USE	SOME ADVANTAGES	SOME ADVERSE EFFECTS AND DISADVANTAGES
Implant				
Nexplanon	0.1	0.1	Convenience; long-term contraception; efficacy not dependent on patient adherence; rapid return of fertility after removal	Irregular bleeding; amenorrhea, insertion and/or removal complications
Intrauterine Devices (IUDs)			Convenience; long-term contraception; efficacy not dependent on patient adherence; rapid return of fertility after removal	Rare uterine perforation; risk of infection with insertion
ParaGard T380A	0.8	0.6	Effective for 10 yr; nonhormonal	Irregular/heavy bleeding and dysmenorrhea
Mirena	0.1	0.1	Effective for 8 yr; decreased menstrual bleeding and improved symptoms of dysmenorrhea	Irregular bleeding in first 3-6 mo, followed by amenorrhea; unpredictable suppression of ovulation and potential ovulatory SE (ovarian cysts, PMS, dysmenorrhea)
Liletta	0.1	0.1	Decreased menstrual bleeding and improved symptoms of dysmenorrhea	Irregular bleeding in first 3-6 mo; unpredictable suppression of ovulation and potential ovulatory SE (ovarian cysts, PMS, dysmenorrhea)
Kyleena	0.2	0.2	Smaller T-frame and narrower insertion tube	Irregular bleeding in first 3-6 mo; unpredictable suppression of ovulation and potential ovulatory SE (ovarian cysts, PMS, dysmenorrhea), unpredictable bleeding pattern for the duration of use
Skyla	0.4	0.3	Smaller T-frame and narrower insertion tube	Irregular bleeding in first 3-6 mo; unpredictable suppression of ovulation and potential ovulatory SE (ovarian cysts, PMS, dysmenorrhea), unpredictable bleeding pattern for the duration of use
Injectable				
Depo-Provera	4	0.2	Convenience of q3mo injections; same as progestin-only oral contraceptives	Delayed return to fertility, irregular bleeding, and amenorrhea; weight gain; decreased bone mineral density while receiving injections
Combination Oral Contraceptives	7	0.3	Protection against ovarian and endometrial cancer; suppresses ovulation, which can improve symptoms of PMS, PMDD, and dysmenorrhea; quick return to fertility upon discontinuation	Increased rate of thromboembolism, which increases with age and in those with underlying risks for blood clots, nausea; headache; contraindicated with breastfeeding
Progestin-Only Oral Contraceptives	7	0.3	Safe in breastfeeding women and those with underlying risk of blood clots	Irregular, unpredictable bleeding; must take at same time every day, unpredictable suppression of ovulation
Transdermal Patch	7	0.3	Convenience of once-weekly application; same benefits as combination oral contraceptives	Application site reactions; detachment; increased estrogen exposure as compared with oral contraceptives
Vaginal Ring	7	0.3	Convenience of once-monthly application, benefits similar to combination oral contraceptive pills	Discomfort of ring or with insertion; vaginal discharge
Diaphragm with Spermicide	17	16	Low cost	High failure rate; cervical irritation; there can be increased risk of urinary tract infection and toxic shock syndrome with improper and prolonged use; some require fitting by healthcare professional; may be difficult to obtain; available only by prescription
Condoms Only				
Female	21	5	Protection against STIs; covers external genitalia; OTC	High failure rate; difficult to insert; may be less appealing because of need to stop during sexual activity
Male	13	2	Protection against STIs, OTC, male participation	High failure rate; allergic reactions; may be less appealing because of need to stop during sexual activity; breakage possible
Cervical Cap	16–32	9–26	Effective for 48 hr; can be used for ~2 yr	High failure rate, cervical irritation, risk of toxic shock, limited sizes, requires prescription
Withdrawal	20	4	No drugs or devices	High failure rate
Sponge	14–27	9–20	OTC; low cost; no fitting required; provides 24 hr of protection	High failure rate; contraindicated during menses; increased risk of toxic shock syndrome with improper and prolonged use

Continued

Table 160.1 Efficacy of Contraceptives—cont'd

METHOD	FAILURE RATE (%)* TYPICAL USE	PERFECT USE	SOME ADVANTAGES	SOME ADVERSE EFFECTS AND DISADVANTAGES
Fertility Awareness–Based Methods	15	—	Low cost; no drugs or devices	High failure rate; can be difficult to use properly if periods/ovulation are not well established/regular, requires periods of abstinence
Spermicide			Available OTC	High failure rate; local irritation; must be reapplied with repeat intercourse; unknown effect on HIV transmission, cost
Nonoxynol-9	21	16	—	
Phexxi	14	5	Microbicidal effect, increased viscosity as compared to other spermicides	Requires a prescription, local irritation; must be reapplied with repeat intercourse; cannot be used with vaginal ring, cost/insurance coverage
No Method	85	85	—	—

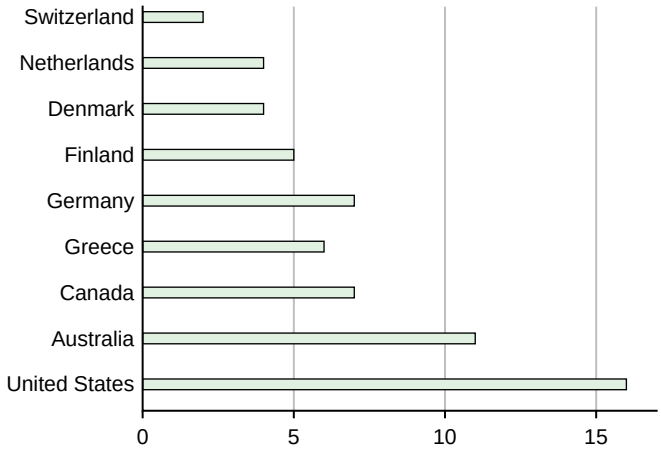

Fig. 160.2 Teen birthrates in high-income countries, 2020. Live births per 1,000 females age 15-19 yr. (*Data from The World Bank Group. United Nations Population Division, World Population Prospects.* https://data.worldbank.org/indicator/SP.ADO.TFRT.)

Although U.S. teens and European teens have similar levels of **sexual activity** and ages of **sexual debut**, U.S. teens are less likely to use contraception and less likely to use the most effective methods. Teen pregnancy rates have been declining worldwide—a result of delayed initiation of sexual activity and increased contraceptive use. Despite this decline, the United States still had the highest teen birthrate in the Western industrialized world as of 2020, with 16.7 live births per 1,000 females age 15-19 years (Fig. 160.2). This is 8 times higher than the teen birthrate in Switzerland, which has the lowest rate in Western Europe. As of 2020 the teenage pregnancy rate in the United States is 31 pregnancies per 1,000 women, with a rate of 13.6/1,000 in those 15-17 years and 56.9/1,000 in those 18-19 years. The majority of these pregnancies are unintended, and one in five births are a repeat birth, indicating an unmet need for reliable, effective contraception that teens will correctly and consistently use.

USE OF CONTRACEPTION AMONG TEENS

According to the 2017–2019 National Survey of Family Growth, 78% of females and 89% of males who had their first sexual intercourse before age 20 years used a contraceptive method at first intercourse. The method most used by teenage females is the condom, followed by withdrawal (both least effective methods) and then the pill (a moderately effective method). IUDs and implants, the most effective reversible methods, are used by 20% of females 15-19 years, with the implant being more commonly used (15%). Use of contraception at first sex has greatly increased over the last 50 years. Factors associated with contraceptive use at first sex include increasing age among teens up to age 17 years, time spent in college, and planning their sexual debut.

More than half of sexually experienced female teens are currently using the most effective reversible contraceptives or moderately effective contraceptive methods. U.S. teens' use of hormonal methods at last intercourse is less frequent compared with teens in other developed countries. A higher likelihood of female current contraceptive use is associated with older age at sexual initiation, aspirations for higher academic achievement, acceptance of one's own sexual activity, and a positive attitude toward contraception. Despite the importance of dual-method use to protect against both unwanted pregnancy and STIs, only 33% of sexually active female U.S. teens report using a barrier method (condoms) plus another method of contraception at last sexual activity.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

160.2 Contraceptive Counseling

Mary E. Romano and Elizabeth M. Alderman

The adolescent preventive health visit offers opportunities for confidential discussions with all adolescents and the opportunity to identify and discuss sexual practices that may be putting the adolescent at risk for STIs or unintended pregnancy. It is also a time to discuss safe sexual behaviors, including abstinence (see Chapter 151). It is important to ask specifically about adolescents' sexual behaviors to make sure your counseling is appropriate for their sexual activity. Adolescents with medical conditions, either chronic or acute, are particularly vulnerable to having sexual and reproductive health omitted from their visits, although they have similar sexual health and contraceptive needs (see Chapter 756). Their comorbidities or concurrent medication use may make STIs and unintended pregnancy an increased health risk and may affect contraceptive counseling/options. The **U.S. Medical Eligibility Criteria for Contraceptive Use** (MEC) outlines medical conditions associated with increased risk for adverse health events with pregnancy and provides recommendations for who can safely use specific contraceptive methods.

The goals of adolescent contraceptive counseling are to (1) understand adolescent experiences, preferences, perceptions, and misperceptions about pregnancy and use of contraceptives; (2) help adolescents understand the risks of unprotected sexual intercourse, including STIs and unintended pregnancy; (3) educate adolescents about the various contraceptive methods available using information that is medically accurate, balanced, and provided in a nonjudgmental manner; and (4) engage in patient-centered counseling so the adolescent feels empowered to choose a safe and effective method that can either be

provided on site or be easily obtained through prescription or by referral. If adolescents are comfortable and willing to include their parents in this discussion, it is also always helpful to engage parents in the decision-making process and address any parental questions and concerns. Providers should be aware of state laws affecting confidentiality and an adolescent's ability to access confidential contraceptive services (see Chapter 151). Most states allow adolescents confidential access to contraceptive services, but given that many adolescents are under their parents' insurance plan, confidentiality may be unintentionally breached through billing and explanation of benefit statements, as well as through the open notes mandate. This should be discussed with adolescents, especially those who are very concerned about disclosing sexual health information to their parents or guardians.

Counseling should include a review of all contraceptive methods available that the adolescent can use safely (see U.S. MEC). **Long-acting reversible contraception** (LARC/IUDs and implants) is a safe and effective option for many adolescents, including those who have not been pregnant or given birth. The adolescent should be counseled about method effectiveness using typical-use failure rates. Although it is important to highlight the methods most effective at preventing pregnancy, it is also imperative to provide contraceptive counseling within the framework of reproductive justice and to avoid any coercion due to provider preference or bias. The focus of contraceptive counseling should be on the priorities of the adolescent, and the adolescent should be allowed to explore all options and determine which method is most appropriate for their contraceptive needs and priorities. It is important to ask about use of **withdrawal** and discuss its risks given that 60% of female teens have used it for contraception and it has a typical-use failure rate of 20%. **Abstinence** should also be discussed as an option even if teens have engaged in sexual intercourse in the past. Abstinence may be the best option if adolescents do not have another method available at a particular time.

Necessary concepts to address while discussing individual methods include how effective the method is, how long the method works, what behaviors are required for correct and consistent use, what side effects may be seen, any noncontraceptive benefits of the method (e.g., reduced menstrual bleeding, protection from STIs), and what signs or symptoms of complications should prompt a return visit. Reviewing common side effects allows teens to anticipate and cope with any changes with reassurance and may avoid method discontinuation. Weighing the possibility of certain side effects with the possibility of an unintended pregnancy may also help with the conversation. It is also important to address any specific misperceptions teens may have for certain contraceptives regarding side effects, effectiveness, or effect on future fertility.

Once an adolescent chooses a method, the provider and adolescent should discuss clear plans on correct and consistent use of the chosen method and strategies for appropriate follow-up (see Table 160.1). Providers should help the adolescent consider potential barriers to correct and consistent use (e.g., forgetting to take a pill daily) and develop strategies to deal with each barrier (e.g., use of reminder systems such as daily text messages or phone alarms). The provider should assess whether the teen understood the information discussed and may confirm by asking the teen to repeat back key concepts.

The U.S. Selected Practice Recommendations for Contraceptive Use provides guidance for providers regarding when to start contraception, how to be certain the woman is not pregnant at contraception initiation, and what examinations and tests are recommended before initiating contraception. Generally, women may start a contraceptive method other than an IUD at any time, and an IUD may be placed when a provider is reasonably certain that a woman is not pregnant. The Centers for Disease Control and Prevention (CDC) defines this as a patient who has no symptoms or signs of pregnancy, is ≤7 days after the start of normal menses, has not had sexual intercourse since the start of last normal menses, and has been correctly and consistently using a reliable method of contraception

Most women do not require any special exam or additional screening for STIs before initiating contraception if they have been recently screened according to the CDC's STI treatment guidelines. A blood pressure reading is advisable. A pelvic examination is only required for placement of an IUD, unless otherwise indicated. STI screening is appropriate at and/or before IUD placement, even if a patient does not report sexual activity, as some patients may choose to not disclose this information to their provider. Gonorrhea and chlamydia screening using a self- or provider-collected vaginal swab or urine sample is recommended unless symptoms require a pelvic exam. IUD placement should not be delayed to receive screening results. Cervical cancer screening is not recommended until age 21.

Providers should offer confidential services to adolescents and observe all relevant state laws and legal obligations (e.g., notification or reporting of sexual abuse). Chapter 151 discusses confidentiality and consent issues related to contraceptive management. Providers should also encourage adolescents to involve parents or guardians in their healthcare decisions, while giving parents clear information on their teen's right to confidentiality, privacy, and informed consent. All services should be provided in a youth-friendly manner, meaning that they are accessible, equitable, acceptable, appropriate, comprehensive, effective, and efficient. Resources are available that describe ways to ensure a **teen-friendly** reproductive health visit.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

160.3 Long-Acting Reversible Contraception

Mary E. Romano and Elizabeth M. Alderman

Long-acting reversible contraception **(LARC)** includes four **levonorgestrel (LNG)** IUDs, the **copper (Cu)** IUD, and the etonogestrel subdermal implant. LARC methods are the only Tier 1 methods that are reversible (see Fig. 160.1). Their efficacy is the result of the fact that LARC does not require frequent office or pharmacy visits and does not depend on user adherence for effectiveness. In the Contraceptive CHOICE Project in St. Louis, Missouri, >9,000 women were given the contraceptive method of their choice at no cost and were followed for 2-3 years. The failure rates among women of all ages, including adolescents who used oral contraceptive pills, transdermal patch, or vaginal ring, were >20 times higher than the failure rates for those using a LARC method. Acceptance, continuation, and satisfaction in this project were also higher among adolescents using LARC compared with adolescents using non-LARC methods. *ACOG and AAP support the use of LARC methods for adolescents.* The U.S. MEC supports safe use of both IUDs and implants for adolescents and nulliparous women. Implants are considered Category 1 for all ages, and IUDs are considered Category 2 for women <20 years old and for nulliparous women (Table 160.2).

INTRAUTERINE DEVICES

IUDs are small, flexible, plastic objects introduced into the uterine cavity through the cervix. They differ in size, shape, presence or absence of hormone, and dose of hormone delivered daily. In the United States, five IUDs are currently approved by the Food and Drug Administration (FDA): the CuT380A (Paragard) and four LNG IUDs (Liletta, Kyleena, Mirena, and Skyla).

The LNG IUDs also have various actions, from thickening of cervical mucus and inhibiting sperm survival to suppressing the endometrium. LNG IUDs are effective and approved for use from 3 to 8 years. The Cu IUD releases copper ions into the uterine cavity, which induces an inflammatory response within the endometrium. Copper also impairs sperm motility/migration, inhibits the acrosomal reaction, and impairs implantation. As with the other IUDs, the Cu IUD is reversible, safe for use in nulliparous women, and effective for at least 10 years. All IUDs have typical-use failure rates of <1% (see Fig. 160.1). All LARC methods are appropriate and safe to use in the postpartum period.

Mirena is FDA approved for the treatment of heavy menstrual bleeding, and studies in adults have demonstrated an 80% reduction in menstrual blood loss in Mirena users, with 50% of users reporting amenorrhea after 2 years of use. Among the other LNG IUDs,

Table 160.2 Categories of Medical Eligibility Criteria for Contraceptive Use

Category 1: A condition for which there is no restriction for the use of the contraceptive method
Category 2: A condition for which the advantages of using the method generally outweigh the theoretical or proven risks
Category 3: A condition for which the theoretical or proven risks usually outweigh the advantages of using the method
Category 4: A condition that represents an unacceptable health risk if the contraceptive method is used

Table 160.3 Conditions Classified as Category 3 and 4 for Combined Hormonal Contraceptive Use

Category 4 (a condition that represents an unacceptable health risk if the contraceptive method is used)
Complicated valvular heart disease
Current breast cancer
Severe decompensated cirrhosis
Deep venous thrombosis/pulmonary embolism (acute; history, not on anticoagulation or on established therapy for at least 3 mo with higher risk recurrence; major surgery with prolonged immobilization)
Complicated diabetes with nephropathy, retinopathy, neuropathy, or other vascular disease or duration of diabetes >20 yr
Migraine with aura
Poorly controlled hypertension (blood pressure >160/100 mm Hg) or hypertension with vascular disease
Ischemic heart disease (history of or current)
Hepatocellular adenoma
Malignant liver tumor
Peripartum cardiomyopathy (diagnosed <6 mo before or with moderately or severely impaired cardiac function)
Postpartum <21 days
History of cerebrovascular accident
Systemic lupus erythematosus with positive antiphospholipid antibodies
Thrombogenic pathogenic variants
Viral hepatitis (acute or flare)
Category 3 (a condition for which the theoretical or proven risks usually outweigh the advantages of using the method)
Past breast cancer with no evidence of disease for 5 yr
Breastfeeding and <1 mo postpartum
Deep venous thrombosis/pulmonary embolism (history of DVT/PE with lower risk recurrence)
Gallbladder disease (current, medically treated)
History of malabsorptive bariatric surgery
History of cholestasis and past combined oral contraceptive–related
Hypertension (adequately controlled or blood pressure <160/100 mm Hg)
Peripartum cardiomyopathy with mild impairment or >6 mo
Postpartum 21-42 days with other risk factors for venous thromboembolism
Drug interactions (ritonavir-boosted protease inhibitors; certain anticonvulsants; rifampin or rifabutin)
First-degree family member with a history of a blood clot/clotting disorder/thromboembolic event

From Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. medical eligibility criteria for contraceptive use, 2016, *MMWR Recomm Rep* 2016;65(RR-3):1–104.

amenorrhea at 2 years is reported at 26% for Liletta users, and Kyleena and Skyla report prolonged and irregular bleeding at 1 year in 5–20% of users. Heavier bleeding patterns and increased dysmenorrhea are reported in users of the Cu-IUD. Patients should be counseled on bleeding patterns and expected changes to their menstrual bleeding after IUD insertion (Table 160.3).

Common misconceptions of IUDs among healthcare providers are that IUDs can cause or increase the risks of infections, cause infertility, and generally are not safe or tolerated by teens or nulliparous women; these misconceptions can be a barrier for teens desiring an IUD to access these highly effective and safe methods. IUDs do not increase risk of infertility and may be inserted safely in teenagers regardless of parity (Category 2; see Table 160.2).

Although early studies suggested an increased risk for upper genital tract infection, because of the passing of a foreign body through the cervix, new studies have refuted these concerns. Therefore clinicians are encouraged to consider the use of IUDs in adolescents despite relatively high prevalence rates of STIs in this population. Teens should be screened for gonorrhea and chlamydia at and/or before IUD placement, although placement should not be delayed if results have not returned and there are no signs of current infection (e.g., purulent discharge, erythematous cervix). If STI testing is positive with an IUD in place, the patient may be treated without removing the IUD if she wants to continue the method.

There has been evidence that rates of IUD expulsion are higher in adolescents as compared to older women. The data are limited, but the risk seems to be higher with Cu-IUD vs hormonal IUD, previous IUD expulsion, and concomitant use of the menstrual cup. A paracervical block with lidocaine may reduce patient discomfort during placement and, along with other medications (e.g., NSAIDs, anxiolytics), may be considered on an individual patient basis, but these are not routinely recommended.

IMPLANTS

One contraceptive implant is available in the United States. The single rod that releases 60 μg/day of **etonogestrel** has been updated to a radiopaque rod with a new inserter. This **progestin-only method** keeps etonogestrel at steady serum levels for at least 3 years and primarily works to inhibit ovulation. Similar to the levonorgestrel IUD, the progestin acts on the uterus to cause an atrophic endometrium and thicken cervical mucus to block sperm penetration; its typical-use failure rate is also <1% (see Fig. 160.1). Unlike the IUD, no pelvic exam is required for insertion. A trained provider can quickly place or remove the implant in the upper arm under local anesthesia. The most common side effect of the contraceptive implant is irregular and unscheduled/unpredictable bleeding. This can include irregular or infrequent bleeding, amenorrhea, and less often, prolonged or frequent bleeding. Although the continuation rates are favorable and comparable to the IUD, the most common reason for discontinuation is dissatisfaction with bleeding patterns. It is important that adolescents be appropriately counseled on the potential for changes to their bleeding pattern before insertion of the implant. Adolescents who present with troublesome bleeding should be evaluated for any underlying gynecologic abnormalities, bleeding or blotting disorders, and the presence of an STI. If these are not present and adolescents desire treatment, they can be treated with a short course of NSAIDs (5-7 days) or low-dose combined oral contraceptives (COCs) if no contraindications to estrogen exist (10-20 days). Any and all adolescents desiring implant removal because of side effects should be offered prompt removal as indicated.

One potential unique complication of this method relates to localized infection and other side effects after implantation, such as bleeding, hematoma, or scarring, and if inserted too deeply into the muscle, neural damage or migration; however, these events are rare, occurring in <1% of patients. Minor side effects, such as bruising or skin irritation, are more common but most often resolve without treatment.

160.4 Other Progestin-Only Methods

Mary E. Romano and Elizabeth M. Alderman

Several progestin-only contraceptive methods are available and include the LNG IUDs and implant (see Chapter 160.3), as well as an injectable and progestin-only pills. These methods do not contain estrogen and may be useful for teens with contraindications to estrogen use or in

Table 160.4 Hormonal Intrauterine Devices

	MIRENA	KYLEENA	LILETTA	SKYLA
Duration of use	FDA approved 8 yr	FDA approved 5 yr	FDA approved 8 yr	FDA approved 3 yr
Daily hormone delivery over time	20 mcg LNG/day → 9 mcg/day (52 mcg total)	17.5 mcg LNG/day → 7.4 mcg/day (19.5 mcg total)	19.5 mcg LNG/day → 9.8 mcg/day (52 mcg total)	14 mcg LNG/day → 5 mcg/day (13.5 mcg total)
Device size	32 mm × 32 mm	28 mm × 30 mm	32 mm × 32 mm	28 mm × 30 mm
Diameter of insertion rod	4.4 mm	3.8 mm diameter	4.4 mm diameter	3.8 mm diameter

FDA, Food and Drug Administration; LNG, levonorgestrel.

patients who prefer a method without estrogen such as gender-diverse adolescents and young adults (Table 160.4). They are considered safe for use in teens (Category 1 or 2; see Table 160.2). Progestins thicken cervical mucus to block sperm entry into the uterine cavity and induce an atrophic endometrium leading to either amenorrhea or less menstrual blood loss; the implant and injectable also suppress ovulation, whereas the progestin-only pills and LNG IUDs may affect the frequency of ovulation but do not suppress it completely. Teens should be provided anticipatory counseling regarding bleeding irregularities that may normally occur in the first 3-6 months of any hormonal contraception use.

DEPO-PROVERA

An *injectable progestin,* depot **medroxyprogesterone acetate** (**DMPA**, Depo-Provera) is a Tier 2 contraceptive method available as a deep intramuscular (IM) injection (150 mg) or as a subcutaneous (SC) injection (104 mg) with typical-use failure rates of 4% (see Table 160.1). Both preparations must be readministered every 3 months (13 weeks). When appropriate, DMPA can be given up to 3 weeks before or 7 days after the 13 weeks scheduled interval without any effect on contraceptive efficacy. DMPA works by inhibiting ovulation and thickening cervical mucus. DMPA may be preferred by patients or parents who are caring for a child with intellectual disabilities. Common concerns with DMPA include bleeding changes, bone effects, and weight gain. After 1 year of use, 50% of DMPA users develop amenorrhea, which may be an added advantage for teens with heavy menstrual bleeding, dysmenorrhea, anemias, or blood dyscrasias. It may also be advantageous for those desiring menstrual suppression because of physical or developmental disabilities that make hygiene difficult or those in whom menstruation causes gender dysphoria. Studies have demonstrated bone mineral density (BMD) loss in adolescents with DMPA use, but this has not been shown to directly increase fracture risk. It is unclear how this decrease in BMD affects the risk for osteoporosis later in life. Other studies have found that BMD is recovered after discontinuation of this method, and it is thus considered safe for use in this population with appropriate counseling and consideration of other risk factors for bone health. Healthcare providers should speak at length with teens and parents, when appropriate, who are already at high risk for low BMD, such as those receiving chronic corticosteroid therapy or those with eating disorders (see Chapter 749). They should discuss and decide together if DMPA is an appropriate contraceptive choice. Patients and providers need to balance the potential bone effects of DMPA with the bone effects that can occur with a teenage pregnancy. Although the FDA issued a black box warning in 2004 because of Depo's BMD effects, the AAP and ACOG do not recommend limiting duration of DMPA use and do not recommend routine BMD screening for females using it. Early weight gain may be predictive of progressive gain over time; thus those teens gaining weight in the first 3-6 months after the initiation of DMPA should be monitored and continue to engage in discussions about healthy eating and exercise habits.

PROGESTIN-ONLY PILLS

Progestin-only oral contraceptive pills **(POPs)** are available and safe for use in adolescents. POPs **(mini pills)** are quickly effective after 2 days of initiation in thickening cervical mucus, but do not reliably inhibit ovulation. Prior to 2019, the only progestin pill available in the United States contained 0.35 mg of norethindrone. Norethindrone has a short half-life, and it is important that this pill is taken at the same time every day, which can make adherence difficult. If a pill is >3 hours late from normal time, an unintended pregnancy may occur. POPs have a typical-use failure rate of 7% (see Table 160.1). Norethindrone POPs are taken continuously, and as a result, the bleeding pattern is variable—ranging from amenorrhea to irregular and unpredictable breakthrough bleeding. Acceptance by adolescents is limited by the necessity of taking the pill at the same time daily, and bleeding irregularities

In 2019 the FDA approved a new POP—Slynd—which contains 4 mg of drospirenone. This is higher than the dose found in COCs. Drospirenone is an analog of spironolactone with a longer half-life of ~25-30 hours, which allows for more flexibility with timing of pills. It also has some antimineralocorticoid activity and therefore should be used with caution in those who may take other medications or have medical comorbidities that can put them at risk for hyperkalemia. Slynd comes in a 28-day pill pack with four inactive pills intended to cause a scheduled withdrawal bleed. Slynd primarily suppresses ovulation. Studies have demonstrated its safety and efficacy along with high rates of satisfaction among users (85%). There may still be unscheduled bleeding, but it seems to be more favorable than what is experienced with norethindrone use.

160.5 Combined Hormonal Contraceptives

Mary E. Romano and Elizabeth M. Alderman

Combined hormonal contraceptives **(CHCs)** are methods that include an estrogen in combination with a progestin that has progestational, estrogenic, and androgenic properties. Methods available in the United States include several formulations of **COCs**, a transdermal patch, and a vaginal ring. The major mechanism of action of the **estrogen-progestin** combination is to prevent the surge of luteinizing hormone and thereby inhibit ovulation. Additional effects to the reproductive tract include thickening of the cervical mucus, which prevents sperm penetration, and thinning of the endometrial lining, which may decrease menstrual blood loss. Typical-use failure rates for all CHCs are the same at 7%.

The COCs, patch, and vaginal ring are classified together as CHCs in the U.S. MEC for Contraceptive Use, and recommendations mostly consider estrogen exposure for a given condition or characteristic (see Tables 160.3 and 160.4). Thromboembolic events such as venous thromboembolism (VTE), pulmonary embolism, or stroke are some of the more serious potential complications of exogenous estrogen use. These serious adverse events are exceedingly rare in adolescents who do not have other risk factors for thromboembolic events. Although the risk of blood clots is increased in those who smoke cigarettes, the likelihood of its occurrence is very small in adolescents, and thus clinically insignificant, compared to the risk of morbidity and mortality from other pregnancy-related complications, including blood clots

associated with the high estrogen levels that occur during pregnancy and in the postpartum period.

COMBINED ORAL CONTRACEPTIVES

Oral contraceptive pills (OCs) can be either COCs or POPs and are commonly referred to as "the pill." The pill is one of the most common contraceptive methods used among women of all ages. To decrease risk of pregnancy and increase continuation, providers are encouraged to provide OCs at the time of patient presentation to start immediately rather than waiting for next menses, as long as the provider is reasonably sure that the patient is not pregnant. Providers are also encouraged to provide up to 13 pill packs at a time, based on evidence that more pill packs provided is associated with higher continuation rates. However, it is important to see an adolescent in follow-up once starting contraception to discuss adherence and satisfaction with the method selected. Advanced provision of emergency contraceptive pills is also recommended should patients miss pills and have unprotected sex. The effectiveness of COCs depends on adherence, and it can be difficult for any patient to remember to take a pill each day. Figures 160.3 and 160.4 list the rules for missed pills or after vomiting or diarrhea.

COCs contain between 50 μg and 10 μg of an estrogenic substance, typically **ethinyl estradiol**, and as many as 10 progestins are available in the United States for combined pills. Multiple preparations are available to help select the formulation that satisfies an individual patient, with minimal side effects. Studies looking at the effects of estrogen dosing on bone health have found lower rates of bone accrual in those taking COCs containing 20 mcg as compared with nonusers. It is recommended that adolescents start on a COC containing 30-35 μg of an estrogenic substance.

COCs can be packaged as 28-day *monophasic* pills, which contain the same dose of active pills for 21 or 24 days, followed by 7 or 4 days of placebo pills, respectively. Monophasic formulations are also available for extended cycles of 91 days or 1 year so that withdrawal bleeding does not occur each month, but at the end of each extended cycle. **Extended cycling** of monophasic COCs for adolescents has some anticipated benefits associated with increased ovarian activity suppression and may decrease failure rates. Other advantages include menstrual suppression in those patients in whom that is a priority and diminished frequency of hormonal withdrawal (premenstrual) effects, including headaches and migraines, mood changes, and heavy monthly bleeding. The most common side effect of extended-cycle OCs is intermenstrual bleeding and/or spotting, with the total days of bleeding over the first year of treatment being similar for extended-cycle users and users following a 28-day-cycle regimen. The unscheduled bleeding pattern diminishes over time. *Multiphasic* pill packs contain various levels of estrogen and progestin for 21 active pills and contain 7 placebo pills. Multiphasic formulations are not available for extended-cycle use. Providers can refer to the U.S. Selected Practice Recommendations for Contraceptive Use to counsel patients on how to manage late or missed COCs.

The short-term adverse effects of COCs, such as nausea and weight gain, often interfere with compliance in adolescent patients. These effects are usually transient and may be overlooked by the beneficial effects of a shortened menses and the relief of dysmenorrhea. The inhibition of ovulation or the suppressant effect of estrogens on prostaglandin production by the endometrium makes COCs effective in preventing dysmenorrhea (see Chapter 159). Acne is typically improved by COCs, as estrogen can reduce the effects of circulating androgens. There is no evidence that one particular COC is superior to

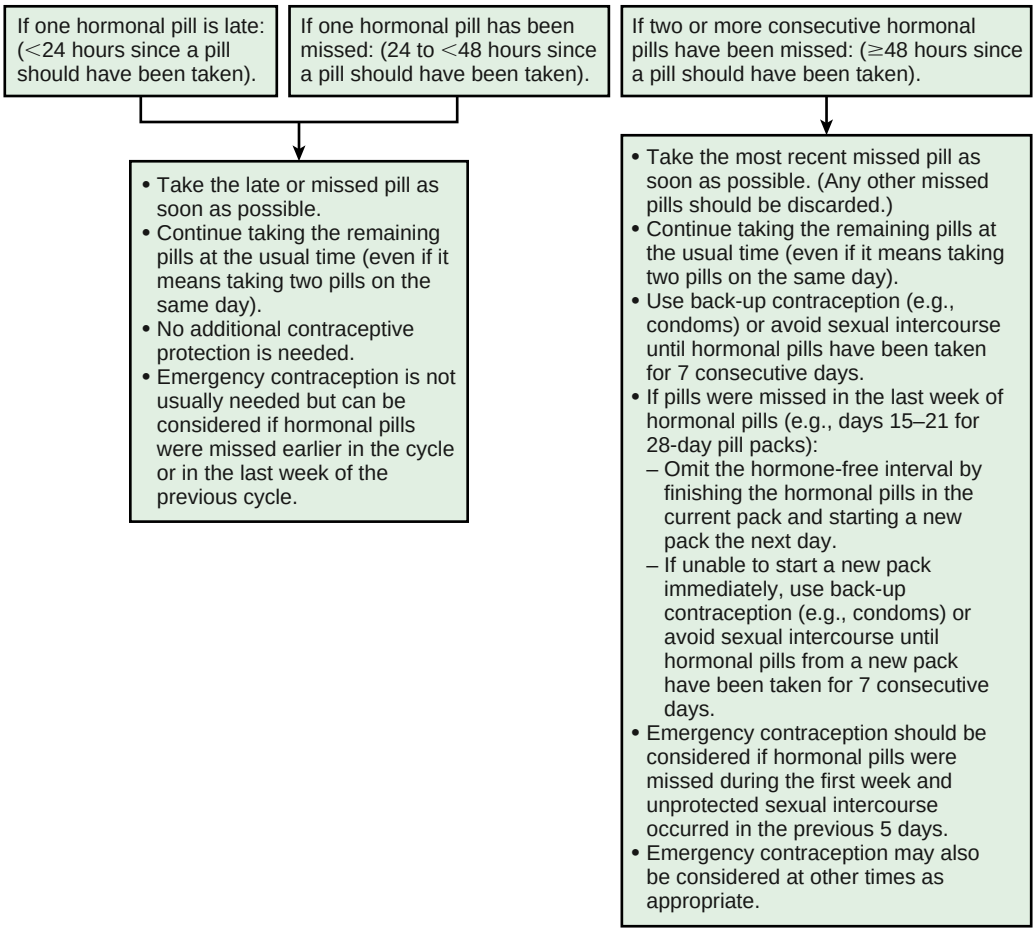

Fig. 160.3 Algorithm showing recommended actions after late or missed combined oral contraceptives. (*From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016. MMWR Recomm Rep 2016;65[RR-4]:1–66, Fig. 2, p. 28.*)

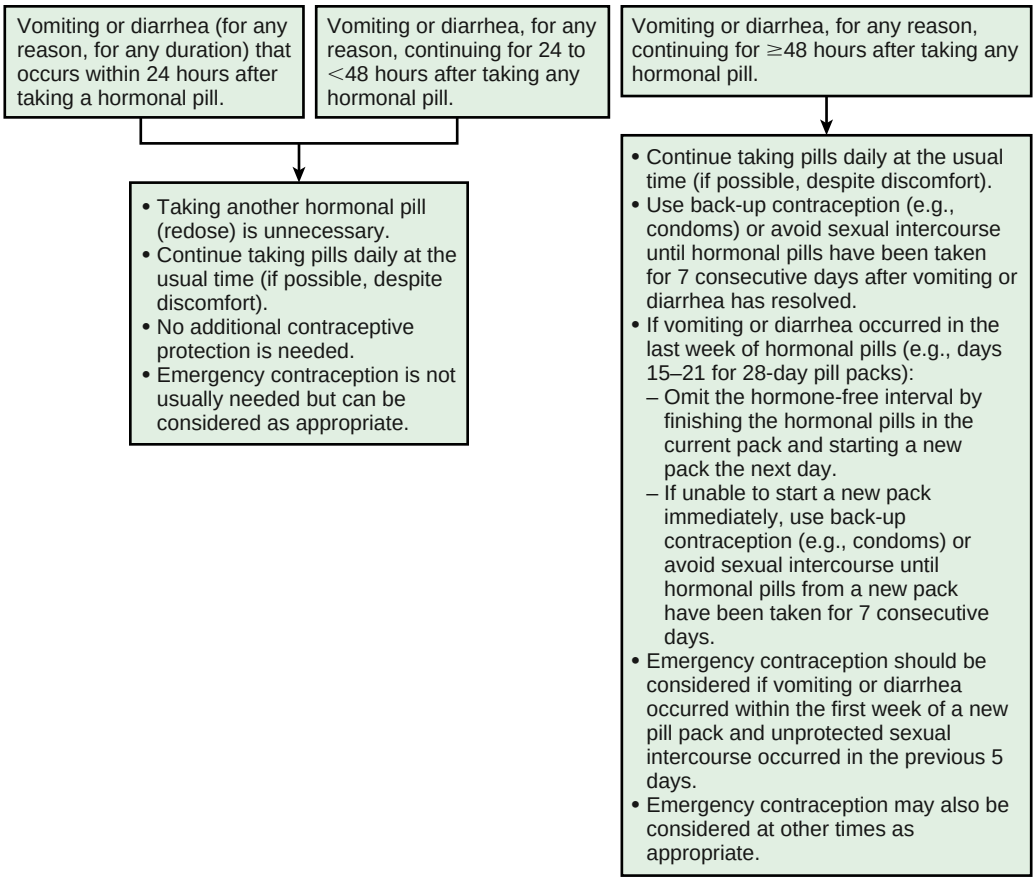

Fig. 160.4 Algorithm showing recommended steps after vomiting or diarrhea while using combined oral contraceptives. (*From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016. MMWR Recomm Rep 2016;65[RR-4]:1–66, Fig. 5, p. 30.*)

another in targeting acne, but theoretically it would be better to use a pill with nonandrogenic progestins (see Chapter 710). **Drospirenone**, a progestin with antimineralocorticoid activity, has been shown to reduce premenstrual symptomatology, but the potential for hyperkalemia as a side effect eliminates patients with renal, liver, or adrenal diseases and patients taking certain medications.

The FDA has concluded that drospirenone-containing OCs may be associated with a higher risk of VTE than other progestin-containing pills. Although no studies have provided consistent estimates of the comparative risk of VTE between OCs that contain drospirenone and those that do not, or accounted for patient characteristics that may affect VTE risk, there has been a threefold increased risk of VTE reported for drospirenone-containing pills as compared with products containing levonorgestrel or other progestins. As a result, the FDA requires that labeling be revised for the OCs marketed under the Beyaz, Safyral, Yasmin, and Yaz brands. This clot risk has not been established for Slynd, which contains 4 mg of drospirenone and no estrogenic component. Despite the risk of VTE with all OCs, the absolute risk remains lower than the risk of developing VTE during pregnancy or the postpartum period.

TRANSDERMAL PATCH

The transdermal patch releases a combination of ethinyl estradiol and a progestin daily. It is applied to the lower abdomen, buttocks, or upper body, excluding the breasts. It is worn continuously for 1 week and changed weekly for a total of 3 weeks, then no patch is worn for the fourth week, at which time bleeding occurs (see Table 160.1). Limited studies in adolescents suggest higher rates of partial or full detachment compared with adults, with high patient satisfaction and 50–83% continuation rates from 3 to 18 months of use (Fig. 160.5). As with other combined hormonal methods, the patch is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed application or detachment of the patch.

The first patch available was Ortho Evra, now available only in a generic version called Xulane. It releases 35 μg ethinyl estradiol and 150 μg norelgestromin daily. Compared with the pharmacokinetics of COCs, the area under the curve for the patch is about 55% higher for patch users. This caused concerns about increased risk of clots with higher estrogen exposure, although there have been no data to confirm this risk. Studies to date have had conflicting data on the risk of VTE in patients using nonoral combined hormonal contraception. There is also concern for efficacy of the patch in those whose weight was >90 kg, and this should be discussed with patients in consideration of use. The Xulane patch can be used to extend cycles similar to COC extended-cycle pills. Patients may choose to wear patches consecutively without any "patch-free week" but should be aware that this can carry a risk of breakthrough bleeding, as occurs with extended-cycle COC use.

In 2020 Twirla was developed to address the need for a lower-dose product to reduce the cumulative estrogen exposure from patch use. Twirla releases 30 μg ethinyl estradiol (EE) and 120 μg levonorgestrel (LNG) daily, and the maximum steady-state concentrations were 60% (EE) and 18% (LNG) as compared with Xulane. Initial studies did not demonstrate a significantly decreased clot risk as compared to other methods of combined hormonal contraception, but as with Xulane, efficacy seemed to be affected by body mass index (BMI), in particular in those who were categorized by BMI as obese. Twirla was not studied for extended use.

VAGINAL RING

The vaginal contraceptive ring is a flexible, transparent, colorless vaginal ring that is inserted into the vagina by the patient. It releases a daily dose of ethinyl estradiol and a progestin. It remains in place for 3 weeks, during which time these hormones are absorbed. It is then typically

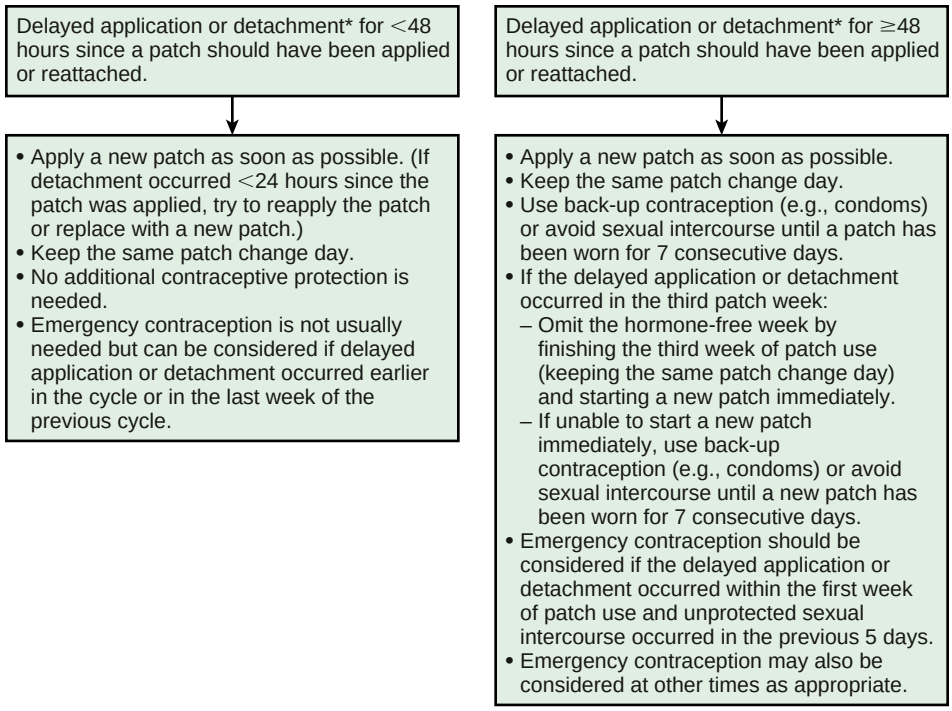

Fig. 160.5 Algorithm showing recommended actions after delayed application or detachment with combined hormonal patch. (*From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. Selected practice recommendations for contraceptive use, 2016. MMWR Recomm Rep 2016;65[RR-4]:1–66, Fig. 3, p. 28.*)

removed for 7 days during which time a withdrawal bleed should occur. If the ring is accidentally expelled or removed for intercourse, it should be reinserted; however, if it is out of place ≥48 hours or the ring is not replaced within 7 days after removal, a backup method of contraception should be used (Fig. 160.6). The vaginal ring is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed insertion or reinsertion with the vaginal ring.

The first contraceptive ring available was NuvaRing, which measures about 2.1 inches in diameter and releases 1 μg ethinyl estradiol and 120 μg etonogestrel daily. Users use one ring per 4-week cycle with 3 weeks in and 1 week out and a scheduled withdrawal bleed. It should be noted that although it is labeled for 28 days of use, it contains enough hormones to be used for up to 35 days and can be replaced once every calendar month. The ring can be used to extend cycles similar to COC extended-cycle pills. Patients may choose to use the Nuva Ring consecutively without any "ring-free week" but should be aware that this can carry a risk of breakthrough bleeding, as occurs with extended-cycle COC use. Annovera is FDA approved and offers a single ring, which can be reused for 13 consecutive cycles and does not require refrigeration when not in use. Annovera has a diameter of about 2.2 inches and releases 13 μg of EE and 150 μg of segesterone acetate daily. It has not been studied for extended use, and initial studies did not include those with a BMI >29 kg/m^2.

CONTRAINDICATIONS

Contraceptive counseling should include a discussion and assessment for any absolute or relative contraindications to estrogen use. Contraindications to the use of estrogen-containing methods include those conditions for which CHCs pose an unacceptable health risk (Category 4) in the U.S. MEC for Contraceptive Use (see Table 160.3); current breast cancer; severe cirrhosis, acute deep venous thrombosis/pulmonary embolism (DVT/PE) or history of DVT/PE with higher risk for recurrence, major surgery with prolonged immobilization, diabetes with nephropathy, retinopathy, or neuropathy, migraines with focal neurologic aura, stage II hypertension, vascular disease, ischemic heart disease, hepatocellular adenoma or malignant liver tumors, multiple risk factors for cardiovascular disease, peripartum cardiomyopathy, postpartum <21 day, complicated solid-organ transplantation, history of cerebrovascular accident, systemic lupus erythematosus with positive antiphospholipid antibodies, thrombogenic pathogenic variants, and complicated valvular heart disease. The initial history taken before prescribing CHCs should specifically address these risks. The U.S. MEC provides contraceptive safety guidance with >1,800 recommendations for >120 medical conditions or characteristics. According to the MEC, obesity is not a contraindication to estrogen or contraceptive use, and these adolescents would be considered at high risk for pregnancy complications. Therefore adolescents with obesity should be counseled on and offered contraception when indicated and if desired by the patient.

Other things to discuss and consider when evaluating an adolescent for COC use are a family history of blood clots or clotting disorders and any medications that might interact with COCs. If a patient has a first-degree relative with history of VTE, evaluation for a familial thrombophilia is advisable. There are few medication interactions for progestin-only methods, but there are medications that may be affected by or affect levels of COCs. This includes certain anticonvulsants and psychotropic medications as well as herbal supplements, which may affect COC levels. The CDC has a resource for antiretrovirals and their potential for interactions with hormonal contraception. Lexicomp and UpToDate provide additional information on interactions with COCs.

160.6 Emergency Contraception

Mary E. Romano and Elizabeth M. Alderman

Unprotected intercourse at mid-cycle carries a pregnancy risk of 20–30%. At other times during the cycle, the risk is 2–4%. Emergency

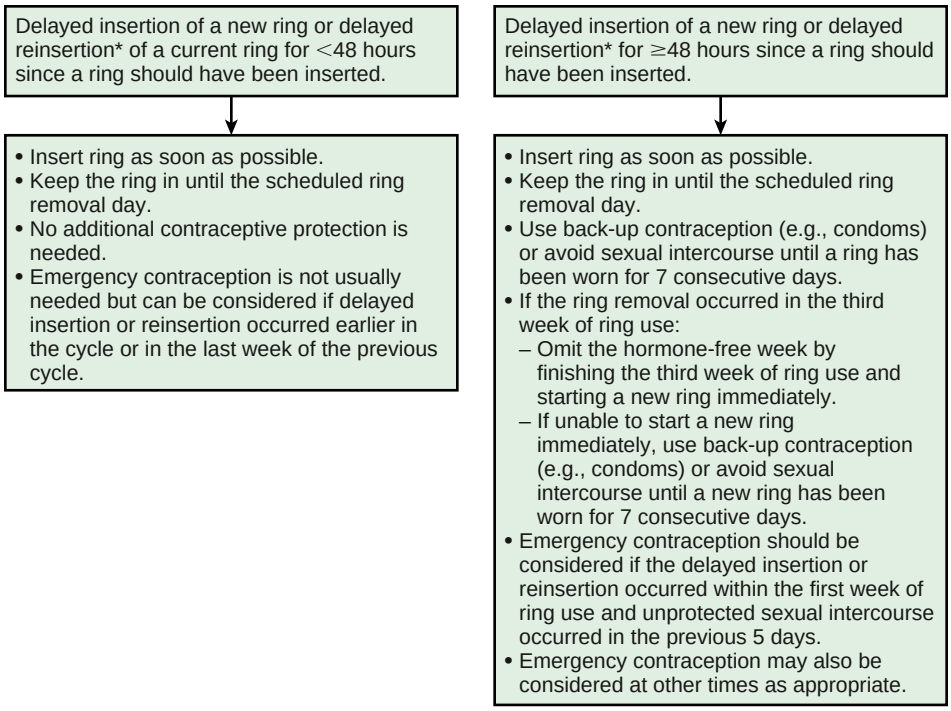

Fig. 160.6 Algorithm showing recommended actions after delayed insertion or reinsertion with combined vaginal ring. (*From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016. MMWR Recomm Rep 2016;65[RR-4]:1–66, Fig. 4, p. 29.*)

Table 160.5 Possible Indications for Emergency Contraception

SEXUAL ASSAULT
HIGH-RISK SEXUAL ACTIVITY
No contraception during intercourse
Intoxication (alcohol, drugs)
Coitus interruptus
CONTRACEPTION FAILURES
Condom breaking, spillage, leaks, intentional removal
Dislodgement and/or breaking of diaphragm, female condom, cervical cap
Expulsion of IUD
Spermicide failure to melt before coitus
DELAYED OR MISSED CONTRACEPTION
2 consecutive missed days of combined oral contraceptive
1 missed day of progestin-only oral contraceptives
>2-wk late injection of depot medroxyprogesterone
≥2 days late start of vaginal ring or patch cycle
Incorrect timing of spermicide/gel before sexual activity
OTHER
Exposure to teratogens in the absence of contraception

IUD, Intrauterine device.

contraception (EC) refers to methods of contraception that are used after sexual intercourse to reduce the risk of pregnancy but do not interrupt an existing pregnancy. EC may be used up to 120 hours after unprotected intercourse or contraceptive failure. Table 160.5 lists the indications for use of EC. EC methods include the Cu IUD, LNG 52-mg IUD, and emergency contraceptive pills, which include ulipristal acetate, LNG, and COCs following the Yuzpe method. Although the mechanism of action of the IUD as EC is unclear, all emergency contraceptive pills work to delay ovulation and are effective only for intercourse that occurs before administration. Initiation of a regular contraceptive method is necessary to prevent pregnancy for any intercourse that occurs for the remainder of the cycle and for future cycles. If pregnancy has already occurred, emergency contraceptive pills will not terminate an existing pregnancy or have teratogenic effects on the fetus.

Teens can access EC information through a hotline at 888-NOT-2-LATE to obtain EC pills over the counter (OTC). The Guttmacher Institute maintains an up-to-date listing on EC. The ACOG and AAP recommend advance provision of EC pills for at-risk adolescents to remove barriers to access and increase awareness of the utility of EC. No examination or testing is required before use of EC, but a follow-up appointment is recommended to determine the effectiveness of treatment and to diagnose a possible early pregnancy. The visit also provides an opportunity to counsel the adolescent, explore the situation leading up to the unprotected intercourse or contraceptive failure, test for STIs, offer HIV testing, and engage in a discussion about contraception when appropriate. It is also important to engage adolescent males in discussions about the availability and use of EC if they have engaged in unprotected intercourse, especially when and how to access Plan B, which is available OTC.

COPPER IUD

The CuT380A (Paragard) is not FDA approved for EC, but it has been shown to be >99% effective if used within 5 days (120 hours) after unprotected sex. The additional benefit of using the Cu IUD for EC is that it also provides long-term reversible contraception. Efficacy of the Cu-IUD is not affected by BMI.

LNG 52-mg IUD

The Mirena IUD is not FDA approved for EC, but studies have shown it is as effective/noninferior to the Cu-IUD for EC if used within 5 days (120 hours) after unprotected sex. Similar to the Cu-IUD, it also provides long-term reversible contraception and efficacy is not affected by BMI.

ULIPRISTAL ACETATE

Ulipristal acetate (UPA) is available for EC and is FDA approved for use up to 120 hours after unprotected sex. UPA is available only by prescription regardless of age. A few studies have shown it to be more effective than LNG at and beyond 72 hours. If starting OC pills after taking UPA, it is recommended to start or resume pills no sooner than 5 days after taking UPA to avoid decreased efficacy of contraceptive pills as a result of its antiestrogenic effect. Studies have shown an increased risk of ovulation if COC pills are started immediately after UPA use. Studies have not looked at UPA efficacy when Depo or a progestin-containing LARC is initiated immediately after UPA use. If starting a method requires an extra visit (e.g., IUDs, implant, Depo-Provera), starting the method at the time of ulipristal use may be considered, weighing the risk of decreasing the effectiveness of ulipristal with the risk of not starting a contraceptive method. Patients should be encouraged to take a pregnancy test within 3 weeks after UPA use either in the office or on their own. Studies have suggested UPA is less effective in overweight and obese women (BMI >25). This should be discussed with patients, and all attempts should be made to provide UPA as soon as possible after unprotected sexual activity.

LEVONORGESTREL

In 2013 the FDA approved the emergency contraceptive drug **Plan B** One-Step as an OTC option for all persons of childbearing potential. Experience with adolescents has demonstrated more effective use of EC with advance provision, and this is not associated with more frequent unprotected intercourse or less condom and/or pill use. Nausea and vomiting are uncommon side effects, and LNG has been shown to be more effective at preventing pregnancy than the Yuzpe method. However, LNG has been shown to be less effective than UPA when taken ≥72 hours and in women who are obese and overweight (BMI >25). This should be discussed with women in deciding with EC method is most appropriate for use. Patients should be encouraged to take a pregnancy test within 3 weeks after EC use either in the office or on their own.

Yuzpe Method

The **Yuzpe method** has been replaced by the more effective methods of EC, but may be useful for women who do not have access to other methods and/or already have COCs at home and desire EC. It is most effective when taken up to 72 hours after unprotected intercourse. For EC, COC pills with 200 µg ethinyl estradiol and 2 mg norgestrel or 1 mg levonorgestrel should be taken in two doses, 12 hours apart. This method is effective in reducing the risk of pregnancy by 75%. The most common side effects are nausea (50%) and vomiting (20%), prompting some clinicians to prescribe or recommend antiemetics along with the COCs.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

160.7 Condoms

Mary E. Romano and Elizabeth M. Alderman

The use of condoms is the only contraceptive method that protects against pregnancy and STIs, including HIV. Condoms, also referred to as *barrier contraception,* prevent sperm from being deposited in the vagina. The use of condoms in conjunction with hormonal contraception (or Cu IUD) is always recommended to reduce the risk of pregnancy and protect against STIs. This is sometimes referred to as *dual protection.* Although correct and consistent condom use with every act of sexual intercourse theoretically protects against pregnancy and STIs, providers should encourage adolescents to use condoms for STI/HIV protection along with a more effective method for pregnancy protection.

No major medical side effects are associated with condom use, and condoms are available for use by males and females. Nonlatex condoms are available for those with a latex allergy, and these include lambskin and synthetic polyurethane condoms. Lambskin condoms do not protect against HIV and other viral infections, although they do work to prevent pregnancy. Although condom use at last sexual intercourse had steadily increased from the early 1990s to the mid-2000s, the percentage of students reporting condom use at last intercourse has remained stable, with 54% of adolescents reporting condom use at last intercourse. Earlier increases in condom use were thought to be the result of increased awareness of HIV risks. Only 9% of high school students reported using dual methods of contraception (condom plus something else) at last intercourse. The main advantages of condoms are their low price, availability without prescription, male involvement in the responsibility for contraception, and effectiveness in preventing transmission of STIs, including HIV and human papillomavirus (HPV). The typical-use failure rate for male condoms is 18% for all users and is thought to be higher in adolescents. For the most effective dual protection, male latex condoms are recommended as protection against STIs and should be used in conjunction with another method of contraception. According to the National Survey of Family Growth, only 21.3% of females used another contraceptive method along with a condom at last sex during the past 12 months.

There is only one female condom available in the United States. It is available OTC or can be ordered online. It is nonlatex. It can be harder to use properly and has a higher typical-use failure rate (21%) than the male condoms. There are no human studies demonstrating its effectiveness against STIs. Adolescents intending to use this method should be provided education on proper use and hands-on practice to ensure effective use.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

160.8 Other Barrier Methods

Mary E. Romano and Elizabeth M. Alderman

Although these methods are not widely available or used, they are important to know about for patients who wish to use nonhormonal contraception at the time of intercourse.

DIAPHRAGM, CERVICAL CAP, AND SPONGE

These methods have few side effects but are much less likely to be used by teenagers. Typical-use failure rates exceed 14%. The sponge has limited OTC availability in the United States, and the cervical cap and diaphragm require a visit with a healthcare provider for fitting. The **cervical cap** and **sponge** have lower failure rates in nulliparous women, whereas the **diaphragm** has similar rates among nulliparous and parous women. The sponge is used with water, whereas the cervical cap and diaphragm are used with spermicide before being placed over the cervix. Adolescents may feel less comfortable and be less likely to use these methods because of the messiness of the jelly or the need for insertion and removal interrupting the spontaneity of sex (to be inserted before sex and left in for several hours afterward). Spermicide must be reapplied before every act of intercourse. Adolescents may also be less comfortable touching their genitals.

160.9 Other Contraceptive Methods

Mary E. Romano and Elizabeth M. Alderman

The only OTC spermicide available in the United States is Nonoxynol-9 (N-9). It is available as a foam, film, gel, cream, suppository, and tablet. It must be placed in the vagina no more than 1 hour before intercourse and again before each act of intercourse/ejaculation. Side effects, although rare, include local irritation or contact vaginitis. There have been concerns about the vaginal and cervical mucosal damage observed with N-9 and its impact on HIV transmission. Results thus far have been inconclusive. There were some studies that suggested that N-9 is gonococcicidal and spirocheticidal, but this has not been substantiated in randomized clinical trials. Spermicides should be used in combination with barrier methods because their typical-use failure rate alone is 21%

Phexxi is a prescription vaginal gel that is FDA approved. It is nonhormonal and user controlled. It can be used alone or in conjunction with other methods, although it is not recommended for use with the intravaginal ring. It is prepackaged in a single-dose applicator and must be inserted intravaginally up to 1 hour before vaginal intercourse. It works to maintain vaginal pH in an acidic range (~3.5 to 4.5) despite the presence of alkaline semen/sperm, which limits motility and incapacitates sperm. When compared with other OTC spermicidal gels, Phexxi has a higher viscosity, which minimizes vaginal leakage of the product and is thought to further affect sperm motility and provide an additional barrier to cervical penetration. Data also suggest Phexxi may have microbicidal effects in that by maintaining an acidic vaginal pH, Phexxi may enhance the vagina's natural microbicidal mechanisms. This effect seems more consistent and reliable than what has been found with the use of N-9. As with N-9, the most commonly reported side effect was vaginal discomfort and irritation. There has been no evidence that it affects HIV transmission. It should not be used in women with recurrent urinary tract infections (UTIs) or any urinary tract abnormalities.

WITHDRAWAL

The pregnancy risk with use of withdrawal as a contraceptive method is probably underestimated in adolescents, and a high typical-use failure rate of 20% should be specifically addressed with all adolescents, given that up to 60% of teens have reported using withdrawal for contraception.

FERTILITY AWARENESS–BASED METHODS

Fertility awareness methods require that one be aware of the fertile days of their menstrual cycle and either avoid intercourse during that time or use barrier contraception. Methods typically involve calculating the length of one's menstrual cycle, observing changes in body temperature and/or cervical secretions. Fertility awareness methods are based on regular ovulatory cycles, which are less common in teens, and therefore fertility awareness methods may be difficult for a teenager to use effectively. Methods include the Standard Days method, basal body temperature method, Billings method, and lactational amenorrhea. Be aware that the lactational amenorrhea method may be a highly effective, temporary contraceptive method if the following criteria are met: (1) no return of menses, (2) the infant is <6 months old, and (3) the woman is exclusively breastfeeding. There is an FDA-approved mobile application—Natural Cycles—that may be used to best predict fertility days to plan for abstinence or barrier contraceptive use. Other apps do exist, but they are not FDA approved.

Chapter 161

Adolescent Pregnancy

Cora Collette Breuner

EPIDEMIOLOGY

There has been a trend of decreasing teen births and pregnancies since 1991 (Fig. 161.1). Teen birthrates in the United States are at a historic low secondary to increased use of contraception at first intercourse, use of dual methods of condoms and hormonal contraception among sexually active teenagers, and access to abortion (see Chapter 161.1). Despite these data, the United States continues to lead other industrialized countries in having high rates of adolescent pregnancy, with >700,000 pregnancies per year. Nonetheless, the National Survey of Family Growth (NSFG) 2006–2010 revealed that less than one third of 15- to 19-year-old females consistently used contraceptive methods at last intercourse.

The improvement in U.S. female teen birthrates is attributed to three factors: more teens are delaying the onset of sexual intercourse, are using some form of contraception when they begin to have sexual intercourse, and are using long-lasting contraceptive agents such as injections, implants, and intrauterine devices (IUDs).

Most pregnancies among U.S. adolescents are **unintended** (unwanted or mistimed); 88% of births to teenagers 15-17 years old were the result of unintended pregnancies. Birthrate statistics underestimate actual adolescent pregnancy rates because the birthrate numerator includes the number of actual births per 1,000 individuals in that age-group, but the pregnancy rate includes actual births, abortions, and best estimates of fetal loss per 1,000 adolescents in that age-group.

The *reported* **abortion** rate among adolescents in 2019 for those <15 years of age was 0.4 per 1,000 females (of the same age-group), and for those 15-19 years, it was 6.0 per 1,000; this compares to the most common age for having an abortion (20-29) of 18-19 per 1,000 females. It is unknown how many abortions go unreported (see Chapter 161.1).

ETIOLOGY

In industrialized countries with policies supporting access to protection against pregnancy and sexually transmitted infections **(STIs)**, older adolescents are more likely to use hormonal contraceptives and condoms, resulting in a lowered risk of unplanned pregnancy. Younger teenagers are likely to be less deliberate and logical about their sexual decisions, and their sexual activity is likely to be sporadic or even coercive, contributing to inconsistent contraceptive use and a greater risk of unplanned pregnancy. Better personal hopes for employment and higher educational goals are associated with lowered probability of childbearing in most groups. In nonindustrialized countries, laws permitting marriage of young and mid-teens, poverty, and limited female education are associated with increased adolescent pregnancy rates.

CLINICAL MANIFESTATIONS

Adolescents may experience the traditional symptoms of pregnancy: morning sickness (vomiting, nausea that may also occur *any* time of the day), swollen tender breasts, weight gain, and amenorrhea. Often the presentation is less classic; headache, fatigue, abdominal pain, dizziness, and scanty or irregular menses are common presenting complaints.

In the pediatric office, some teens are reluctant to divulge concerns of pregnancy. Denial of sexual activity and menstrual irregularity should not preclude the diagnosis in face of other clinical or historical information. An unanticipated request for a complete checkup or a visit for contraception may uncover a suspected pregnancy. *Pregnancy is still the most common diagnosis when adolescents present with secondary amenorrhea.*

DIAGNOSIS

Table 161.1 provides classic symptoms, laboratory tests, and physical changes in the diagnosis of pregnancy.

On physical examination, the findings of an enlarged uterus, cervical cyanosis **(Chadwick sign)**, a soft uterus **(Hegar sign)**, or a soft cervix **(Goodell sign)** are highly suggestive of an intrauterine pregnancy. A confirmatory pregnancy test is always recommended, either *qualitative* or *quantitative*. Modern **qualitative** urinary detection methods are efficient at detecting pregnancy, whether performed at home or in the office. These tests are based on detection of the beta subunit of human chorionic gonadotropin **(hCG)**. Although claims for nonprescription home pregnancy tests may indicate 98% detection on the day of the first missed menstrual period, sensitivity and accuracy vary considerably. Office or point-of-care tests have increased standardization and generally have increased sensitivity, with the possibility of detecting a pregnancy within 3-4 days after implantation. However, in any menstrual cycle, ovulation may be delayed, and in any pregnancy, the day of implantation may vary considerably, as may rate of production of hCG. This variability, along with variation of urinary concentration, may affect test sensitivity. *Consequently, each negative test should be*

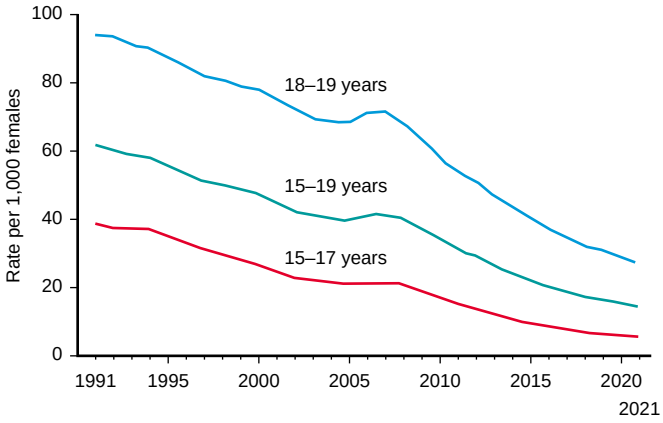

Fig. 161.1 Birth rates for teenagers by age of mother: United States, final 1991–2020 and provisional 2021. Source: National Center for Health Statistics, National Vital Statistics System, Natality. (*From Hamilton BE, Martin JA, Osterman JA, Division of Vital Statistics, National Center for Health Statistics. Births: provisional data for 2021. Nat Vital Stats Rapid Release. 2022;20, Fig. 2.*)

Table 161.1 Diagnosis of Pregnancy Dated from First Day of Last Menstrual Cycle

CLASSIC SYMPTOMS
Missed menses, breast tenderness, nipple sensitivity, nausea, vomiting, fatigue, abdominal and back pain, weight gain, urinary frequency.
Teens may present with unrelated symptoms that enable them to visit the doctor and maintain confidentiality.
LABORATORY DIAGNOSIS
Tests for human chorionic gonadotropin in urine or blood may be positive 7-10 days after fertilization, depending on sensitivity.
Irregular menses make ovulation/fertilization difficult to predict.
Home pregnancy tests have a high error rate.
PHYSICAL CHANGES
2-3 wk after implantation: cervical softening and cyanosis.
8 wk: uterus size of orange.
12 wk: uterus size of grapefruit and palpable suprapubically.
20 wk: uterus at umbilicus.
If physical findings are not consistent with dates, ultrasound will confirm.

repeated in 1-4 weeks if there is a heightened suspicion of pregnancy. The most sensitive pregnancy detection test is a serum **quantitative βhCG radioimmunoassay**, with reliable results within 7 days after fertilization. This more expensive test is used primarily during evaluations for ectopic pregnancy, to detect retained placenta after pregnancy termination, or in the management of a molar pregnancy. It is used when serial measurements are necessary in clinical management.

Although not used for primary diagnosis of pregnancy, pelvic or vaginal **ultrasound** can be helpful in detecting and dating a pregnancy. Pelvic ultrasound will detect a gestational sac at about 5-6 weeks (dated from last menstrual period) and vaginal ultrasound at 4.5-5 weeks. This tool may also be used to distinguish diagnostically between intrauterine and ectopic pregnancies.

PREGNANCY COUNSELING AND INITIAL MANAGEMENT

Once the diagnosis of pregnancy is made, it is important to begin addressing the psychosocial and the medical aspects of the pregnancy. The patient's response to the pregnancy should be assessed and her emotional issues addressed. It should not be assumed that the pregnancy was unintended. Discussion of the patient's options should be initiated. These options include (1) releasing the child to an adoptive family, (2) electively terminating the pregnancy, and (3) raising the child herself with the help of family, father of the baby, friends, and/or other social resources. Options should be presented in a supportive, informative, nonjudgmental fashion; for some young women, they may need to be discussed over several visits. Physicians who are uncomfortable in presenting options to their young patients should refer their patients to a provider who can provide this service expeditiously. Pregnancy terminations implemented early in the pregnancy are generally less risky and less expensive than those initiated later. These include the prescription use of mifepristone and misoprostol within 10 weeks (the World Health Organization [WHO] recommends 12 weeks) of the pregnancy (see Chapter 161.1).

Other issues that may need discussion are how to inform and involve the patient's parents and the father of the infant; implementing strategies for ensuring continuation of the young mother's education; discontinuation of tobacco, alcohol, and illicit drug use; discontinuance and avoidance of any medications that may be considered teratogenic; starting folic acid, calcium, and iron supplements; proper nutrition; and testing for STIs. Especially in younger adolescents, the possibility of **coercive sex** (see Chapter 162) must be considered and appropriate social work/legal referrals made if abuse has occurred, although most pregnancies are not a result of coercive sex. Patients who elect to continue their pregnancy should be referred as soon as possible to an adolescent-friendly obstetric provider.

Risk factors for teen pregnancy include growing up in poverty, having parents with low levels of education, growing up in a single-parent family, fewer opportunities in their community for positive youth involvement, neighborhood physical disorder, foster care (such teens are more than twice as likely to become pregnant than those not in foster care), and having poor performance in school (see "Psychosocial Outcomes/Risks for Mother and Child" later).

The Importance of Prevention

Teen pregnancy and childbearing bring substantial social and economic costs through immediate and long-term impacts on teen parents and their children. In 2010, teen pregnancy and childbirth accounted for at least $9.4 billion in costs for increased healthcare and foster care, increased incarceration rates among children of teen parents, and lost tax revenue because of lower educational attainment and income among teen mothers.

ADOLESCENT FATHERS

Those who become fathers as adolescents also have poorer educational achievement than their age-matched peers. They are more likely than other peers to have been involved with illegal activities and with the use of illegal substances. Adult men who father the children of teen mothers are poorer and educationally less advanced than their age-matched peers and tend to be 2-3 years older than the mother, but any combination of age differences may exist. Younger teen mothers are more likely to have a greater age difference between themselves and the father of their child, raising the issue of coercive sex or statutory rape (see Chapter 162).

Male partners have a significant influence on the young woman's decision/desire to become pregnant and to parent her child. Sensitively and appropriately including the male partner in discussions of family planning, contraception, and pregnancy options may be a useful strategy in improving outcomes for all. This can only be successful if the young female patient is willing to have her partner involved in such discussions.

MEDICAL COMPLICATIONS OF MOTHERS AND BABIES

Although pregnant teens are at higher-than-average risk for some complications of pregnancy, most teenagers have pregnancies that are without major medical complications, delivering healthy infants. The

miscarriage/stillbirth risk for adolescents is estimated at 15–20%. In the United States, elective pregnancy termination rates peaked from 1985 to 1988 at 41–46%, decreasing since then to approximately 30% in 2008. Teen mothers have low rates of age-related chronic disease (diabetes or hypertension) that might affect the outcomes of a pregnancy. They also have lower rates of twin pregnancies than older women. They tolerate childbirth well with few operative interventions. However, compared with 20- to 39-year-old mothers, teens have higher incidences of low birthweight infants, preterm infants, neonatal deaths, passage of moderate to heavy fetal meconium during parturition, and infant deaths within 1 year after birth. The highest rates of poor outcomes occur in the youngest and most economically disadvantaged mothers. *Gastroschisis,* although rare, has a much higher incidence in infants of teen mothers, for reasons that are unclear. Teen mothers also have higher rates of anemia, pregnancy-associated hypertension, and eclampsia, with the youngest teens having rates of pregnancy-associated hypertension higher than the rates of women in their 20s and 30s. The youngest teens also have a higher incidence of poor weight gain (<16 lb) during their pregnancy. This correlates with a decrease in the birthweights of their infants. Poor maternal weight gain also has correlated strongly with teens' late entrance into prenatal care and with inadequate use of prenatal care. Sexually active teens have higher rates of STIs than older sexually active women.

Globally, many young women who become pregnant have been exposed to violence or abuse in some form during their lives. There is some evidence that teenage women have the highest rates of **violence** during pregnancy of any group. Violence has been associated with injuries and death as well as preterm births, low birthweight, bleeding, substance abuse, and late entrance into prenatal care. An analysis of the Pregnancy Mortality Surveillance System indicates that in the United States 1991–1999, homicide was the second leading cause of injury-related deaths in pregnant and postpartum women. Women age 19 years and younger had the highest pregnancy-related homicide rate (see Chapter 156).

Ectopic pregnancy occurs in 1–2% of conceptions and is more common in women with a previous history of an ectopic pregnancy, pelvic inflammatory disease, prior appendicitis, infertility, in utero exposure to diethylstilbestrol, and possibly an IUD. Most ectopic pregnancies are in the fallopian tube (tubal pregnancy). Manifestations include vaginal spotting after a missed menstrual period that may progress to more intense vaginal bleeding (suggestive of spontaneous abortion); vaginal bleeding is absent in 10–20%. Abdominal pain is associated with distention of the fallopian tube; tubal rupture results in more intense pain, hemorrhagic shock, and peritonitis. Some women have nonspecific abdominal complaints and are misdiagnosed with gastroenteritis. Cervical motion and adnexal tenderness (and adnexal mass) may be present. **Transvaginal sonography** (not transabdominal) is the diagnostic test of choice to detect an ectopic pregnancy and reveals an adnexal mass and no uterine pregnancy. Nonetheless, some women will have pregnancy of unknown location by transvaginal sonography; approximately 20% of these will have an ectopic pregnancy. Measurement of sensitive quantitative serum βhCG levels together with transvaginal sonography has value in diagnosing an ectopic pregnancy. If the initial βhCG is above the *discriminatory zone* (level at which one expects an intrauterine pregnancy) but on transvaginal sonography there is no intrauterine pregnancy, there may be an ectopic pregnancy or an abnormal uterine pregnancy. In addition, if the βhCG is below the discriminatory level (usually <3,000 mIU/mL) with no definitive diagnosis by sonography, serial βhCG testing should be performed every 48 hours. In a normal uterine pregnancy, βhCG levels should increase approximately 50% every 48 hours; declining levels may suggest a miscarriage or an ectopic pregnancy. Some would perform a dilation and curettage and check for products of conception or follow serial βhCG levels. If there are no products of conception or if βhCG levels plateau or increase, an ectopic pregnancy is present. Treatment of unstable or advanced patients is usually by laparoscopic surgery or by laparotomy. Because of early detection, many patients remain stable *(unruptured).* Stable patients with an unruptured ectopic pregnancy may be treated with single-dose, or more often, multidose methotrexate to induce abortion. Contraindications to methotrexate in a stable patient include size of the ectopic mass (>3.5 cm) and embryonic cardiac motion.

Prematurity and low birthweight increase the perinatal morbidity and mortality for infants of teen mothers. These infants also have higher-than-average rates of sudden infant death syndrome (see Chapter 423), possibly because of less use of the supine sleep position or cosleeping, and are at higher risk of both intentional and unintentional injury (see Chapter 17). One study showed that the risk of homicide is 9-10 times higher if a child born to a teen mother is not the mother's firstborn compared with the risk to a firstborn of a woman age 25 years or older. The perpetrator is often the father, stepfather, or boyfriend of the mother.

After childbirth, **depressive symptoms** may occur in as many as 50% of teen mothers. Depression seems to be greater with additional social stressors and with decreased social supports. Support from the infant's father and the teen's mother seems to be especially important in preventing depression. Pediatricians who care for parenting teens should be sensitive to the possibility of depression, as well as to inflicted injury to mother or child; appropriate diagnosis, treatment, and referral to mental health or social agencies should be offered and facilitated.

PSYCHOSOCIAL OUTCOMES/RISKS FOR MOTHER AND CHILD

Educational Issues

Pregnancy and birth are significant contributors to high school dropout rates among girls. Only about 50% of teen mothers receive a high school diploma by age 22, whereas approximately 90% of women who do not give birth during adolescence graduate from high school. Mothers who have given birth as teens generally remain 2 years behind their age-matched peers in formal educational attainment at least through their third decade. Maternal lack of education limits the income of many of these young families (see Chapter 1).

The children of teenage mothers are more likely to have lower school achievement and to drop out of high school, have more health problems, and face unemployment as a young adult.

Substance Use

See also Chapter 157.

Teenagers who abuse drugs, alcohol, and tobacco have higher pregnancy rates than their peers. Most substance-abusing mothers appear to decrease or stop their substance use while pregnant. Use begins to increase again about 6 months postpartum, complicating the parenting process and the mother's return to school.

Repeat Pregnancy

In the United States, approximately 20% of all births to adolescent mothers (age 15-19) are second order or higher. Prenatal care is begun even later with a second pregnancy, and the second infant is at higher risk of poor outcome than the first birth. Mothers at risk of early repeat pregnancy (<2 years) include those who do not initiate long-acting contraceptives after the index birth, those who do not return to school within 6 months of the index birth, those with mood disorders, those receiving major childcare assistance from the adolescent's mother, those who are married or living with the infant's father, those having peers who were adolescent parents, and those who are no longer involved with the baby's father and who meet a new boyfriend who wants to have a child. To reduce repeat pregnancy rates in these teens, programs must be tailored for this population, preferably offering comprehensive healthcare for both the young mother and her child. Healthcare providers should remember to provide positive reinforcement for teen parenting successes (i.e., compliment teen parents when they are doing a good job).

Children Born to Teen Mothers

Many children born to teen mothers have behavioral problems that may be seen as early as the preschool period. Many drop out of school early (33%), become adolescent parents (25%), or, if male, are incarcerated (16%). Explanations for these poor outcomes include poverty, parental learning difficulties, negative parenting styles of teen parents,

maternal depression, parental immaturity, poor parental modeling, social stress, exposure to surrounding violence, and conflicts with grandparents, especially grandmothers. Continued positive paternal involvement throughout the child's life may be somewhat protective against negative outcomes. Many of these poor outcomes appear to be attributable to the socioeconomic/demographic situation in which the teen pregnancy has occurred, not solely to maternal age. Even when socioeconomic status and demographics are controlled, infants of teen mothers have lower achievement scores, lower high school graduation rates, increased risk of teen births themselves, and, at least in Illinois (where records include age of birth mother), a higher probability of abuse and neglect.

Comprehensive programs focused on supporting adolescent mothers and infants using life skills training, medical care, and psychosocial support demonstrate higher employment rates, higher income, and less welfare dependency in participating adolescents.

PREVENTION OF TEEN PREGNANCIES

Adolescent pregnancy is a multifaceted problem that requires multifactorial solutions. The provision of contraception and education about fertility risk from the primary care physician is important but insufficient to address the problem fully. Family and community involvement are essential elements for teen pregnancy prevention. Strategies for primary prevention (preventing first birth) are different from the strategies needed for secondary prevention (preventing second or more births). Over the past 30 years, many models of teen pregnancy prevention programs have been implemented and evaluated. Table 161.2 lists the common components of successful evidence-based programs.

Abstinence-only sexual education aims to teach adolescents to wait until marriage to initiate sexual activity but, unfortunately, does not mention contraception. Abstinence education is sometimes coupled with "virginity pledges" in which teenagers pledge to remain abstinent until they marry. Other educational programs emphasize HIV and STI prevention and in the process prevent pregnancy, whereas others include both abstinence and contraception in their curricula. Sex education and teaching about contraception do not lead to an increase in sexual activity. Teenagers who participate in programs with **comprehensive** sex education components generally have lower rates of pregnancy than those exposed solely to abstinence-only programs or no sex education at all.

In many U.S. communities, programs that engage youth in community service and that combine sex education and youth development are also successful in deterring pregnancy. Programs vary in their sites of service from schools to social agencies, health clinics, youth organizations, and churches. Programs must be tailored to the cultural background, ethnicity, age-group, and gender of the group being targeted for the prevention services.

Table 161.2 Common Components of Most Successful Evidence-Based Programs to Prevent Teen Pregnancy

- Information is provided about the benefits of abstinence.
- Information is provided about contraception for those who are already sexually active.
- Information is provided about the signs and symptoms of STIs and how to prevent STIs.
- Interactive sessions on peer pressure are presented.
- Teenagers are taught communication skills.
- Programs are tailored to meet the needs of specific groups of young people (e.g., young men or young women, cultural groups, younger or older teens).

STI, Sexually transmitted infection.
Adapted from Suellentrop K. *What Works 2011–2012: Curriculum-Based Programs That Help Prevent Teen Pregnancy*. Washington, DC: National Campaign to Prevent Teen and Unplanned Pregnancy, http://www.c-hubonline.org/sites/default/files/resources/main/What_Works_0.pdf.

Secondary prevention programs are fewer in number. In the United States, some communities have tried to "pay" young mothers not to become pregnant again, but these efforts have not always been fruitful. **Home visiting** by nurses has been successful in some areas, and many communities have developed "Teen Tot" clinics that provide a "one-stop shopping model" for healthcare for both the teen mother and the baby in the same site at the same time. Both programs have reported some successes.

In the practice setting, the identification of the sexually active adolescent through a confidential clinical interview is a first step in pregnancy prevention. The primary care physician should provide the teenager with factual information in a nonjudgmental manner and then guide the teenager in the decision-making process of choosing a contraceptive (see Chapter 160). The practice setting is an ideal setting to support the teenager who chooses to remain abstinent. When a teenager does become pregnant and requires prenatal care services, healthcare providers should remember that the pregnant teenager is an adolescent who has become pregnant, not a pregnant woman who happens to be an adolescent.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

161.1 Abortion

Alison S. Kliegman and Robert M. Kliegman

Abortion is a safe, common, and essential reproductive healthcare evidence–based intervention. Worldwide ~30% of all pregnancies and ~60% of all unintended pregnancies are voluntarily terminated. In the past by age 45 ~25% of U.S. pregnant persons had an abortion. The WHO defines abortion as the termination of pregnancy before 20 weeks' gestation. Abortions can be voluntary or spontaneous (miscarriages). Access to reproductive care, including abortion care, is considered by all health organizations as a basic human right. The American Academy of Pediatrics supports a young person's right of "access to comprehensive, evidence-based reproductive healthcare services, including abortion." Abortion should be available to any person requesting it without a specific indication. The most common indication is unintended (unplanned) pregnancy, which includes not being able to afford a child, poorly timed pregnancy, and not having a suitable partner; additional indications include being subjected to coercive sexual encounters, as well as medical conditions that place the pregnant person at risk and certain fatal fetal conditions.

EPIDEMIOLOGY

Most abortions occur in patients between 20 and 30 years of age (Table 161.3). In addition, the majority of abortions occur in the first trimester (Fig. 161.2). The highest ratio of abortion (number of abortions per 1,000 live births) is noted in persons <15 years (Fig. 161.3). Among 15- to 19-year-olds, the United States has one of the highest rates of adolescent pregnancy but among one of the lowest rates of adolescent pregnancies ending in abortion when compared to other developed countries (Fig. 161.4). Seventy-five percent of adolescent pregnancies in the United States are unplanned, while ~30% end with an abortion (among those 15-17 years).

Abortion Care

The WHO 2022 report recommends that:

- Abortions must be decriminalized
- Be made available at request
- Be made available by telemedicine
- Be made available for self-management, not just in clinic
- Have a wide range of eligible providers
- Provide an enabling environment (Fig. 161.5)

The National Academies of Sciences, Engineering and Medicine provides an outline for continuum of abortion care; preabortion, pregnancy termination, and post-abortion care (Fig. 161.6).

Table 161.3 Characteristics of Persons Who Had an Abortion in an Outpatient Setting in 2014, by Percent

CHARACTERISTIC	PERCENT
Age*	
<15-17	3.6
18-19	8.2
20-24	33.6
25-29	26.3
30-34	16.0
35+	12.2
Prior Pregnancies*	
No prior pregnancies	29.2
Prior birth only	26.0
Prior abortion only	11.7
Prior birth and abortion	33.1
Education*	
Not a high school graduate	12.2
High school graduate or GED	29.0
Some college or associate's degree	39.2
College graduate	19.7
Family Income as a Percentage of Federal Poverty Level†	
<100	49.3
100-199	25.7
≥200	25.0

Methods

Abortion methods vary depending on gestational age, location (in clinic vs self-managed), and procedure (medical vs surgical). Medically managed abortion ("abortion pill") is FDA approved up to 10 weeks, although the WHO suggests up to 12 weeks and has also been used "off label" at later gestational ages. It consists of mifepristone

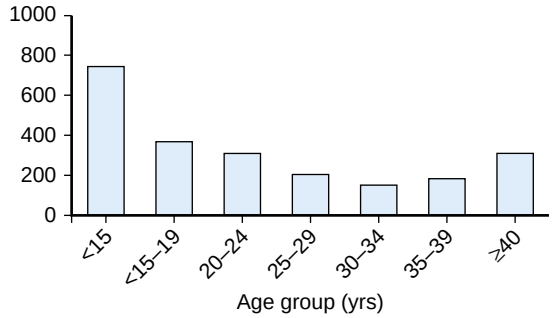

Fig. 161.3 Abortion ratio by age-group of persons who obtained a legal abortion in selected states of the United States in 2001. Abortion ratio refers to number of abortions per 1,000 live births. (*From Strauss LT, Herndon J, Chang J, et al. Abortion surveillance–United States, 2001. MMWR Surveill Summ. 2004;53:1–32.*)

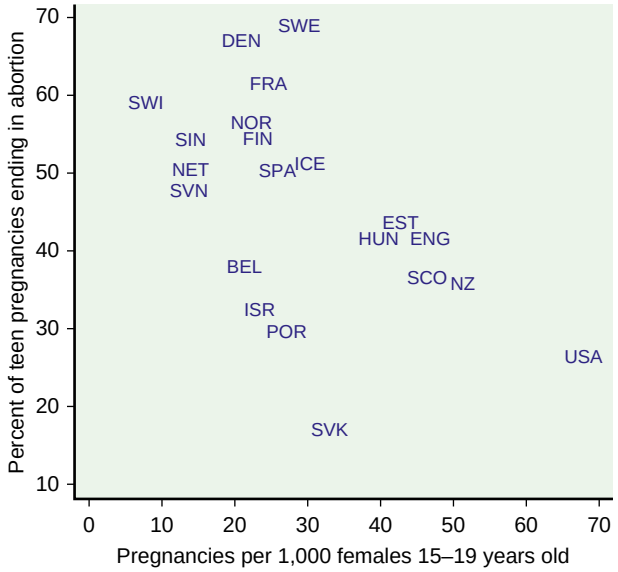

Fig. 161.4 Percentage of teen pregnancies ending in abortion is inversely correlated with teen pregnancy rate. (a potent progesterone antagonist) 200 mg PO × one dose, followed within 24-48 hours by misoprostol 800 µg (a prostaglandin to induce uterine contractions) by buccal, sublingual, or vaginal routes. Medical abortion represents ~50% of abortions in the United States (Fig. 161.7). This treatment is available in clinic but also via telehealth, where a prescriber then mails the medication to be taken at home (self-managed medical abortion). This latter mail order availability is FDA-approved. Self-managed medical abortion is safe and ~96% effective; complications are rare (~1%) and include hemorrhage or infection; no deaths have been reported from self-managed medical abortion. Contraindications include porphyria, a bleeding disorder, taking anticoagulants, adrenal insufficiency, long-term systemic steroid use, ectopic pregnancy, and the presence of an IUD.

Acute side effects during a self-managed abortion are to be expected and include nausea and vomiting, headaches, diarrhea, and flulike symptoms and, once the abortion starts, cramping and bleeding. Excessive bleeding (two or more pads per hour for >2 hours), fever (>100°F), or severe abdominal pain requires medical attention. After

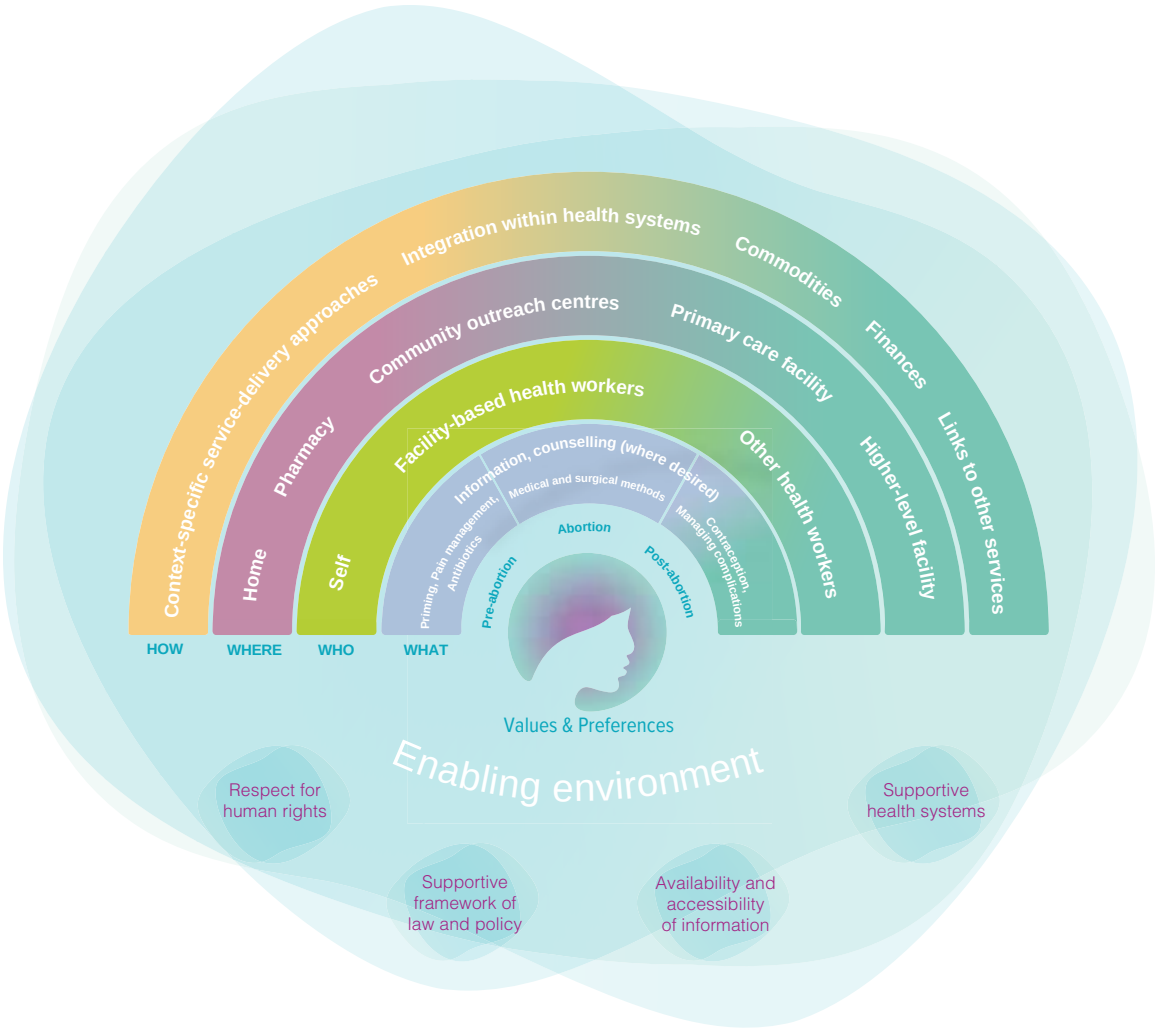

Fig. 161.5 Conceptual framework of the WHO abortion care guidelines. (*From World Health Organization. Abortion Care Guideline. Geneva: World Health Organization; 2022. License: CC BY-NC-SA 3.0 IGO. Fig.1* https://www.who.int/publications/i/item/9789240039483.)

the abortion, do not use tampons for ~5 days and get a pregnancy test ~3 weeks later to ensure a complete abortion. After that, a contraceptive should be started in sexually active individuals (may not be indicated in cases of rape or incest). Medical abortion has an exceptional safety record; long-term studies demonstrate no adverse effect on fertility, premature birth, breast cancer, or mental health issues.

The medications can be available by online consultation from Aid Access (aidaccess.org); pills will be mailed directly from Aid Access to persons in all states permitting self-managed abortion. "Shield laws" protect telemedicine providers serving patients in states where abortion is illegal.

Surgical methods for abortion require in-clinic presence and a skilled provider. These include suction curettage (aspiration method) used between ~6 and 16 weeks' gestation, dilation, and evacuation (~12-24 weeks); induction of labor; and, if necessary, rarely a hysterotomy (C-section) at >24 weeks. Anesthesia (local or general) is needed for these procedures.

Restricting access to or banning legal abortions will not reduce the total number of abortions but increases the risk of criminalization and potentially the number of unsafe procedures. On a global basis, unsafe abortions represent ~45% of all abortions. Unsafe abortion increases the risk of incomplete abortion (retained products of conception), hemorrhage, infection, uterine perforation, other organ injury, and infertility. Restricting access to abortion with resultant pregnancy will have adverse economic and educational consequences for the pregnant adolescent (see Chapter 161). In addition, the United States has one of the highest maternal mortality rates (23.8 deaths per 100,000 live births in 2020) of developed countries. The risk of death from pregnancy is much higher than from any form of legal abortion.

Challenges and Barriers

There are multiple logistic and legal challenges to obtaining an abortion. Some are generalizable to all ages, whereas others are specific to adolescent patients.

Some states have a complete ban against abortions, necessitating travel to another state or country. In other states, there is a limit to gestational age (usually first trimester). Many are limiting abortion to 6 weeks or when fetal heart beats are detected. The majority of states require a physician to perform an abortion. Some states restrict the use of public funding, and others restrict private insurance use for abortions. In one study, ~45% of fees were paid by the pregnant person; in states that ban Medicaid funding for abortion, the patient pays the full cost. States vary in the requirement for preabortion "counseling" and a waiting period. If "counseling" is needed, it should be from an abortion provider, not a state mandated program, which may be biased against abortion.

The criminalization of abortion (the pregnant person, the provider, others involved) has created a climate of enhanced surveillance and added barriers. Laws have been proposed to require abortion providers to register all patients requesting an abortion. These reporting mandates will compromise patient-provider confidentiality and possibly violate Health Insurance Portability and Accountability Act (HIPAA) regulations. Nonetheless HIPAA may not be applicable if legal action is filed against a patient and/or provider. Other laws will

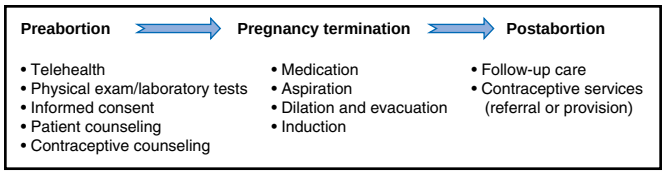

Fig. 161.6 Continuum of abortion care. (*Modified from National Academies of Sciences, Engineering, and Medicine; Health and Medicine Division; Board on Health Care Services; Board on Population Health and Public Health Practice; Committee on Reproductive Health Services. Fig. 161.7 As of 2020, medication abortions account for the majority of all U.S. abortions. *Based on preliminary data. (*From Guttmacher Institute. Medication abortion now accounts for more than half of all US abortions, 2022. https://www.guttmacher.org/print/article/2022/02/medication-abortion-now-accounts-more-half-all-us-abortions.*)

permit private citizens to sue pregnant persons having an abortion or those who help (even those transporting the pregnant person to another state). With these legal obstacles in place, patients seeking an abortion must be vigilant in keeping abortion-seeking behaviors private and unavailable to litigious prosecution. This should include internet browsing and searches, text messages, period tracking apps, payments, and travel plans, all of which may be used as evidence. Although a self-managed medically induced abortion is clinically indistinguishable from a spontaneous miscarriage, a prosecutor may use electronic information as evidence to identify an induced abortion.

The concept of fetal personhood and laws defining this as starting at conception add another legal concern. Fetal personhood proponents suggest that the unborn fetus has rights similar to a child after birth and that any action thought to harm the fetus will be considered illegal. Pregnant persons can thus be detained or arrested for actions perceived as harmful to the fetus (beginning in the first trimester). Most of the cases have been related to a pregnant person's use of drugs; such patients have been accused of child abuse or even distributing drugs to a minor. In addition to the effects that the concept of fetal personhood will have on abortions, it may have implications for persons with an IUD, those using emergency contraception, embryos created for IVF, and those experiencing an ectopic pregnancy.

In addition to challenges experienced by all persons seeking an abortion, adolescents who are minors have age-specific barriers. Minors may not be able to travel to locations providing abortion (finances, driver's license, purchase airline ticket) and in most states, they are required to have some form of parental (grandparent or other adult relative in some states) involvement by notification or actual consent (PNA). PNA can be avoided by using a judicial bypass after appealing to a judge. In this case, the judge will determine if the adolescent requesting an abortion is "mature and informed." States with legal access to abortion may eliminate PNA altogether (e.g., Illinois).

Various organizations have facilitated access to self-managed abortions or to provide referrals to the nearest abortion provider. Aid Access (http://www.aidaccess.org) is an online international abortion consult service that will make mifepristone/misoprostol available by mail (including minors). Another site (http://www.ineedana.com) helps locate the nearest abortion provider, and http://www.elevatedaccess.org helps arrange flights to legal abortion sites.

Other resources include Women on Web http://www.womenonweb.org/en/ and Planned Parenthood as a patient navigator or provider of abortions.

Chapter 162

Adolescent Sexual Assault

Allison M. Jackson, Adrianne R. Artis, and Norrell K. Atkinson

Rape is an act of violence, not an act of sex. Rape is historically defined as coercive sexual intercourse involving physical force or psychologic manipulation of a female or a male. Recognizing that sexual intercourse is not a requirement for the definition, the U.S. Department of Justice (DOJ) defines rape as "the penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim." Though definitions may vary by state, **sexual assault** is a more inclusive term that according to the U.S. DOJ "means any nonconsensual sexual act proscribed by Federal, tribal, or State law, including when the victim lacks capacity to consent."

EPIDEMIOLOGY

Exact figures on the incidence of rape are unavailable because sexual assault is underreported. In the 2019 National Crime Victimization Survey, only 0.56 per 1,000 persons over 12 years of age reported sexual assault to police. According to the National Intimate Partner and Sexual Violence Survey of 2015 (NISVS 2015), over 43% women and nearly 25% of men experienced some form of **sexual violence** in their lifetime. Females exceed males as reported rape victims, but male rape may be more underreported than female rape.

Adolescence is a high-risk age-group for sexual assault, with 43.2% of females and 51.3% of males experiencing their first sexual assault before the age of 18 years, and 81.3% of females and 70.8% males experiencing their first sexual assault before the age of 25 years (NISVS 2015). Between 1995 and 2013 the rate of rape and sexual assault was highest for adolescent females between ages 18 and 24 years. The National Survey of Children's Exposure to Violence (NatSCEV 2014) revealed that 12.9% of 14- to 17-year-olds experienced any sexual victimization in the past year, 21.7% had experienced any sexual victimization in their lifetime, 4.2% experienced sexual assault in the past year, and 10.2% in their lifetime. This survey also demonstrated how other experiences with violence compound the risk for sexual victimization. Youth with a history of maltreatment by a caregiver were four times more likely to experience sexual victimization and more than four times more likely to experience sexual victimization if they were a witness to violence. Among older adolescents age 18-24 years, the rate of rape and sexual

Chapter 162

Adolescent Sexual Assault

Allison M. Jackson, Adrianne R. Artis, and Norrell K. Atkinson

Rape is an act of violence, not an act of sex. Rape is historically defined as coercive sexual intercourse involving physical force or psychologic manipulation of a female or a male. Recognizing that sexual intercourse is not a requirement for the definition, the U.S. Department of Justice (DOJ) defines rape as "the penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim." Though definitions may vary by state, **sexual assault** is a more inclusive term that according to the U.S. DOJ "means any nonconsensual sexual act proscribed by Federal, tribal, or State law, including when the victim lacks capacity to consent."

EPIDEMIOLOGY

Exact figures on the incidence of rape are unavailable because sexual assault is underreported. In the 2019 National Crime Victimization Survey, only 0.56 per 1,000 persons over 12 years of age reported sexual assault to police. According to the National Intimate Partner and Sexual Violence Survey of 2015 (NISVS 2015), over 43% women and nearly 25% of men experienced some form of **sexual violence** in their lifetime. Females exceed males as reported rape victims, but male rape may be more underreported than female rape.

Adolescence is a high-risk age-group for sexual assault, with 43.2% of females and 51.3% of males experiencing their first sexual assault before the age of 18 years, and 81.3% of females and 70.8% males experiencing their first sexual assault before the age of 25 years (NISVS 2015). Between 1995 and 2013 the rate of rape and sexual assault was highest for adolescent females between ages 18 and 24 years. The National Survey of Children's Exposure to Violence (NatSCEV 2014) revealed that 12.9% of 14- to 17-year-olds experienced any sexual victimization in the past year, 21.7% had experienced any sexual victimization in their lifetime, 4.2% experienced sexual assault in the past year, and 10.2% in their lifetime. This survey also demonstrated how other experiences with violence compound the risk for sexual victimization. Youth with a history of maltreatment by a caregiver were four times more likely to experience sexual victimization and more than four times more likely to experience sexual victimization if they were a witness to violence. Among older adolescents age 18-24 years, the rate of rape and sexual

assault was 1.2 times higher for those not enrolled in college than those in college. Further, several studies of youth in the juvenile justice system demonstrate a particularly high prevalence of prior sexual victimization of young females in that setting. Rape occurs worldwide and is especially prevalent in war and armed conflicts. The World Health Organization estimates that rape and domestic violence are responsible for 5–16% of healthy years of life lost by females of reproductive age.

Female adolescents and young adults have the highest rates of rape compared to any other age-group. The normal developmental growth tasks of adolescence may contribute to this vulnerability in the following ways: (1) the emergence of independence from parents and the establishment of relationships outside the family may expose adolescents to environments with which they are unfamiliar and situations that they are unprepared to handle; (2) dating and becoming comfortable with one's sexuality may result in activities that are unwanted, but the adolescent is too inexperienced to avoid the unwanted actions; and (3) young adolescents may be naïve and more trusting than they should be (see Chapter 150). Many teens are technologically competent, which gives sexual perpetrators access to unsuspecting vulnerable populations who were previously beyond their reach. Social media and online dating sites represent a major risk for adolescents, as they facilitate correspondence with individuals unknown to them or protective family members, while simultaneously providing a false sense of security because of remote electronic communications. A determined perpetrator can obtain specific information to identify the adolescent and arrange for a meeting that is primed for sexual victimization.

Some adolescents are at higher risk of being victims of rape than others (Table 162.1).

TERMINOLOGY

Sexual violence is a term that broadly encompasses criminal acts including **sexual assault**, **rape** and **sexual abuse**, and which disproportionately affects adolescents and young adults. Because of the prevalence of sexual violence in the adolescent population, it is important for healthcare providers to have a general understanding of the types of sexual violence that may affect children and adolescents. Providers should also be aware that every state carries their own legal definition of these crimes. These definitions dictate if or how a crime is prosecuted, which could affect survivors who have disclosed sexual violence.

Delayed disclosures of sexual violence are common. The circumstances and relationship of the assailant to the survivor can often affect if, when, and how a child or youth discloses an assault. Sexual violence is typically perpetrated by someone who knows their victim; less frequently the assailant is a stranger. The gender of the survivor may also affect the disclosure process. Males are less likely to disclose sexual violence compared with females. Individuals who are transgender, gender nonconforming, nonbinary, or other noncisgender identities are less likely to disclose sexual assault than those who identify as cisgender.

Table 162.1 Adolescents at High Risk of Rape Victimization

MALE, FEMALE, NONBINARY ADOLESCENTS
Drug and alcohol users
Runaways
Those with intellectual disability or developmental delay
Street youths
Transgender youth
Youths with a history of sexual abuse
PRIMARILY FEMALES
Survivors of prior sexual assault
Newcomers to a town or college
PRIMARILY MALES
Those in institutionalized settings (detention centers, prison)
Gay males

In any scenario where rape is facilitated by threats, coercion, physical force, or illicit and/or legal substances, the disclosure process for a survivor of sexual assault can be impacted.

TYPES OF SEXUAL VIOLENCE

Sexual assault is defined as sexual contact or behavior that occurs without explicit consent of the victim. It can include things such as attempted rape, rape, fondling, or forcing a person to perform sexual acts. It is important to remember that force is not always physical, but it can also be intimidation or coercive control of the person. Force may also include threatening to hurt the person or those close to them.

Rape is a form of sexual assault involving penetration. Not all sexual assaults are rape. Rape can further be defined as **stranger rape** vs **acquaintance rape**. **Intimate partner sexual violence** is a form of acquaintance rape. An intimate partner is defined as a person with which the survivor has had a close personal or sexual relationship; thus this form of sexual violence can be prevalent among adolescents. Intimate partner sexual violence can often start with controlling or emotionally abusive behaviors, which then escalate to assault.

Rape can frequently involve illicit and/or legal substances to facilitate the assault. Drug-facilitated rape involves perpetrators administering substances such as γ-hydroxybutyric acid (GHB), flunitrazepam (Rohypnol), and ketamine hydrochloride to their victim. More commonly, substances such as alcohol, tetrahydrocannabinoids (THC), benzodiazepines, stimulants, barbiturates, opioids, or other drugs are used during the course of an assault. Detection of these drugs requires a high index of suspicion, and a medical evaluation within 8-12 hours is necessary for prompt detection of these substances, Specific testing is used that is more sensitive than routine toxicology screens, which are often insufficient.

Sexual abuse is a type of child abuse (see Chapter 17). The American Academy of Pediatrics defines child sexual abuse as a child or adolescent who engages in sexual activities that they cannot comprehend, for which they are developmentally unprepared and unable to give informed consent, and/or when there is a violation of the legal or social taboos of society. It includes many things ranging from oral, genital, or anal contact and fondling by or of the child, to noncontact abuses, such as exhibitionism, voyeurism, or various forms of child exploitations such as pornography.

The **commercial sexual exploitation of children (CSEC)**, also known as **sex trafficking**, is a more complex form of sexual violence and is considered a form of child abuse (see Chapter 16). Sex trafficking is federally defined as the recruiting, harboring, transporting, providing, obtaining, patronizing, or soliciting of an individual through the means of force, fraud, or coercion for commercial sex. Although a pimp often personally recruits victims, they may use others to recruit. These youth may experience physical and sexual assault by the pimp as well as the "johns." Many of these youth have a history of child maltreatment, increasing their vulnerability to this form of abuse. Fear of the consequences of disclosure and the survival skills acquired often yield a very guarded presentation in the healthcare setting.

Survivors of sexual violence often experience long-term symptoms related to the trauma they have sustained. Untreated trauma can negatively affect the physical and emotional health of an adolescent into adulthood. Engagement in trauma-focused therapy, combined with a supportive environment for the adolescent to grow, can help to mitigate the effects of the trauma that they have sustained. Providers should be knowledgeable of trauma-focused therapists in their community where adolescent survivors of sexual violence can receive care.

CLINICAL MANIFESTATIONS

The adolescent's acute presentation after a rape may vary considerably, from histrionics to near-mute withdrawal. Even if they do not appear afraid, most victims are extremely fearful and very anxious about the incident, the rape report, the examination, and the entire process, including potential repercussions. Because adolescents are between the developmental lines of childhood and adulthood, their responses to rape may have elements of both child and adult behaviors. Many teens,

particularly young adolescents, may experience some level of cognitive disorganization.

Adolescents may be reluctant to report rape for a variety of reasons, including self-blame, fear, embarrassment, or in the circumstances of drug-facilitated rape, uncertainty of event details. Adolescent victims, unlike child victims who elicit sympathy and support, often face intense scrutiny regarding their credibility and inappropriately misplaced societal blame for the assault. This view is baseless and should not be used during an evaluation of any teenage victim of sexual violence. When adolescents do not report a rape, they may present at a future date with concerns for pregnancy; symptoms of or concerns for a sexually transmitted infection (STI); and symptoms of posttraumatic stress disorder (see Chapter 38), such as sleep disturbances, nightmares, mood swings, and flashbacks. Other teens may present with psychosomatic complaints or difficulties with schoolwork. All adolescents should be screened for possible sexual victimization at health examination visits.

INTERVIEW AND PHYSICAL EXAMINATION

The purpose of the adolescent medical evaluation after a sexual assault is to provide medical care for the teen and to collect and document evidence of the assault when applicable. Although many teens delay seeking medical care, others present to a medical facility within 72 hours (or up to 96 hours depending on the protocol used) of the rape, at which time forensic evidence collection should be offered to the patient. Whether presenting acutely or more remotely, a comprehensive physical exam is recommended to the extent that the patient allows. Experienced clinicians with training and knowledge of forensic evidence collection and medical-legal procedures should complete the rape evaluation or supervise the evaluation when possible.

The clinician's responsibilities are to provide support, obtain the history in a nonjudgmental and noncoercive manner, conduct a complete examination without retraumatizing the victim, and collect forensic evidence. The clinician must complete laboratory testing, administer prophylaxis treatment for STIs and emergency contraception, arrange for counseling services, and file a report to appropriate authorities in accordance with the law. In some jurisdictions, healthcare professionals are required to report all sexual assaults of minors regardless of the relationship of the victim to the perpetrator. Although healthcare professionals are legally mandated to report sexual abuse, when the perpetrator is an acquaintance or stranger, some jurisdictions leave the decision of reporting up to the victim, requiring the victim to report the sexual assault. It is not the clinician's responsibility to decide whether a sexual assault has occurred; the legal system will make that determination. Furthermore, absence of injury does not exclude the possibility that sexual assault occurred.

Ideally, a clinician trained in forensic interviewing should obtain the history. In all cases, the history should be obtained by asking *only* open-ended questions to obtain information about (1) what happened, (2) where it happened, (3) when it happened, and (4) who did it. After obtaining a concise history, including details of the type of physical contact that occurred between the victim and the assailant, the clinician should conduct a thorough and complete physical examination and document all injuries (nongenital and genital). Clinicians should provide sensitive, nonjudgmental support during the entire evaluation, as the adolescent victim has experienced a major trauma and is susceptible to retraumatization during this process. Each component of the evaluation should be explained in detail to the victim, allowing the adolescent as much control as possible, including refusal to complete any part or all of the forensic evidence collection process. For sensitive examinations like these, a chaperone should be offered. Additionally, it is often useful to permit a trusted supportive person, such as a family member, friend, or rape crisis advocate, to be present during the evaluation if that is the adolescent's wish.

The examining clinician should be familiar with **forensic evidence collection** and the physical evidence recovery kit (PERK) before initiating the examination. In the United States, each state's PERK is different, but most include some or all of the following components: swabs of suspected semen deposits, swabs of bite mark impressions to collect genetic markers (DNA, ABO group); swabs of any penetrated orifice or body surface where saliva may be present; and documentation of acute cutaneous injuries using body diagram charts and photographs with visible standard measurements. Areas of restraint should be carefully inspected for injuries; these areas include the extremities and neck. Inspection of the skin may also reveal suction injuries or bite impressions. Inspection of the mouth, with particular attention to the oral frenula and palate, may reveal mucosal injury. Although use of alternative light sources, such as the Wood lamp or blue light, enhance detection of semen and saliva, other common substances such as urine and lotion also fluoresce with alternative light sources. Swabs of sites that fluoresce under such light should be obtained for further forensic analysis.

The genital examination of a female rape victim should be undertaken with the patient in the lithotomy position. The prone knee-chest position may be used as an exam-clarifying technique, specifically to evaluate the posterior rim of the hymen and perianal area. The genital exam of a male rape victim should be undertaken with the patient in the supine position. The clinician's exam should include careful inspection of the entire pelvic, genital, and perianal areas. The clinician should document any acute injuries such as edema, erythema, petechiae, bruising, hemorrhage, or tearing. Aqueous solution of toluidine blue (1%), which adheres to nucleated cells, may be used during the acute examination to improve visualization of microtrauma in the perianal area. Any disruption to the superficial epidermis will allow for dye uptake and thus cannot differentiate between disruption of the skin from trauma, irritation, or infection. Additionally, a colposcope may be used to provide magnification and photo documentation of injuries.

LABORATORY DATA

When adolescents present for medical care within 72-120 hours of a sexual assault, a forensic evidence collection kit should be offered to the patient. The time frames of eligibility for forensic evidence collection vary according to jurisdiction, so it is important to know the criteria of the jurisdiction investigating the assault. Regardless of an adolescent's decision to have evidence collection completed, medical care, including physical examination, laboratory testing (Table 162.2), and prophylactic therapies, should be offered to the patient. Follow-up evaluations should be scheduled to repeat these laboratory studies.

TREATMENT

Treatment includes **prophylactic antimicrobials** for STIs (see Chapter 163) and emergency contraception (see Chapter 160.6). The Centers for Disease Control and Prevention (CDC) reports that trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydia are the most frequently diagnosed infections among women who have been sexually assaulted. Antimicrobial prophylaxis is recommended for adolescent rape victims because of the risk of acquiring an STI and the risk of pelvic inflammatory disease (Table 162.3). HIV **postexposure prophylaxis (PEP)** must be considered and an infectious disease specialist consulted if higher transmission risk factors are identified (e.g., knowing that the perpetrator is HIV-positive, significant mucosal injury of the victim) to prescribe a triple-antiretroviral regimen (Fig. 162.1). Hepatitis B infection can be prevented with immunoglobulin and/or vaccination depending on the victim's immunization status and the perpetrators status; thus similar considerations should be made for possible exposure

Table 162.2 Laboratory Evaluation of Sexual Assault

Within 8-12 hr (if Indicated by History)
- Urine and blood for date rape drugs (GHB, Rohypnol, and ketamine)

Within 24 hr (if Indicated by History)
- Blood for comprehensive toxicology screen (for other classes of drugs)

Within 72 hr (or up to 96 hr Depending on Protocol Used)
- Forensic evidence kit
- Pregnancy test
- Hepatitis B screen (hepatitis B surface antigen, surface antibody, and core antibody)
- Syphilis (rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL])
- HIV (HIV 1/2 Ag/Ab immunoassay, point-of-care testing can be useful in persons unlikely to follow up with a provider)
- Bacterial vaginosis (BV) and candidiasis: point-of-care testing and/or wet mount of vaginal secretions with measurement of pH and KOH application for whiff test
- Trichomonas vaginalis: nucleic acid amplification tests (NAATs) by urine or vaginal specimen or point-of-care testing (i.e., DNA probes) from vaginal specimen
- Chlamydia and *Neisseria gonorrhoeae*: NAATs at sites of penetration or attempted penetration:
  - *N. gonorrhoeae:* oropharynx (*), rectum (*), urine (**)
  - *Chlamydia*: rectum (*), urine (**)

*Men who have sex with men (MSM) should be offered screening of gonorrhea and chlamydia if they report receptive oral or anal sex during the preceding year even if there was not contact at these sites during the assault.
**NAAT can be obtained on a dirty urine sample as an alternative to a genital swab.
From Centers for Disease Control and Prevention. Sexually transmitted diseases: treatment guidelines 2015, *MMWR Recomm Rep*. 2015;64(RR-3):1–140; and Updated guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, or other nonoccupational exposure to HIV—United States, 2016. *MMWR Morb Mortal Wkly Rep*. 2016;65:458.

to the hepatitis B virus in vaccinated/unvaccinated individuals. Human papilloma virus (HPV) vaccination is also recommended because persons who have been sexually assaulted are also at risk for infection, and the efficacy of the HPV vaccine is high. Clinicians should review the importance for the patient's compliance with medical treatment, psychologic treatment, and follow-up care. Counseling should be provided about the symptoms of STIs and the need for urgent follow-up if symptoms develop. Abstinence from sexual intercourse should be recommended until the completion of the STI prophylactic course.

At the time of presentation, the clinician should address the need for follow-up care, including psychologic counseling. Adolescent victims are at increased risk of posttraumatic stress disorder, depression, self-abusive behaviors, suicidal ideation, delinquency, substance abuse, eating disorders, and sexual revictimization. It is important for the adolescent victim and parents to understand the value of timely counseling services to decrease these potential long-term sequelae. Counseling services should be arranged during the initial evaluation, with follow-up arranged with the primary care physician to improve compliance.

FOLLOW-UP

Follow-up evaluation should be arranged within 1 week of the initial evaluation with a child abuse pediatrician or a Child Advocacy Center to provide an opportunity for prompt review of STI test results, to monitor for medication adherence and possible side effects, to ensure healing and documentation of injuries, and to evaluate for the resolution of symptoms initially present, the development of new physical symptoms, or emerging mental health concerns. If no STI prophylaxis was given, follow-up testing for gonorrhea, chlamydia, and trichomonas can be repeated in 1-2 weeks after the assault. If prophylaxis was provided, follow-up testing is not needed unless symptoms develop. If infection in the assailant cannot be ruled out, serologic testing for syphilis can be repeated in 4-6 weeks and 3 months, and for HIV in 6 weeks and 3 months.

Table 162.3 Postexposure Prophylaxis (PEP) for Acute Sexual Assault Victims

ROUTINE	
Recommended regimen for STI prophylaxis	• Ceftriaxone 500 mg IM once in a single dose* PLUS • Doxycycline 100 mg orally twice a day for 7 days (azithromycin 1 g orally in a single dose should be considered in persons at high risk for noncompliance) PLUS (for females) • Metronidazole 500 mg orally twice a day for 7 days (2 g orally in a single dose should be considered in persons at high risk for noncompliance)
Pregnancy prophylaxis	Levonorgestrel (Plan B) 1.5 mg orally in a single dose ***Ulipristal acetate (Ella) 30 mg is effective for up to 120 hr*
HPV	Assess HPV vaccination history; vaccine should be provided at initial evaluation if unimmunized or partially immunized • If unimmunized and >15 yr at the time of the initial exam, give first dose and, two follow-up doses at 1-2 mo and 6 mo • If <15 yr, a single follow-up dose at 6-12 mo • If partially immunized, a follow-up dose if >5 mo since the first dose or >12 wk since the second dose
AS INDICATED	
HIV†	*Preferred regimen* • Tenofovir 300 mg and fixed-dose combination emtricitabine 200 mg (Truvada) once daily PLUS • Raltegravir 400 mg orally twice a day OR • Dolutegravir 50 mg orally once a day All persons with a potential exposure within 72 hours should be offered PEP, which includes a 28-day course of a three-drug antiretroviral regimen.
Hepatitis B	*Alternative regimens available.* Specific indications for vaccine, immunoglobulin, and/or booster depend on assailant's status

*If ≥150 kg, give 1 g of ceftriaxone IM once.
**Provided for patients with negative urine pregnancy screen. In addition, an antiemetic (Compazine, Zofran) can be prescribed for patients receiving emergency contraception.
†HIV PEP is provided for patients with penetration and when the assailant is known to be HIV-positive or at high risk because of a history of incarceration, intravenous drug use, or multiple sexual partners. If provided, laboratory studies must be drawn before administration of medication (HIV, CBC, LFTs, BUN/Cr, amylase, lipase), and follow-up must be arranged.
Data from Workowski, KA, Bachmann, LH, Chan, PA Sexually Transmitted Infections Treatment Guidelines, 2021. *MMWR Recomm Rep* 2021;70:128-135.

PREVENTION

Primary prevention may be accomplished through education of preadolescents and adolescents on the issues of consent, rape, healthy

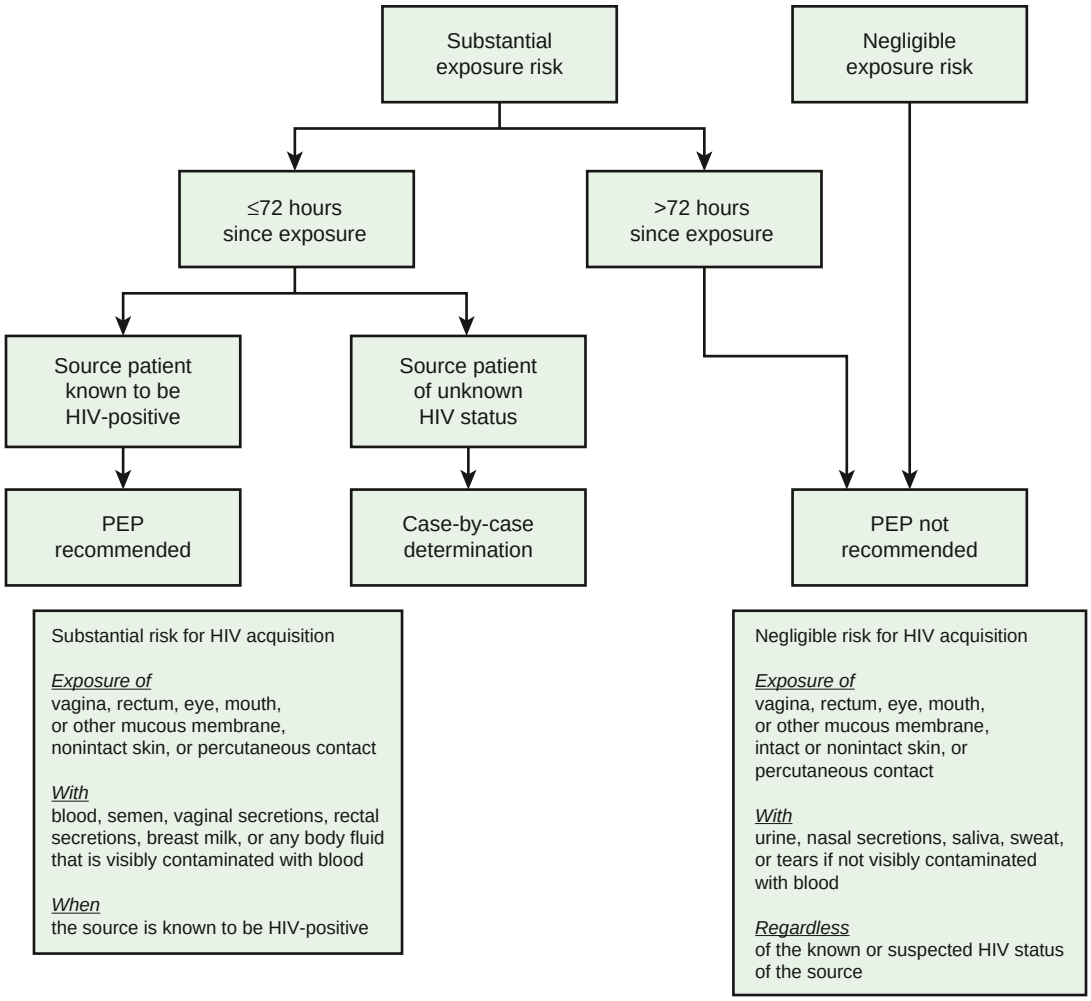

Fig. 162.1 Algorithm to evaluate the need for nonoccupational HIV postexposure prophylaxis among adult and adolescent survivors of sexual assault. *(From Workowski, KA, Bachmann, LH, Chan, PA. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:128–135; adapted from Announcement: updated guidelines for antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV—United States, 2016. MMWR Morb Mortal Wkly Rep. 2016;65:458.)*

relationships, internet dangers, and drug- and alcohol-facilitated rape. Prevention messages should be targeted at males, females, and nonbinary youth at high schools and colleges. Particular emphasis on prevention efforts during college orientation is highly recommended. High-risk situations that may increase the likelihood of a sexual assault should be discouraged, such as the use of drugs or alcohol, drinking from a container that has been left unattended, and accepting drinks from strangers. **Secondary prevention** includes informing adolescents of the benefits of timely medical evaluations when rape has occurred. Individual clinicians should ask adolescents about past experiences of forced and unwanted sexual behaviors and offer help in dealing with those experiences. The importance of prevention cannot be overstated because adolescents are disproportionately affected by sexual assault, and they are particularly vulnerable to long-term consequences.

Counseling services for family members of the victim may improve their ability to provide appropriate support to the adolescent victim. Caution parents not to use the assault as a validation of their parental guidance, as it will only serve to place blame inappropriately on the adolescent victim.

Chapter 163

Sexually Transmitted Infections

Tamera Coyne-Beasley, Nefertiti H. Durant, and Samantha V. Hill

Age-specific rates of many sexually transmitted infections **(STIs)** are highest among sexually experienced adolescents and young adults, after controlling for sexual activity. Although some STI pathogens present as STI syndromes with a specific constellation of symptoms, most are asymptomatic and only detected by a laboratory test. The approach to prevention and control of these infections lies in education, screening, and early diagnosis and treatment.

ETIOLOGY

Any adolescent who has had oral, vaginal, or anal sexual intercourse is behaviorally vulnerable to acquiring an STI. Not all adolescents are at equal risk; physical, behavioral, and social factors contribute to an adolescent's risk. Adolescents who initiate sex at a younger age; youth residing in detention facilities; youth attending STI clinics; youth involved in commercial sex exploitation or survival sex and exchange sex for drugs, money, food, or housing; young males having sex with males (YMSM); adolescent women and young adult women having sex with older men; transgender youth; youth with disabilities; and youth who are injection drug users are at higher risk for STIs. Risky behaviors, such as sex with multiple concurrent partners or multiple sequential partners of limited duration, failure to use barrier protection consistently and correctly, and increased biologic susceptibility to infection also contribute to risk (Table 163.1). Although all 50 states and the District of Columbia explicitly allow minors to consent for their own sexual health services (at varying ages), many adolescents encounter multiple obstacles to accessing this care, including poverty, insurance coverage, and fears of lack of confidentiality (see Table 163.1). Adolescents who are survivors of sexual assault need reassurance, protection, and appropriate intervention when these circumstances are uncovered (see Chapter 162).

Table 163.1 Circumstances Contributing to Adolescents' Susceptibility to Sexually Transmitted Infections

PHYSICAL
Younger age at puberty
Cervical ectopy
Smaller introitus leading to traumatic sex
Asymptomatic nature of sexually transmitted infection
Uncircumcised penis
BEHAVIOR INFLUENCED BY DEVELOPMENTAL STAGES
Early adolescence: Lack ability to think abstractly
Middle adolescence: Believe in uniqueness and lack of vulnerability
SOCIAL FACTORS
Poverty
Limited access to "adolescent-friendly" healthcare services
Adolescent health-seeking behaviors (forgoing care because of confidentiality concerns or denial of health problem)
Sexual abuse, trafficking, and violence
Lower levels of condom use
Mental health issues and substance use/abuse
Decreased access to confidential medical care leading complexity in seeking care
Homelessness
Young adolescent females with older partners
Young men having sex with men

Data from Wangu, G Burstein. Adolescent sexuality: updates to the Sexually Transmitted Infection Guidelines. *Ped Clin North Am.* 2017;64:389–341; and Spear LP. Adolescent neurodevelopment. *J Adolesc Health.* 2013;52:S7–S13.

EPIDEMIOLOGY

STI prevalence varies by age, gender, race, and ethnicity. In the United States, although adolescents and young adults ages 15-24 represent 25% of the sexually experienced population, this age-group accounts for almost 50% of all incident STIs each year.

Chlamydia is the most frequently reported infectious disease in the United States and is the second most common STI in U.S. adolescents and young adults after human papillomavirus (HPV). In 2019, young adult females ages 20-24 (3,797.8 cases per 100,000 females) followed by females ages 15-19 (2,697.0 cases per 100,000 females) had the highest rates of chlamydia in the United States (Fig. 163.1). Notably age-specific rates of reported cases of chlamydia among males, although substantially lower than rates among females, were still highest in young adult males 20-24 years (1,680.0 cases per 100,000 males). Chlamydia remains common among all races and ethnic groups. In 2021, a total of 1,644,416 cases of *Chlamydia trachomatis* infection were reported to the CDC, making it the most common notifiable sexually transmitted infection in the United States for that year. This case count corresponds to a rate of 495.5 cases per 100,000 population, an increase of 3.9% compared with the rate in 2020. During 2020 to 2021, rates of reported chlamydia increased among both males and females, in all regions of the United States, among most age groups, and among all race/Hispanic ethnicity groups. Rates of reported chlamydia are highest among adolescents and young adults. In 2021, almost two-thirds (58%) of all reported chlamydia cases were among persons aged 15–24 years.

Reported rates of other bacterial STIs are also high among adolescents and young adults. In 2021, gonorrhea rates among adolescents were 360.1/100,000 for males ages 15-19 compared to 587.8/100,000 for young women ages 15-19. Gonorrhea rates for young adult males ages 20-24 years old (844.2/100,000) were significantly higher than rates for males at any other age/sex group and slightly lower than for young women ages 20-24 (873.2/100,000).

Pelvic inflammatory disease (PID) is a clinical syndrome that results from the ascension of microorganisms from the cervix and vagina to the upper genital tract. PID is a serious complication of chlamydia and gonorrhea, two of the most common reportable infectious diseases and STIs in the United States. PID rates are highest among females ages 15-24 compared with older women.

Syphilis rates have increased at an alarming rate, especially among males, since 2000. In 2021, young adult males age 20-24 had the third highest rate of primary and secondary syphilis at 51.2 per 100,000. Rates among adolescent males ages 15-19 were lower at 12.0 per 100,000.

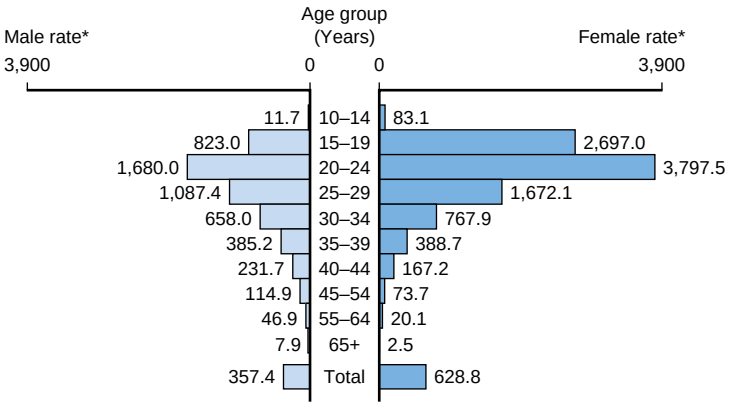

Fig. 163.1 Chlamydia: Rates of reported cases by age group and sex, United States, 2021. (*Data from the Centers for Disease Control and Prevention:* www.cdc.gov/std/statistics/2021/data.zip.)

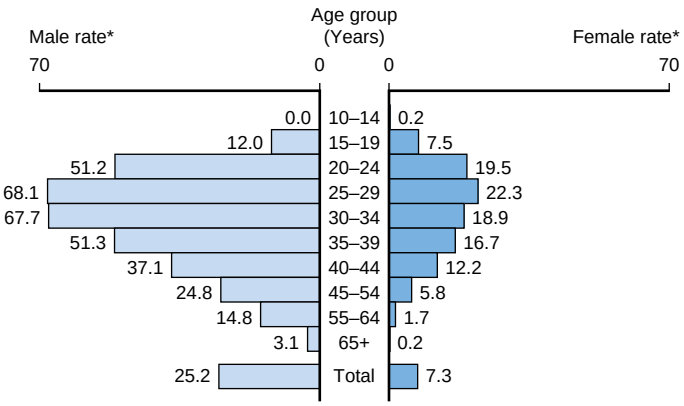

Fig. 163.2 Primary and secondary syphilis—Rates of reported cases by age group and sex, United States, 2021. (*Data from the Centers for Disease and Control and Prevention:* www.cdc.gov/std/statistics/2021/data.zip.)

Fig. 163.3 Cervical ectopy. (*From Seattle STD/HIV Prevention Training Center, University of Washington, Claire E. Stevens.*)

Rates of female primary and secondary syphilis are much lower than male rates (7.5/100,000 among 15-19 year olds; 19.5/100,000 among 20-24 year olds).

Adolescents also carry a large burden of viral STIs. U.S. youth are at persistent risk for **HIV infection**. However, according to the 2021 Youth Risk Behavior Survey, only 6% of high school students have ever been tested for HIV. Adolescents (persons aged 13–19 years) and young adults (persons aged 20–24 years) accounted for 21% of the 36,801 diagnoses of HIV infection in 2019 in the United States and 6 dependent areas. They are the least likely of any age group to be aware of their HIV infection, retained in care, or have a suppressed viral load. From 2015 through 2019 in the United States and 6 dependent areas, the number of diagnoses of HIV infection among adolescents and young adults for males, females, and transgender MTF decreased. In 2019, diagnoses of HIV infection among adolescent and young adult males (85%) and females (12%) accounted for approximately 97% of HIV diagnoses. Transgender MTF adolescents and young adults accounted for 3% of annual diagnoses. From 2015 through 2019 in the United States, the rate of diagnosis of HIV infection for Asian, Black/African American, and multiracial adolescents decreased. The rates of diagnosis of HIV infection for Hispanic/Latino and White adolescents remained stable. In 2019, the highest rate was 23.5 for Black/African American adolescents, followed by 6.3 for Hispanic/Latino, and 4.2 for multiracial adolescents. Racial and ethnic disparities persist.

Human papillomavirus (HPV) is the most frequently acquired STI in the United States. According to the National Health and Nutrition Examination Survey (NHANES), prevalence of HPV vaccine types 6, 11, 16, and 18 **(4vHPV)** declined between the prevaccine (2003–2006) and vaccine (2009–2012) eras: from 11.5% to 4.3% among females ages 14-19 and from 18.5% to 12.1% among females ages 20-24. Within 6 years of introduction of the HPV vaccine, there was a 64% decrease in 4vHPV-type prevalence among female youth ages 14-19 and a 34% decrease among young adult women ages 20-24. Efforts are ongoing to improve vaccination among all youth.

Herpes simplex virus type 2 (HSV-2) is the most prevalent viral STI (see Chapter 299). According to NHANES data, prevalence of both HSV-1 and HSV-2 decreased from 1999–2000 to 2015–2016 (from 59.4% to 48.1% and from 18.0% to 12.1%, respectively). According to Centers for Disease Control and Prevention (CDC) data, seroprevalence for HSV-2 for adolescents ages 14-19 was low, at 0.8. It is important to note that among young adults ages 20-29, HSV-2 prevalence is higher, at 7.6%. Prevalence of HSV-1 among 14- to 19-year-olds was 27% compared to 41% among those ages 20-29. There are notable ethnic, racial, and gender disparities in HSV prevalence. Prevalence of HSV-1 was highest among Mexican American persons and lowest among non-Hispanic White persons. HSV-2 prevalence was highest among Hispanic Black persons and lowest among non-Hispanic Asian persons. Both HSV-1 and HSV-2 were higher among females than males.

PATHOGENESIS

During puberty, increasing levels of estrogen cause the vaginal epithelium to thicken and cornify and the cellular glycogen content to rise, with the latter causing the vaginal pH to fall. These changes increase the resistance of the vaginal epithelium to penetration by certain organisms (including *Neisseria gonorrhoeae*) and increase the susceptibility to others (*Candida albicans* and *Trichomonas*; see Chapter 330). The transformation of the vaginal cells leaves columnar cells on the ectocervix, forming a border of the two cell types on the ectocervix known as the *squamocolumnar junction*. The appearance is referred to as *ectopy* (Fig. 163.3). With maturation, this tissue involutes. Before involution, it represents a unique vulnerability to infection for adolescent females. The association of early sexual debut and younger gynecologic age with increased risk of STIs supports this explanation of the pathogenesis of infection in young adolescents.

SCREENING

Early detection and treatment are primary *STI control strategies*. Some of the most common STIs in adolescents, including HPV, HSV, chlamydia, and gonorrhea, are usually asymptomatic and, if undetected, can be spread inadvertently by the infected host. **Screening** initiatives for chlamydial infections have demonstrated reductions in PID cases by up to 40%. Federal and professional medical organizations recommend annual chlamydia and gonorrhea screening for sexually active females <25 years old (Table 163.2). The lack of a dialog about STIs or the provision of STI services at annual preventive service visits to sexually experienced adolescents is a missed opportunity for screening and education. Comprehensive, confidential, reproductive health services, including STI screening, should be offered to all sexually experienced adolescents (see Table 163.2).

COMMON INFECTIONS AND CLINICAL MANIFESTATIONS

STI syndromes are generally characterized by the location of the manifestation (vaginitis, enteritis) or the type of lesion (genital ulcer). Certain constellations of presenting symptoms suggest the inclusion of a possible STI in the differential diagnosis.

Urethritis

Urethritis is an STI syndrome characterized by inflammation of the urethra, usually caused by an infectious etiology. Urethritis may present with urethral discharge, dysuria, urethral irritation, or meatal pruritus. Urgency, frequency of urination, erythema of the urethral meatus, and urethral pain or burning are less common clinical presentations. Approximately 30–50% of males are asymptomatic but may have signs of discharge on diagnosis. On examination, the classic finding is mucoid or purulent discharge from the urethral meatus (Fig. 163.4). If no discharge is evident on exam, providers may attempt to

Table 163.2 Routine Laboratory Screening Recommendations for Sexually Transmitted Infections in Sexually Active Adolescents and Young Adults

CHLAMYDIA TRACHOMATIS AND *NEISSERIA GONORRHOEAE*

- Routine screening for *C. trachomatis* and *N. gonorrhoeae* of all sexually active females age <25 yr is recommended annually.
- Extragenital chlamydia and gonorrhea screening (pharyngeal or rectal) can be considered on the basis of reported sexual behaviors and exposure, through shared clinical decision-making between the patient and the provider.
- Routinely screen sexually active adolescent and young adult MSM at sites of contact for chlamydia (urethra, rectum) and gonorrhea (urethra, rectum, pharynx) at least annually regardless of condom use. NAAT is preferred for provider or self-collected specimens. More frequent screening (i.e., at 3- to 6-mo intervals) is indicated for MSM, including those taking PrEP and those with HIV infection, if risk behaviors persist or if they or their sex partners have multiple partners or anonymous partners or have sex with illicit drug use.
- Consider screening for *C. trachomatis* of sexually active adolescent and young adult males annually who have a history of multiple partners in clinical settings with high prevalence rates, such as jails or juvenile correction facilities, national job training programs, STD clinics, high school clinics, or adolescent clinics.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

The following recommendations apply to testing for HIV:

- HIV testing is recommended for all adolescents and young adults seeking STI evaluation and/or treatment who are not already known to have HIV infection. Testing should be routine at the time of the STI evaluation, regardless of whether the patient reports any specific behavioral risks for HIV.
- The CDC and USPSTF recommend HIV screening at least once for all persons age 13-64 yr or 15-65, respectively.
- Persons at higher risk for HIV acquisition, including sexually active gay, bisexual, and other MSM, should be screened for HIV at least annually. Providers can consider the benefits of offering more frequent screening (e.g., every 3-6 months) among MSM at increased behavioral risk for acquiring HIV.
- All pregnant adolescents should be tested for HIV during the first prenatal visit. A second test during the third trimester, preferably at <36 weeks' gestation, should be considered and is recommended for adolescents and young adults who are at high risk for acquiring infection.
- HIV screening should be voluntary and free from coercion. Patients should not be tested without their knowledge.
- Providers should use a laboratory-based antigen/antibody (Ag/Ab) combination assay as the first test for HIV, unless persons are unlikely to follow up with a provider to receive their HIV test results; in those cases screening with a rapid POC test can be useful.
- Providers should test for HIV RNA if initial testing according to the HIV testing algorithm recommended by the CDC is negative or indeterminate when concerned about acute HIV infection (https://stacks.cdc.gov/view/cdc/50872).
- HIV screening should be discussed and offered to all adolescents at least once by age 16-18 yr and throughout young adulthood in healthcare settings. HIV risk should be assessed annually for >13 yr and offered if HIV risk factors are identified.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3- to 6-mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.

SYPHILIS

- Syphilis screening should be offered to sexually active adolescents reporting risk factors, including MSM.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3- to 6-mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.
- Screen women at 1st prenatal visit, at 28 weeks, at delivery if at greater behavioral risk.
- Screen asymptomatic women who may have increased behavioral vulnerability (history of incarceration, transactional sex, higher rate in community).
- Providers should consult with their local health department regarding local syphilis prevalence and associated risk factors that are associated with syphilis acquisition.

HEPATITIS B VIRUS

- All MSM should be screened with HBsAg, HBV core antibody, and HBV surface antibody.
- Vaccination against both HAV and HBV is recommended for all MSM when a previous infection or vaccination cannot be documented.

HEPATITIS C VIRUS AND UNIVERSAL HEPATITIS C SCREENING

- The CDC recommends hepatitis C screening at least once in a lifetime for all adults age 18 yr and older, except in settings where the prevalence of HCV infection (HCV RNA positivity) is <0.1%.
- Hepatitis C screening for all pregnant women during each pregnancy, except in settings where the prevalence of HCV infection (HCV RNA positivity) is less than 0.1%.
- Screening adolescents younger than 18 yr old for HCV who report risk factors, that is, injection drug use, receipt of an unregulated tattoo, received blood products or organ donation before 1992, received clotting factor concentrates before 1987, or long-term hemodialysis.
- Given the high HCV prevalence among young injection drug users, screening should be strongly considered.
- All people living with HIV should be screened during the initial HIV evaluations and at least annually thereafter.
- Screening should be performed using HCV antibody assays followed by HCV RNA testing for those with a positive antibody test.
- Routine screening of adolescents and young adults who are asymptomatic for certain STIs (i.e., syphilis, trichomoniasis, BBV, HSV, HAV, and HB) is not typically recommended.

From Centers for Disease Control and Prevention: https://www.cdc.gov/std/treatment-guidelines/screening-recommendations.htm and https://www.cdc.gov/hepatitis/hcv/guidelinesc.htm.

express discharge by applying gentle pressure to the urethra from the base distally to the meatus 3-4 times. *Chlamydia trachomatis* and *N. gonorrhoeae* are the most commonly identified pathogens. *Mycoplasma genitalium* has been associated with urethritis, but data supporting *Ureaplasma urealyticum* have been inconsistent. *Trichomonas vaginalis* can cause nongonococcal urethritis (NGU), but the prevalence varies. HSV-1, HSV-2, and Epstein-Barr virus (EBV) are also potential urethritis pathogens in some cases. Sensitive diagnostic *C. trachomatis* and *N. gonorrhoeae* tests are available for the evaluation of urethritis. However, other pathogens can be considered when NGU is not responsive to treatment. Noninfectious causes of urethritis include urethral trauma or foreign body. Unlike in females, urinary tract infections (UTIs) are rare in males who have no genitourinary medical history. In the typical sexually active adolescent male, dysuria and urethral discharge suggest the presence of an STI unless proven otherwise.

Epididymitis

The inflammation of the epididymis in adolescent males is most often associated with an STI, most frequently *C. trachomatis* or *N. gonorrhoeae*. The presentation of unilateral scrotal swelling and tenderness, often accompanied by a hydrocele and palpable swelling of the epididymis, associated with the history of urethral discharge constitute the presumptive diagnosis of epididymitis. Males who practice insertive anal intercourse are also vulnerable to *Escherichia coli* infection. **Testicular torsion**, a surgical emergency usually presenting with sudden onset of severe testicular pain, should be considered in the differential

Fig. 163.4 Gonococcal urethral discharge. (*From Seattle STD/HIV Prevention Training Center, University of Washington, Connie Celum and Walter Stamm.*)

diagnosis (see Chapter 582). The evaluation for epididymitis should include obtaining evidence of urethral inflammation by physical exam, Gram stain of urethral secretions, urine leukocyte esterase test, or urine microscopy. A *C. trachomatis* and *N. gonorrhoeae* nucleic acid amplification test (NAAT) should be performed.

Vaginitis

Vaginitis is a superficial infection of the vaginal mucosa frequently presenting as vaginal discharge, with or without vulvar involvement (see Chapter 586). **Bacterial vaginosis**, **vulvovaginal candidiasis**, and **trichomoniasis** are the predominant infections associated with vaginal discharge. Bacterial vaginosis is caused by replacement of the normal hydrogen peroxide (H_2O_2)–producing *Lactobacillus* species vaginal flora by an overgrowth of anaerobic microorganisms, as well as *Gardnerella vaginalis, Ureaplasma,* and *Mycoplasma*. It is diagnosed based on an individual having at least three out of four of **Amsel's criteria**: (1) thin, gray, homogenous discharge, (2) vaginal pH >4.5, (3) fishy odor after the addition of potassium hydroxide (KOH) to discharge, and (4) at least 20% clue cells present on wet prep. It is important to note that research has shown there to be significant variability in providers' abilities to read wet preps; thus standardization of wet prep analysis via laboratories is recommended. BV NAATs are also available but should be used only by symptomatic women because accuracy has not been determined for asymptomatic women. Researchers do not know the cause of bacterial vaginosis or how some women acquire it. We do know the condition typically occurs in sexually active women. We also know that sexual activity is associated with increased frequency of bacterial vaginosis. Additionally, history of a diagnosis of bacterial vaginosis increases the risk of acquisition of other STIs. Vulvovaginal candidiasis, usually caused by *C. albicans,* can trigger vulvar pruritus, pain, swelling, redness, and dysuria. Findings on vaginal examination include vulvar edema, fissures, excoriations, or thick curdy vaginal discharge. Trichomoniasis is caused by the protozoan *T. vaginalis*. Infected females may present with symptoms characterized by a diffuse, malodorous, yellow-green vaginal discharge with vulvar irritation or may be diagnosed by screening an asymptomatic patient. Cervicitis can sometimes cause a vaginal discharge. Laboratory confirmation is recommended because clinical presentations may vary and patients may be infected with more than one pathogen.

Fig. 163.5 Mucopurulent cervical discharge positive swab test. (*From Seattle STD/HIV Prevention Training Center, University of Washington, Claire E. Stevens and Ronald E. Roddy.* http://www2a.cdc.gov/stdtraining/ready-to-use/pid.htm.)

Fig. 163.6 Inflamed cervix caused by gonococcal cervicitis. (*From Centers for Disease Control and Prevention: STD clinical slides.* http://www.cdc.gov/std/training/clinicalslides/slides-dl.htm.)

Cervicitis

The inflammatory process in cervicitis involves the deeper structures in the mucous membrane of the cervix uteri. Vaginal discharge can be a manifestation, but cervicitis is frequently asymptomatic. Patients also present with complaints of irregular or postcoital bleeding. Two major diagnostic signs characterize cervicitis: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen (e.g., swab sign; Fig. 163.5), called **mucopurulent cervicitis** or cervicitis, and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os, signifying friability. Cervical changes associated with cervicitis must be distinguished from cervical ectopy in the younger adolescent to avoid the overdiagnosis of inflammation (Fig. 163.6 and see Fig. 163.3). The pathogens identified most frequently with cervicitis are *C. trachomatis* and *N. gonorrhoeae,* although no pathogen is identified in most cases. HSV is a less common pathogen associated with ulcerative and necrotic lesions on the cervix.

Pelvic Inflammatory Disease

PID encompasses a spectrum of inflammatory disorders of the female upper genital tract, including **endometritis**, **salpingitis**, **tuboovarian abscess**, and **pelvic peritonitis**, usually in combination rather than as separate entities. *N. gonorrhoeae* and *C. trachomatis* predominate as the involved pathogenic organisms in younger adolescents (see Chapters 238 and 271), although PID should be approached as having

a multiorganism etiology, including pathogens such as anaerobes, *G. vaginalis, Haemophilus influenzae*, enteric gram-negative rods, and *Streptococcus agalactiae.* In addition, cytomegalovirus, *Mycoplasma hominis*, *U. urealyticum*, and *M. genitalium* may be associated with PID. PID (tuboovarian abscess) has rarely been reported in virgins and is usually caused by *E. coli* and associated in some patients with obesity and possible pooling of urine in the vagina.

PID is difficult to diagnose because of the wide variation in symptoms and signs. Many females with PID have subtle or mild symptoms, resulting in many unrecognized cases. Healthcare providers should consider the possibility of PID in young, sexually active females presenting with vaginal discharge or abdominal pain.

The clinical diagnosis of PID is based on the presence of at least one of the minimal criteria, either cervical motion tenderness, uterine tenderness, or adnexal tenderness, to increase the diagnostic sensitivity and reduce the likelihood of missed or delayed diagnosis. Providers should also consider that adolescents are the population in whom PID is typically diagnosed and thus should have a low threshold for initiating empirical treatment. In addition, the majority of females with PID have either mucopurulent cervical discharge or evidence of white blood cells (WBCs) on a microscopic evaluation of a vaginal fluid–saline preparation. If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated. Specific, but not always practical, criteria for PID include evidence of endometritis on biopsy, transvaginal sonography or MRI evidence of thickened, fluid-filled tubes, or Doppler evidence of tubal hyperemia or laparoscopic evidence of PID.

Enteritis

Among men who have sex with men (MSM), both *Chlamydia* and the gonococcus can cause enteric (colitis, proctitis) symptoms. In addition, infections with enteric pathogens (*Shigella, Campylobacter, Ameba)* have been noted.

Sepsis

Although there are rare urogenital tract cases of meningococcal infections with heterosexual intercourse (similar to gonococcus), men who have sex (particularly oral sex) with men are at increased risk for invasive meningococcal infections, which often occur as an outbreak. Meningococcus may colonize the pharyngeal, anal, or urethral mucosa. Meningococcemia must be distinguished from disseminated gonococcal infection (DGI), which will manifest with a gram-negative diplococci-positive blood culture along with tenosynovitis, septic arthritis, petechial/pustular rash, and less often, endocarditis.

Genital Ulcer Syndromes

An **ulcerative lesion** in a mucosal area exposed to sexual contact is the unifying characteristic of infections associated with genital ulcer syndromes. Genital ulcer lesions are most frequently seen on the penis and vulva, but also occur on oral and rectal mucosa, depending on the adolescent's sexual practices. HSV and *Treponema pallidum* (syphilis) are the most common organisms associated with genital ulcer syndromes. Table 163.3 presents the clinical characteristics differentiating the lesions of the most common infections associated with genital ulcers, along with the required laboratory diagnosis to identify the causative agent accurately.

Genital herpes, the most common ulcerative STI among adolescents, is a chronic, lifelong viral infection. Two sexually transmitted HSV types have been identified: HSV-1 and HSV-2. The majority of cases of recurrent genital herpes are caused by HSV-2. However, among young women and MSM, an increasing proportion of anogenital herpes has been HSV-1. Most HSV-2–infected persons are unaware of their diagnosis because they experience mild or unrecognized infections but continue to shed virus intermittently in the genital tract. Therefore most genital herpes infections are transmitted by asymptomatic persons who are unaware of their infection.

Although the initial herpetic lesion is a vesicle, by the time the patient presents clinically, the vesicle often has ruptured spontaneously, leaving a shallow, painful ulcer (Fig. 163.7A). Recurrences are generally less intense and painful (see Fig. 163.7B). Up to 50% of first genital herpes episodes are caused by HSV-1. However, recurrences and subclinical shedding are much more frequent for genital HSV-2 infection.

Syphilis is a less common cause of genital ulcers in adolescents than in adults. Syphilis is caused by *T. pallidum*. Primary syphilis presents as a single painless ulcer or chancre at the site of infection. However, it can also present with multiple atypical or painful lesions. Secondary syphilis manifestations include skin rash,

Table 163.3 Signs, Symptoms, and Presumptive and Definitive Diagnoses of Genital Ulcers

SIGNS/SYMPTOMS	HERPES SIMPLEX VIRUS	SYPHILIS (PRIMARY)	CHANCROID
Ulcers	Vesicles rupture to form shallow ulcers	Ulcer with well-demarcated, indurated borders and a clean base (chancre)	Nonindurated and undermined borders and a purulent base
Painful	Painful	Painless*	Painful
Number of lesions	Usually multiple	Usually single	Multiple
Inguinal lymphadenopathy	First-time infections may cause constitutional symptoms and lymphadenopathy	Usually mild and minimally tender	Unilateral or bilateral painful adenopathy in >50% Inguinal bubo formation and rupture may occur
Clinical suspicion	Typical lesions; positive HSV-2 type–specific virologic test from the lesion by NAAT or culture OR Type-specific serologic testing	A presumptive diagnosis requires two laboratory serologic tests, a nontreponemal test (i.e., VDRL or RPR), and a treponemal test (TP-PA] assay, various EIAs, chemiluminescence assays [CIA], and immunoblots or rapid treponemal assay)	If all four criteria are met: 1. ≥1 Painful genital ulcers 2. Typical ulcers and regional lymphadenopathy 3. No evidence of *T. pallidum* 4. HSV-1 or HSV-2 NAAT or HSV culture performed on the ulcer exudate or fluid are negative
Definitive diagnosis	Detection of HSV by culture or PCR from ulcer scraping or aspiration of vesicle fluid	Identification of *Treponema pallidum* from a chancre or lymph node aspirate on dark-field microscopy	Detection of *Haemophilus ducreyi* by culture

*Primary syphilitic ulcers may be painful if they become coinfected with bacteria or one of the other organisms responsible for genital ulcers.
EIA, Enzyme immunoassay; HSV, herpes simplex virus; PCR, polymerase chain reaction; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories.
From https://www.cdc.gov/std/treatment-guidelines/default.htm

Fig. 163.7 A, Initial herpes infection showing multiple erosions with polycyclic outlines surrounded by an erythematous halo and associated with intense pain. B, Erosions surrounded by an erythematous halo. Clinical signs and symptoms of recurrences are usually less intense than those of initial infection. (*From Martín JM, Villalón G, Jordá E. Update on treatment of genital herpes. Actas Dermosifiliogr. 2009;100:22–32, Figs. 1 and 2.*)

mucocutaneous lesions, and lymphadenopathy in addition to other nonspecific symptoms (e.g., sore throat, malaise), gastrointestinal symptoms (e.g., hepatitis), and renal symptoms. Tertiary syphilis presents with cardiac involvement, gummatous lesions, tabes dorsalis, and general paresis. Latent syphilis lacks clinical manifestations and is detected by serologic testing. Latent syphilis acquired within the preceding year is referred to as *early latent syphilis*. Latent syphilis acquired at least 1 year prior is referred to as *late latent syphilis*. Infections of the central nervous system (CNS) (neurosyphilis), of the visual system (ocular syphilis), or auditory system (otosyphilis) can occur at any stage.

Lymphogranuloma venereum caused by *C. trachomatis* serovars L1-L3 is uncommon, although outbreaks do occur in MSM. In these circumstances, proctitis or proctocolitis is the usual manifestation. HIV is often present in affected men. Unusual infectious causes of genital, anal, or perianal ulcers in the United States and other industrialized countries include chancroid and donovanosis.

Monkeypox (see Chapter 767) has been reported after sexual contact, particularly among MSM.

The differential diagnosis of genital ulcers also includes Behçet disease (see Chapter 202), Crohn disease (see Chapter 382.2), aphthous ulceration, and acute genital ulcers caused by cytomegalovirus (see Chapter 302) or EBV (see Chapter 301). Acute genital ulcers often follow a flu or mononucleosis-like illness in an immunocompetent person and are unrelated to sexual activity. The lesions are 0.5-2.5 cm in size, bilateral, symmetric, multiple, painful, and necrotic and are associated with inguinal lymphadenopathy. This primary infection is also associated with fever and malaise. The diagnosis may require EBV titers or polymerase chain reaction (PCR) testing. Treatment is supportive care, including pain management.

Genital Lesions and Ectoparasites

Lesions that present as outgrowths on the surface of the epithelium and other limited epidermal lesions are included under this categorization of syndromes. HPV can cause genital warts and genital-cervical abnormalities that can lead to cancer (see Chapter 313). **Genital HPV** types are classified according to their association with cancer. Infections with low-risk types, such as **HPV types 6 and 11**, can cause benign or low-grade changes in cells of the cervix, genital warts, and recurrent respiratory papillomatosis. High-risk HPV types can cause cervical, anal, vulvar, vaginal, head, and neck cancers. **High-risk HPV types 16 and 18** are detected in approximately 70% of **cervical cancers**. Persistent infection increases the risk of cervical cancer. **Molluscum contagiosum** and **condyloma latum** associated with secondary syphilis complete the classification of genital lesion syndromes.

As a result of the close physical contact during sexual contact, common ectoparasitic infestations of the pubic area occur as **pediculosis pubis** or the papular lesions of **scabies** (see Chapter 709.2).

HIV, Hepatitis B, and Hepatitis C

HIV and hepatitis B virus (HBV) present as asymptomatic, unexpected occurrences in most infected adolescents. High vaccination coverage rates among infants and adolescents have resulted in substantial declines in acute HBV incidence among U.S.-born adolescents. Risk factors identified in the history or routine screening during prenatal care are much more likely to result in suspicion of infection, leading to the appropriate laboratory screening, than are clinical manifestations in this age-group (see Chapters 322 and 406). HIV incidence among adolescents has also declined, though disparities based on race, ethnicity, gender, and region persist. Young adults continue to be affected by HIV as well. The US Preventive Services Task Force (USPSTF) recommends all individuals between ages 15 and 65 be tested for HIV at least once in their life, and the CDC recommends HIV testing once between 13 and 64 and once a year based on behaviors. Hepatitis C virus (HCV) incidence continues to be on the rise not only among individuals known to be part of the "baby boomer" generation but also among young adults. Because of the rise in injection opioid use and HCV, the American Association for the Study of Liver Disease and Infectious Disease Society of America (AASLD–IDSA), and CDC recommend HCV screening among all individuals 18 years old and older. They also recommend screening based on risk behaviors among individuals younger than age 18 (see Table 163.2).

DIAGNOSIS

Most often, adolescents infected with bacterial and viral STI pathogens do not report symptoms suggestive of infection. With the use of very sensitive, noninvasive chlamydia and gonorrhea NAAT, providers are finding that most genital infections in females and many males are asymptomatic. A thorough sexual history is key to identifying adolescents who should be screened for STIs and for identifying those who require a laboratory diagnostic evaluation for an STI syndrome.

When eliciting a sexual health history, discussions should be appropriate for the patient's developmental level. In addition to questions regarding vaginal or urethral discharge, genital lesions, and lower abdominal pain among females, one should ask about prior treatment of any STI symptoms, including self-treatment using nonprescription medications. **Dyspareunia** is a consistent symptom in adolescents with **PID**. Providers must ask about oral or anal sexual activity to determine sites for specimen collection.

Urethritis should be objectively documented by evidence of inflammation or infectious etiology. Patient complaint without objective clinical or laboratory evidence does not fulfill diagnostic criteria. Inflammation can be documented by (1) observing urethral mucopurulent discharge, (2) ≥2 WBCs per high-power field on microscopic examination of Gram stain urethral secretions, (3) urine microscopic findings of ≥10 WBCs per high-power field of first-void urine specimen, or (4) a positive urine leukocyte esterase test of a first-void specimen. Laboratory evaluation is essential to identify the involved pathogens to determine treatment, partner notification, and disease control. *C. trachomatis* and *N. gonorrhoeae* NAATs of a urine specimen are recommended. The presence of gram-negative intracellular diplococci on microscopy obtained from a male urethral specimen confirms the diagnosis of gonococcal urethritis.

An essential component of the diagnostic evaluation of vaginal, cervical, or urethral discharge is a chlamydia and gonorrhea NAAT. NAATs are the most sensitive tests available in such cases and are licensed for use with urine, urethral, vaginal, and cervical specimens. Many of the chlamydia NAATs are approved by the U.S. Food and Drug Administration (FDA) to test patient-collected vaginal swabs in the clinical setting and liquid cytology specimens. Female vaginal swab specimens and male first-void urine are considered the optimal specimen types. Female urine remains an acceptable chlamydia and gonorrhea NAAT specimen, but it may have slightly reduced performance when compared with cervical or vaginal swab specimens. Urine is the recommended specimen for male urethral infection. Gonorrhea and chlamydia NAATs perform well on rectal and oropharyngeal specimens and can be performed by clinical laboratories that have completed the appropriate verification studies to obtain Clinical Laboratory Improvement Amendments (CLIA) approval.

Evaluation of adolescent females with **vaginitis** includes laboratory data. Traditionally, the cause of vaginal symptoms was determined by pH and microscopic examination of the discharge. However, CLIA-waived point-of-care vaginitis tests are available. Using pH paper, an elevated pH (i.e., >4.5) is common with bacterial vaginosis and trichomoniasis. Because pH testing is not highly specific, discharge should be further examined. For microscopic exam, a slide can be made with the discharge diluted in 1-2 drops of 0.9% normal saline solution and another slide with discharge diluted in 10% KOH solution. Examining the saline specimen slide under a microscope may reveal motile or dead *T. vaginalis* or clue cells (epithelial cells with borders obscured by small bacteria), which are characteristic of **bacterial vaginosis**. WBCs without evidence of trichomonads or yeast are usually suggestive of cervicitis. This evaluation has been consistently shown to be highly subjective, which is why there are more NAAT tests available for diagnosis. The yeast or pseudohyphae of ***Candida*** species are more easily identified in the KOH specimen (Fig. 163.8). The sensitivity of microscopy is approximately 50% and requires immediate evaluation of the slide for optimal results. Therefore lack of findings does not eliminate the possibility of infection. More sensitive point-of-care vaginitis tests include the OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Lexington, MA), an immunochromatographic capillary flow dipstick technology with reported 83% sensitivity. The OSOM BVBLUE Test (Sekisui) detects

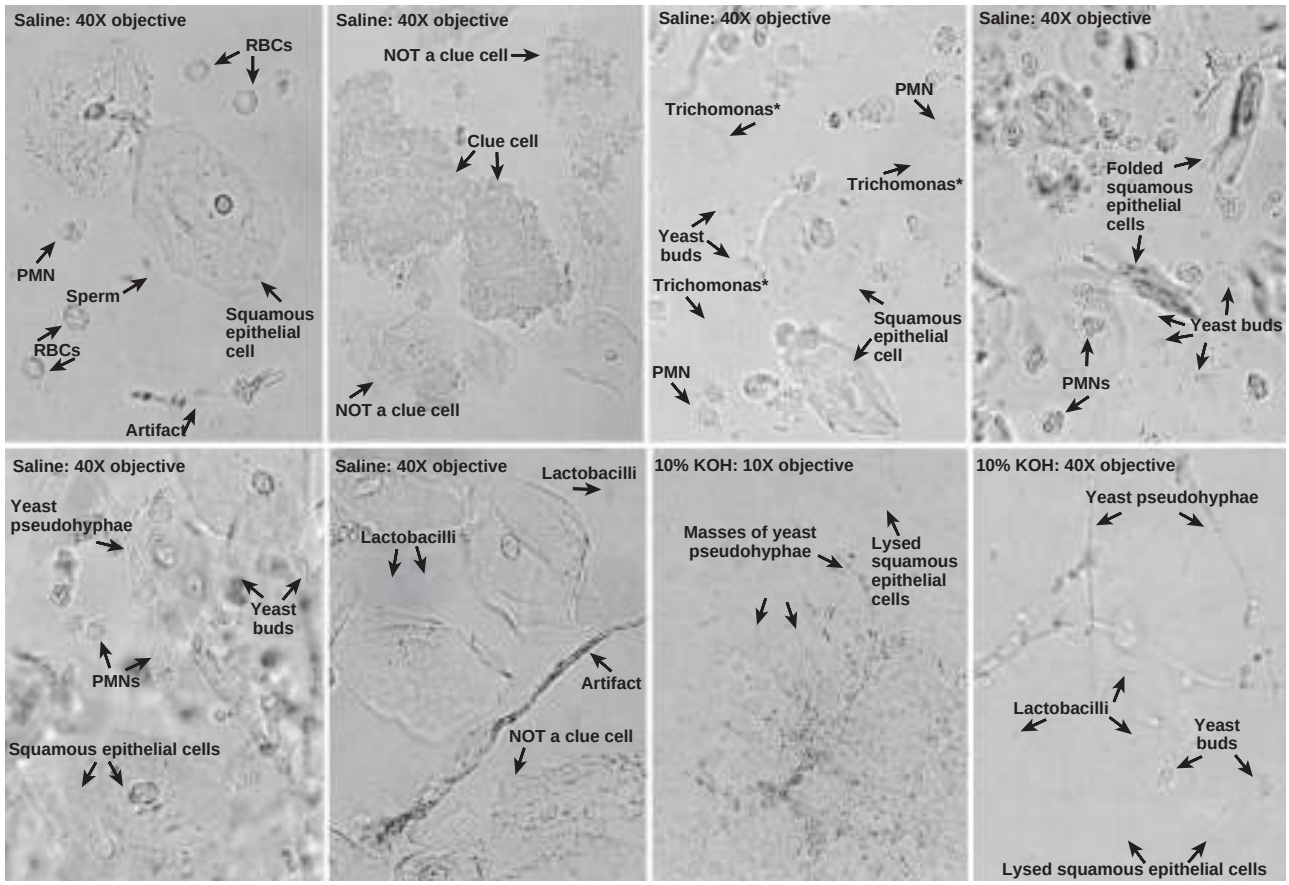

Fig. 163.8 Common normal and abnormal microscopic findings during examination of vaginal fluid. KOH, Potassium hydroxide solution; PMN, polymorphonuclear leukocyte; RBCs, red blood cells. Table 163.4 Pathologic Vaginal Discharge

INFECTIVE DISCHARGE	OTHER REASONS FOR DISCHARGE
COMMON CAUSES	COMMON CAUSES
Organisms	Retained tampon or condom
Candida albicans	Chemical irritation
Trichomonas vaginalis	Allergic responses
Chlamydia trachomatis	Ectropion
Neisseria gonorrhoeae	Endocervical polyp
Mycoplasma genitalium	Intrauterine device
Conditions	Atrophic changes
Bacterial vaginosis	LESS COMMON CAUSES
Acute pelvic inflammatory disease	Physical trauma
Postoperative pelvic infection	Vault granulation tissue
Postabortal sepsis	Vesicovaginal fistula
Puerperal sepsis	Rectovaginal fistula
LESS COMMON CAUSES	Neoplasia
Ureaplasma urealyticum	Cervicitis
Syphilis	
Escherichia coli	

From Mitchell H. Vaginal discharge—causes, diagnosis, and treatment. *BMJ.* 2004;328:1306–1308; and Sexually Transmitted Infections Treatment Guidelines, 2021: Vulvovaginal Itching, Burning, Irritation, Odor or Discharge: https://www.cdc.gov/std/treatment-guidelines/vaginal-discharge.htm.

Table 163.5 Evaluation for Pelvic Inflammatory Disease (PID)

2021 CDC DIAGNOSTIC CRITERIA

Minimal Criteria

- Cervical motion tenderness

or

- Uterine tenderness

or

- Adnexal tenderness

Additional Criteria to Enhance Specificity of the Minimal Criteria

- Oral temperature >38.3°C (101°F)
- Abnormal cervical or vaginal mucopurulent discharge*
- Presence of abundant numbers of WBCs on saline microscopy of vaginal secretions*
- Elevated ESR or C-reactive protein
- Laboratory documentation of cervical *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection

Most Specific Criteria to Enhance the Specificity of the Minimal Criteria

- Transvaginal sonography or MRI techniques showing thickened, fluid-filled tubes, with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
- Endometrial biopsy with histopathologic evidence of endometritis
- Laparoscopic abnormalities consistent with PID

Differential Diagnosis (Partial List)

- Gastrointestinal: appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, irritable bowel syndrome
- Gynecologic: ovarian cyst (intact, ruptured, or torsed), endometriosis, dysmenorrhea, ectopic pregnancy, mittelschmerz, ruptured follicle, septic or threatened abortion, tuboovarian abscess
- Urinary tract: cystitis, pyelonephritis, urethritis, nephrolithiasis
- ESR, Erythrocyte sedimentation rate; WBCs, white blood cells

*If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely and alternative causes of pain should be investigated.

Adapted from Centers for Disease Control and Prevention (CDC): https://www.cdc.gov/std/treatment-guidelines/pid.htm.

elevated vaginal fluid sialidase activity, an enzyme produced by bacterial pathogens associated with bacterial vaginosis, including *Gardnerella, Bacteroides, Prevotella,* and *Mobiluncus,* and has a reported 90% sensitivity. Both tests are CLIA waived, with results available in 10 minutes.

Clinical laboratory–based vaginitis tests are also available. The Affirm VPIII (Becton Dickenson) is a moderate-complexity nucleic acid probe test that evaluates for *T. vaginalis, G. vaginalis,* and *C. albicans* and has a sensitivity of 63% and specificity of >99.9%, with results available in 45 minutes. Some gonorrhea and chlamydia NAATs also offer an assay for *T. vaginalis* testing of female specimens tested for *N. gonorrhoeae* and *C. trachomatis,* considered the gold standard for *Trichomonas* testing.

Objective signs of vulvar inflammation in the absence of vaginal pathogens, along with a minimal amount of vaginal discharge, suggest the possibility of mechanical, chemical, allergic, or other noninfectious irritation of the vulva (Table 163.4).

The **definitive diagnosis of PID** is difficult based on clinical findings alone. Clinical diagnosis is imprecise, and no single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Clinical criteria have a positive predictive value of only 65–90% compared with laparoscopy. Although healthcare providers should maintain a low threshold for the diagnosis of PID, additional criteria to enhance the specificity of diagnosis, such as transvaginal ultrasonography, can be considered (Table 163.5).

Cell culture and PCR are the preferred **HSV tests**. Viral culture sensitivity is low, and intermittent viral shedding causes false-negative results. NAATs, including PCR assays for HSV DNA, are more sensitive and increasingly available for diagnosing genital HSV. The Tzanck test is insensitive and nonspecific and should not be considered reliable.

Accurate type-specific **HSV serologic assays** are based on the HSV-specific glycoproteins G2 (HSV-2) and G1 (HSV-1). Both laboratory-based point-of-care tests are available. Because almost all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. The presence of HSV-1 antibody alone is more difficult to interpret because of the frequency of oral HSV infection acquired during childhood. Type-specific HSV serologic assays might be useful in the following scenarios: (1) recurrent genital symptoms or atypical symptoms with negative HSV cultures; (2) a clinical diagnosis of genital herpes without laboratory confirmation; and (3) a patient with a partner with genital herpes, especially if considering suppressive antiviral therapy to prevent transmission.

For **syphilis testing**, nontreponemal tests, such as the rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL), and treponemal testing, such as fluorescent treponemal antibody absorbed tests, the *T. pallidum* passive particle agglutination (TP-PA) assay, and various enzyme and chemiluminescence immunoassays (EIA/CIA), are recommended. However, many clinical laboratories have adopted a *reverse sequence* of screening in which a treponemal EIA/CIA is performed first, followed by testing of reactive sera with a nontreponemal test (e.g., RPR). Treponemal tests often remain positive for life, with only 15-25% becoming serologically nonreactive, if treated early in primary syphilis. A positive treponemal EIA or CIA test can identify both *previously treated and untreated or incompletely treated syphilis.* False-positive results can occur, particularly among populations with low syphilis prevalence. Persons with a positive treponemal screening test should have a standard nontreponemal test with titer (RPR or VDRL) to guide patient management decisions. If EIA/CIA and RPR/VDRL results are discordant, the laboratory should perform a different treponemal test to confirm the results of the initial test. Patients with discordant serologic results by EIA/CIA and RPR/VDRL testing whose sera are reactive by TP-PA testing are considered to have past or present syphilis; if sera is TP-PA nonreactive, syphilis is unlikely (Fig. 163.9).

Rapid HIV testing with third- and fourth-generation test results available in 10-20 minutes can be useful when the likelihood of adolescents returning for their results is low. Point-of-care CLIA-waived tests for whole blood finger stick (fourth generation) and oral fluid specimen (third generation) testing are available. Clinical studies have demonstrated that the rapid HIV test performance is comparable to those of EIAs. Because some reactive test results may be false positive, every reactive rapid test must be confirmed.

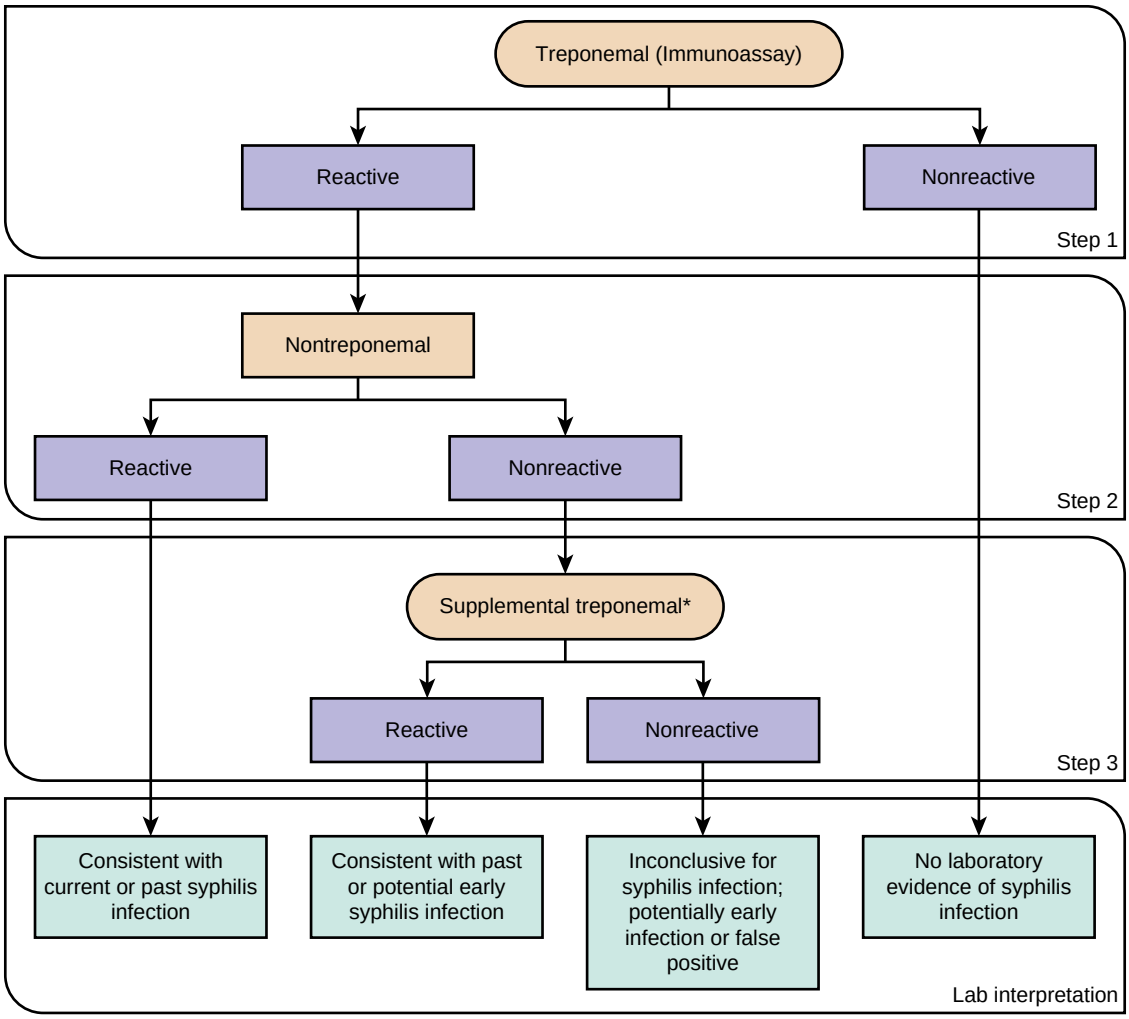

Fig. 163.9 Centers for Disease Control and Prevention (CDC)–recommended algorithm for reverse-sequence syphilis screening: Treponemal test screening followed by nontreponemal test confirmation. *The supplemental treponemal test should use a unique platform and/or antigen different from the first treponemal test. (*From Association of Public Health Laboratories. Suggested Reporting Language for Syphilis Serological Testing. Association of Public Health Laboratories August 2020* https://www.aphl.org/programs/infectious_disease/std/Documents/ID-2020Aug-Syphilis-Reporting-Language.pdf.)

Table 163.6 Management Guidelines for Uncomplicated Bacterial STIs in Adolescents and Adults

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
Chlamydia trachomatis	Doxycycline 100 mg orally 2×/day for 7 days **For pregnancy:** Azithromycin 1 g orally in a single dose	Azithromycin 1 g orally in a single dose **OR** Levofloxacin 500 mg orally 1×/day for 7 days **For pregnancy:** Amoxicillin 500 mg orally 3×/day for 7 days
Neisseria gonorrhoeae (cervix, urethra, and rectum)	Ceftriaxone 500 mg IM in a single dose for persons weighing <150 kg If chlamydial infection has not been excluded, treat for chlamydia with doxycycline 100 mg orally 2×/day for 7 days For person weighing >150 kg, ceftriaxone 1g should be administered	**If cephalosporin allergy or unavailable:** Gentamicin 240 mg IM in a single dose **PLUS** Azithromycin 2 g orally in a single dose **OR** Cefixime 800 mg orally in a single dose
Neisseria gonorrhoeae (pharynx)	Ceftriaxone 500 mg IM in a single dose for person weighing <150 kg Ceftriaxone 1g IM for a person weighing ≥150 kg	
Treponema pallidum (primary and secondary syphilis or early latent syphilis, i.e., infection <12 mo)	Benzathine penicillin G 2.4 million units IM in a single dose	**Penicillin allergy:** Doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg orally 4 times daily for 14 days; limited data suggest ceftriaxone 1-2 g daily either IM or IV for 10-14 days **OR** Azithromycin 2 g orally in a single dose has been effective, but treatment failures have been documented

Continued

Table 163.6 Management Guidelines for Uncomplicated Bacterial STIs in Adolescents and Adults—cont'd

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
Treponema pallidum (late latent syphilis or syphilis of unknown duration)	Benzathine penicillin G 7.2 million units total, administered as three doses of 2.4 million units IM each at 1-wk intervals	**Penicillin allergy:** Doxycycline 100 mg orally twice daily for 28 days or tetracycline 500 mg orally 4 times daily for 28 days, with close serologic and clinical follow-up
Treponema pallidum (neurosyphilis, ocular syphilis, and otosyphilis)	Aqueous crystalline penicillin G 18-24 million units per day, administered as 3-4 million units by IV every 4 hr or continuous infusion, for 10-14 days	Procaine penicillin G 2.4 million units IM 1×/day for 10-14 days **PLUS** Probenecid 500 mg orally 4×/day for 10-14 days
Haemophilus ducreyi (chancroid: genital ulcers, lymphadenopathy)	Azithromycin 1 g orally in a single dose **OR** Ceftriaxone 250 mg IM in a single dose **OR** Ciprofloxacin 500 mg orally 2× daily for 3 days **OR** Erythromycin base 500 mg orally 3× daily for 7 days	
Chlamydia trachomatis serovars L1, L2, or L3 (lymphogranuloma venereum)	Doxycycline 100 mg orally 2× daily for 21 days	**Alternative:** Erythromycin base 500 mg orally 4× daily for 21 days **OR** Azithromycin 1 g orally once weekly for 3 wk

IM, Intramuscularly; IV, intravenously; NAAT, nucleic acid amplification test.

TREATMENT

See Part XV for chapters on the treatment of specific microorganisms and Tables 163.6-163.8. Treatment regimens using nonprescription products for candidal vaginitis and pediculosis reduce financial and access barriers to rapid treatment for adolescents, but potential risks for inappropriate self-treatment and complications from untreated, more serious infections must be considered before using this approach. Minimizing noncompliance with treatment, notifying and treating the sexual partners, addressing prevention and contraceptive issues, offering available vaccines to prevent STIs, and making every effort to preserve fertility are additional physician responsibilities.

Chlamydia- and gonorrhea-infected males and females should be retested approximately 3 months after treatment, regardless of whether they believe that their sex partners were treated, or whenever persons next present for medical care in the 12 months after initial treatment. Adolescents who are pregnant with chlamydia and gonorrhea infections should be retested in approximately 1 month after treatment. Adolescents with oral gonorrhea should be retested in 7-14 days. Once an infection is diagnosed, partner evaluation, testing, and treatment are recommended for sexual contacts within 60 days of symptoms or diagnosis, or the most recent partner if sexual contact was >60 days, even if the partner is asymptomatic. Abstinence is recommended for at least 7 days

Table 163.8 Management Guidelines for Uncomplicated Genital Warts and Genital Herpes in Adolescents and Adults

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
HUMAN PAPILLOMAVIRUS (HPV)		
External anogenital warts (penis, groin, scrotum, vulva, perineum, external anus, and perianus)	**Patient applied:** Imiquimod 3.75–5% cream self-applied to warts at bedtime nightly for up to 16 wk; wash off after 6-10 hr ***OR*** Podofilox 0.5% solution or gel self-applied to warts twice daily for 3 consecutive days each wk followed by 4 days of no therapy. May be repeated for up to four cycles. ***OR*** Sinecatechins 15% ointment self-applied 3 times daily for up to 16 wk. Do not wash off after use, and avoid genital, anal, and oral sexual contact while ointment is on skin. **Provider-administered:** Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1-2 wk. ***OR*** Surgical removal either by tangential scissor excision, electrocautery, tangential shave excision, curettage, laser or electrosurgery. ***OR*** Trichloroacetic acid (TCA) or bichloracetic acid (BCA) 80–90%; small amount applied only to warts and allowed to dry, when white "frosting" develops; can be repeated weekly.	**Provider administered:** Podophyllin resin 10–25% in a compound tincture of benzoin applied to each wart and then allowed to air-dry; thoroughly wash off after 1-4 hr; can be repeated weekly. Systemic toxicity has been reported when podophyllin resin was applied to large areas of friable tissue and was not washed off within 4 hr. Many persons with external anal warts also have **intraanal warts** and might benefit from inspection of anal canal by digital examination, standard anoscopy, or high-resolution anoscopy.
Cervical warts	Cryotherapy with liquid nitrogen ***OR*** Surgical removal ***OR*** TCA or BCA 80–90% solution Management should include consultation with a specialist.	
Vaginal warts	Cryotherapy with liquid nitrogen; avoid cryoprobe use because of risk for vaginal perforation and fistula formation. ***OR*** Surgical removal ***OR*** TCA or BCA 80–90%; small amount applied only to warts and allowed to dry, when white "frosting" develops; can be repeated weekly.	
Urethral meatal warts	Cryotherapy with liquid nitrogen ***OR*** Surgical removal	
Intraanal warts	Cryotherapy with liquid nitrogen ***OR*** Surgical removal ***OR*** TCA or BCA 80–90% applied to warts. A small amount should be applied only to warts and allowed to dry, at which time a white "frosting" develops. Can be repeated weekly.	Management of intraanal warts should include consultation with a specialist.
HERPES SIMPLEX VIRUS (HSV; GENITAL HERPES)		
First clinical episode	**Treat for 7-10 days with one of the following:** Acyclovir 400 mg orally 3× daily Valacyclovir 1 g orally 2× daily Famciclovir 250 mg orally 3× daily	Consider extending treatment if healing is incomplete after 10 days of therapy.
Episodic therapy for recurrences	**Treat with one of the following:** Acyclovir 800 mg orally 2× daily for 5 days Acyclovir 800 mg orally 3× daily for 2 days Valacyclovir 500 mg orally 2× daily for 3 days Valacyclovir 1,000 mg orally once daily for 5 days Famciclovir 1,000 mg orally 2× daily for 1 day Famciclovir 500 mg orally once, then 250 mg 2× daily for 2 days Famciclovir 125 mg orally twice daily for 5 days	Effective episodic treatment of recurrences requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply or a prescription for the medication with instructions to initiate treatment immediately when symptoms begin.
Suppressive therapy to reduce frequency of recurrences	**Treat with one of the following:** Acyclovir 400 mg orally 2× daily Valacyclovir 500 mg orally once daily* or 1 g orally once daily Famciclovir 250 mg orally 2× daily	All patients should be counseled regarding suppressive therapy availability, regardless of number of outbreaks per year. Because the frequency of recurrent outbreaks diminishes over time in many patients, providers should periodically discuss the need to continue therapy.

Continued

Table 163.8 Management Guidelines for Uncomplicated Genital Warts and Genital Herpes in Adolescents and Adults—cont'd

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
Daily suppressive therapy in persons with HIV infection	Acyclovir 400-800 mg orally 2-3× daily ***OR*** Famciclovir 500 mg orally 2× daily ***OR*** Valacyclovir 500 mg orally 2× daily	If lesions persist or recur in a patient receiving antiviral treatment, acyclovir resistance should be suspected and a viral culture obtained for phenotypic sensitivity testing. Consultation with an infectious disease specialist is recommended.
Episodic infection in persons with HIV	Acyclovir 400 mg orally 3× daily for 7-10 days ***OR*** Famciclovir 250 mg orally 3×/day for 7-10 days ***OR*** Valacyclovir 1g orally 2× for 7-10 days	If lesions persist or recur in a patient receiving antiviral treatment, acyclovir resistance should be suspected and a viral culture obtained for phenotypic sensitivity testing. Consultation with an infectious disease specialist is recommended.
Daily suppressive therapy of recurrent genital herpes in pregnant women	**Treatment is recommended to start at 36 wk gestation:** Acyclovir 400 mg orally 3× daily ***OR*** Valacyclovir 500 mg orally 2× per day	

*Valacyclovir 500 mg once daily might be less effective than other valacyclovir or acyclovir dosing regimens in patients who have very frequent recurrences (i.e., ≥10 episodes per yr). Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases: treatment guidelines, *MMWR* 2021;64(RR-3): https://www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf.

Table 163.9 Option for Pre-Exposure Prophylaxis (PrEP) for HIV Prevention

GENERIC	DOSE	FREQUENCY	POPULATION
Tenofovir disproxil fumarate + emtricitabine (F/TDF)*	200 mg/300 mg	Daily pill	Any person weighing at least 35 kg
Tenofovir alafenamide +emtricitabine (F/TAF)	200 mg/25 mg	Daily pill	Individuals engaging in anal sex who are cis male, transwomen weighing at least 35 kg
Cabotegravir	200 mg/mL	Every 2 month injection	Any person weighing at least 35 kg

*F/TDF is also available by brand name and generic depending on insurance. It can also be used as intermittent dosing for cis-men and transwomen engaging in anal sex.

after both patient and partner have completed treatment. A test for pregnancy should be performed for all females with suspected PID because the test outcome will affect management. Repeat testing 3 months after treatment is also recommended for *Trichomonas* infection.

Diagnosis and therapy are often carried out within the context of a **confidential** relationship between the physician and the patient. Therefore the need to report certain STIs to health department authorities should be clarified at the outset. Health departments are Health Insurance Portability and Affordability Act (HIPAA) exempt and will not violate confidentiality. The health department's role is to ensure that treatment and case finding have been accomplished and that sexual partners have been notified of their STI exposure. **Expedited partner therapy (EPT)**, the clinical practice of treating sex partners of patients diagnosed with chlamydia or gonorrhea by providing prescriptions or medications to the patient to take to the partner without the healthcare provider first examining the partner, is a strategy to reduce further transmission of infection. In randomized trials, EPT has reduced the rates of persistent or recurrent gonorrhea and chlamydia infection. Serious adverse reactions are rare with recommended chlamydia and gonorrhea treatment regimens, such as doxycycline, azithromycin, and ceftriaxone. Transient gastrointestinal side effects are more common but rarely result in severe morbidity. Most states expressly permit EPT or may allow its practice. Resources for information regarding EPT and state laws are available at the CDC website.

PREVENTION

Healthcare providers should integrate comprehensive **sexuality education** into clinical practice with children from early childhood through adolescence. Providers should counsel adolescents regarding sexual behaviors associated with risk of STI acquisition and should educate using evidence-based prevention strategies, which include a discussion of abstinence and other risk reduction strategies, such as consistent and correct condom use, and distribution of educational materials for reinforcement. The USPSTF recommends **high-intensity behavioral counseling** to prevent STIs for all sexually active adolescents.

The following recommendations for the primary prevention of STIs through vaccination are based on published guidelines from the Advisory Committee on Immunization Practices:

- HPV vaccination is recommended through age 26 years for males and females not vaccinated previously at the routine age of 11 or 12 years. Vaccination can be started at age 9. Two doses of HPV vaccine are recommended for most persons starting the series before their 15th birthday; three doses are recommended at ≥ 15 years.
- The HBV vaccination series is recommended for all adolescents and young adults who have not previously received the universal HBV vaccine series during childhood.
- Mpox vaccination is recommended for gay, bisexual, transgender persons and if the patient has had sexual or intimate contact with someone who may have mpox. Mpox vaccination is a two-dose schedule separated by 4 weeks.

Preexposure prophylaxis (PrEP) offers another strategy to specifically prevent HIV infection (Table 163.9).

The CDC and USPSTF recommend offering HIV PrEP to adolescents weighing ≥35 kg and young adults who are HIV negative and

Section 1

Evaluation of the Immune System

Chapter 164

Orientation to the Consideration of Inborn Errors of Immunity

Soma Jyonouchi and Kathleen E. Sullivan

Primary immune deficiency diseases (PIDDs) comprise more than 450 disorders that impair the development or function of the immune system. Most these disorders result from a single gene pathogenic variant, although more complex inheritance patterns can also occur.

The initial diagnosis and subsequent treatment of PIDDs are often delayed due to a low index of suspicion, a rare individual disease incidence, protein manifestations including infection, autoimmunity, cutaneous lesions, and failure to thrive all in the background of a higher frequency of more common childhood illnesses (nonspecific viral illness, allergy). This diagnostic delay can lead to irreversible end-organ damage or death.

Newborn screening for severe combined immune deficiency (SCID) has helped the early detection of SCID and other immune deficiencies associated with very low T cells. However, the vast majority of immune deficiencies will not be detected by this method. Physicians must be aware of concerning manifestations or events that suggest an underlying PIDD. The varied presentations and complex phenotypes, some of which have minimal or no infectious manifestations, make the initial diagnosis of PIDDs difficult (Table 164.1). Manifestations of PIDD include recurrent and/or sentinel infections, fever without a focus, periodontitis, poor formation of pus at a site of infection, and unusual inflammatory (including autoimmune) diseases. PIDDs may involve defects in one or more host defense mechanism, or they may be an independent isolated disorder or part of a recognizable syndrome (Table 164.2).

The immune system is primarily responsible for protecting the body against invading infectious pathogens. Recurrent (often in multiple sites), severe, or unusual infections are typical presentations of PIDDs. Viral, bacterial, fungal, and mycobacterial infections each require distinct arms of the immune system for eradication; identification of the microbe causing an infection is helpful in directing the evaluation of a patient with suspected PIDD (see Table 164.1; Table 164.3). Children who exceed the normal *frequency* of infections or who have very *prolonged* symptoms suggesting failure of pathogen clearance may also warrant evaluation. The typical preschool child can have 6-10 viral respiratory infections per year, making this assessment less than straightforward. Patients with PIDD are significantly more likely to have severe infections requiring hospitalization and prolonged or unsuccessful treatment with IV antibiotics. Infections with unusual pathogens (opportunistic organisms) or infections resulting from live attenuated virus vaccines (rotavirus, varicella, MMR) are important warning signs. Neutropenia or lymphocytopenia may be present.

In addition to pathogen defense, the immune system must demonstrate tolerance to the host and prevent excessive inflammation that can result in tissue damage. In addition to infections, patients can present with autoimmune disease and/or autoinflammatory conditions. The presence of a family history of PIDD or consanguinity should increase suspicion for these conditions.

The patient's clinical presentation can help guide the initial laboratory evaluation (Fig. 164.1).

INFECTION RED FLAGS

Infections are one of the more common reasons to initiate an immunologic evaluation. The pattern and etiology of the infections dictate the appropriate diagnostic evaluation. A high burden of infections in a child is the most common reason for referral to an immunology

Table 164.1 Patterns of Infections and Other Conditions in Primary Immunodeficiency

	ILLNESSES	
DISORDER	**TYPE OF INFECTION**	**OTHER CONDITIONS**
Antibody defects	Sinopulmonary infections (*Streptococcus pneumoniae, Haemophilus influenzae,* or *Mycoplasma sp.*) Gastrointestinal (enteroviruses, *Salmonella, Campylobacter, Giardia,* norovirus)	Autoimmune disease (thrombocytopenia, hemolytic anemia, neutropenia) Inflammatory bowel disease Lymphadenopathy, splenomegaly Otitis, mastoiditis
Cell-mediated immunity defects	Pneumonia *(Pneumocystis jirovecii), Mycobacterium avium-intracellulare* Severe Epstein-Barr infection Gastrointestinal disease (viruses, cytomegalovirus) Fungi of the skin, nails, mucous membranes	Failure to thrive Splenomegaly, lymphadenopathy
Defects of phagocytosis	Skin, liver, lymph nodes, abscesses (*Staphylococcus,* gram-negative bacteria, fungi)	Inflammatory bowel disease Granulomatous infiltrations
Defects of complement	Sepsis and other blood-borne encapsulated bacteria; meningitis, *(Streptococcus, Pneumococcus, Neisseria)*	Autoimmune disease (systemic lupus erythematosus, ANA+, glomerulonephritis)

ANA, Antinuclear antibodies.

Table 164.2 Types of Primary Immune Defects

IMMUNODEFICIENCIES AFFECTING CELLULAR AND HUMORAL IMMUNITY	
$T^-B^+NK^-$ SCID	Common gamma chain (IL2RG, X-linked), JAK3
$T^-B^+NK^+$ SCID	IL7-α, T-cell receptor defects, CD45, PNP deficiency
T^-B^- SCID	RAG1, RAG2 defects, adenosine deaminase deficiency
COMBINED IMMUNODEFICIENCIES, GENERALLY LESS SEVERE	
MHC class I and II defects; T-cell receptor defects; DOCK8, IL21, and IL21R, and others	
COMBINED IMMUNODEFICIENCIES WITH SYNDROMIC OR OTHER FEATURES	
With thrombocytopenia	Wiskott-Aldrich syndrome
DNA repair defects	Ataxia telangiectasia, Nijmegen breakage syndrome; Bloom syndrome, dyskeratosis congenital, LIG-4
Hyper-IgE syndromes	STAT3 loss of function, and others
Immuno-osseous dysplasias	Cartilage hair hypoplasia Schimke immuno-osseous dysplasia
Ectodermal dysplasia	IKBKG deficiency (NEMO)
THYMIC DEFECTS WITH ADDITIONAL CONGENITAL ANOMALIES	
DiGeorge, velocardiofacial syndrome CHARGE syndrome	
ANTIBODY DEFECTS	
Agammaglobulinemias	X-linked and autosomal forms of agammaglobulinemia
Hyper-IgM syndromes	X-linked and autosomal forms
IgG or IgA deficiency	IgG subclass and IgA deficiency
IgG, and IgA and or IgM deficiency	Common variable immunodeficiency
DISEASES OF IMMUNE DYSREGULATION	
Familial hemophagocytic lymphohistiocytosis	Perforin deficiency; UNC13D.
With hypopigmentation	Chédiak-Higashi, Griscelli, Hermansky-Pudlak syndromes
With autoimmunity	Autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy, autoimmune lymphoproliferative syndrome
With defects of regulatory T cells	X-linked immune dysregulation, polyendocrinopathy enteropathy (IPEX), defects of CTLA4, STAT3
Leading to severe Epstein-Barr virus	X-linked autoimmune lymphoproliferative syndrome, XIAP deficiency, magnesium transporter 1 (MAGT1)
With colitis	IL-10 defects
CONGENITAL DEFECTS OF PHAGOCYTE NUMBER OR FUNCTION	
Neutropenia	Elastase deficiency, HAX1 deficiency, and others
Defects of motility	Leukocyte adhesion deficiency
Defects of respiratory burst	Chronic granulomatous disease
Other nonlymphoid defects	GATA2 deficiency
DEFECTS IN INTRINSIC AND INNATE IMMUNITY	
Mycobacterial disease	IL-12, IL-23, INF-γ, STAT1 defects, and others
Warts	Epidermodysplasia verruciformis (EVER), hypogammaglobulinemia, infections, myelokathexis syndrome (WHIM)
Viral infections	STAT1, STAT2, IRF7, and others
Herpes simplex encephalitis	TLR3, UNC93B1
Fungal diseases	CARD9, IL17 defects, STAT1
Bacterial susceptibility	IRAK4, MYD88, IRAK1, and others
COMPLEMENT DEFICIENCY	
Classical pathway	C1q-C9 defects
Alternative pathway	Factors B, D, I, H, properdin, and others
Regulatory and membrane controls	Co-factor proteins

CHARGE defect, Disorder with coloboma, heart defects, atresia choanae (also known as choanal atresia), growth retardation, genital abnormalities, and ear abnormalities; Ig, immunoglobulin; MHC, major histocompatibility complex; NK, natural killer; PNP, purine nucleoside phosphorylase; SCID, severe combined immunodeficiency.
From Leung DYM, Akdis CA, Bacharier LB, et al., eds. *Pediatric Allergy Principles and Practice.* 4th ed. Philadelphia: Elsevier; 2021. Table 4.2, p. 33-34.

center; there are certain patterns that can collectively be thought of as **red flags**, mandating an immunologic evaluation.

Recurrent Sinopulmonary Infections

Recurrent bacterial sinopulmonary infections (ear, sinus, pneumonia) with encapsulated organisms are a common presentation for PIDDs. It can be challenging to define a number of infections that represent a threshold to begin an immunologic evaluation. Typically, most patients with a PIDD will have a diversity of sites impacted by infection; the frequency will be higher or the severity more severe than the clinician would expect. Recurrent sinopulmonary infections are highly suggestive of patients with antibody deficiencies, such as common variable immunodeficiency (CVID; see Chapter 165) or X-linked agammaglobulinemia (XLA; see Chapter 166). Patients often require *longer courses*

Table 164.3 Sentinel Infections and Related Genes

INFECTIONS	RECOGNIZED GENE DEFECTS AND WELL-CHARACTERIZED SYNDROMES
VIRUSES	
Herpes simplex encephalitis	*TBK1, TLR3, TRAF3, TRIF, UNC93B*
Cutaneous herpes simplex	Severe T-cell defects, *DOCK8, GATA2, WAS*
EBV—chronic	*CD21, CD27, CORO1A, ITK, MAGT1, PRKCD, CXCR4*
EBV—HLH	*AP3B1, LYST1, PRF1, RAB27A, SH2D1A, STX11, UNC13D, XIAP*
CMV	Severe T-cell defects, Good syndrome, *DOCK8, GATA2, STIM1, WAS*
Papilloma virus	Idiopathic CD4 lymphopenia, *ATM, CD40L, EVER1, EVER2, DOCK8, GATA2, IKBKG, MST1, RORH, STK4, CXCR4*
FUNGI	
Candida	*AIRE, CARD9, IL17F, IL17RA, STAT1*
Aspergillus	Idiopathic CD4 lymphopenia, *CYBA, CYBB, DOCK8, GATA2, ITGB2, NCF1, NCF2, NCF4, STAT3*
BACTERIA	
Pseudomonas	Congenital neutropenia, *IRAK4, ITGB2, MYD88, BTK* (neutropenia), *CD40LG* (neutropenia)
Salmonella	*CYBB, IFNGR1, IFNGR2, IL12B, IL12RB1*
Serratia	*CYBA, CYBB, NCF1, NCF2, NCF4*
Neisseria	*C5, C6, C7, C8A, C8B, C8G, C9, CFD, CFH, CFI, CFP*
Streptococcus pneumoniae	*C1QA, C1QB, C1QC, C4A + C4B, C2, C3, IRAK4, MYD88*
MYCOBACTERIA	
Mycobacteria	*CYBA, CYBB, GATA2, IFNGR1, IFNGR2, IKBKG, IL12, IL12RB1, IRF8, NCF1, NCF2, NCF4, STAT1, TYK2*

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis. From Sullivan KE, Stiehm ER, eds. *Stiehm's Immune Deficiencies.* 2nd ed. London: Elsevier; 2020. Table 1.2.

of antibiotics to clear infections and may not have improvement with standard interventions such as bilateral myringotomy tubes or sinus surgery.

Recurrent Invasive Pneumococcal Infections

Invasive pneumococcal infections (sepsis, septic arthritis, meningitis) may occur in patients with antibody deficiency (Table 164.4). A single episode need not imply a PIDD. Recurrent invasive pneumococcal infections should elicit an evaluation. Pneumococcus has a polysaccharide capsule that permits it to evade the immune system. Antibodies bind to these bacteria (opsonization), which facilitates phagocytosis and bacterial killing. The early complement fragment C3b also opsonizes bacteria, labeling it for destruction. Patients with **early classical complement component deficiencies** (see Chapter 173) have an increased risk of invasive infections with encapsulated bacteria such as pneumococcus. The spleen plays a key role in the phagocytosis and clearance of nonopsonized bacteria. Thus **primary or secondary asplenia** is associated with an increased risk of disseminated infections with pneumococcus (and meningococcus) requiring patients to take antibiotic prophylaxis. Patients with **toll-like receptor (TLR) defects** (IRAK4, MyD88, and NEMO deficiency) develop invasive pneumococcal and *Staphylococcus aureus* infections. These patients uniquely fail to (or minimally) manifest signs of inflammation (fevers, elevated CRP, ESR) despite having invasive infections; this is the result of a block in the pathway that produces inflammatory cytokines such as interleukin (IL)-6 and tumor necrosis factor (TNF)-α, critical for recruitment of neutrophils and fever generation.

Severe Papillomavirus

A number of PIDDs are characterized by recurrent, severe human papillomavirus (HPV) infections (see Table 164.3). Warts are common in the general population but high numbers should suggest a PIDD. Patients with WHIM syndrome (warts, hypogammaglobulinemia, immunodeficiency, myelokathexis) have a unique susceptibility to HPV-induced warts in addition to bacterial sinopulmonary infections and cutaneous abscesses (immunity to other viral infections is intact) (see Fig. 708.6). One of the hallmarks of **DOCK8 deficiency** is severe cutaneous viral infections with HPV, molluscum contagiosum, herpes simplex, and varicella zoster. Patients with **epidermodysplasia verruciformis** have markedly increased susceptibility to cutaneous HPV infections. Patients with **GATA2 deficiency** can suffer from severe disseminated HPV, including genital locations, and molluscum contagiosum infections. Treatment is distinct for each condition, but knowing

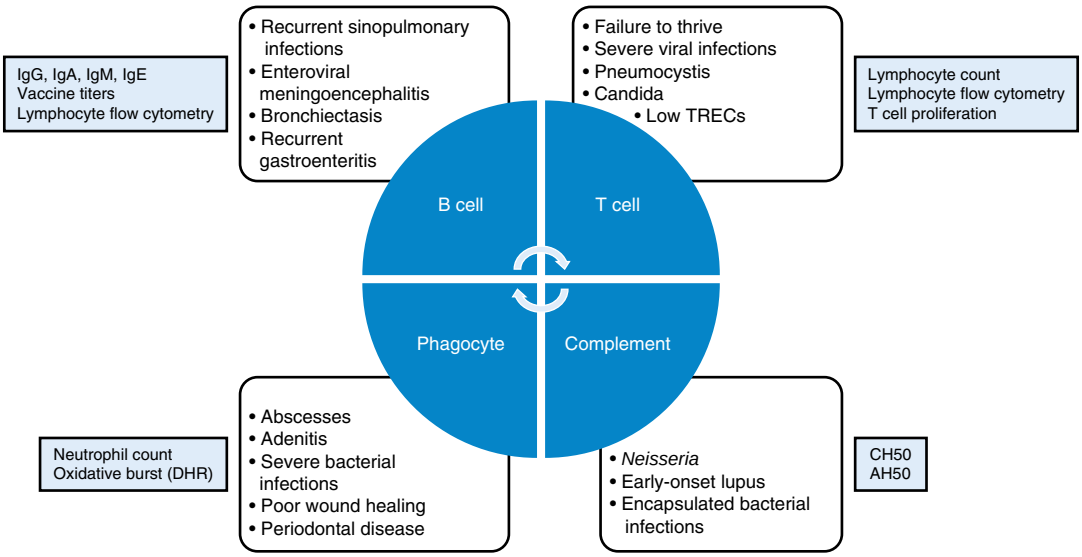

Fig. 164.1 When infections are the major manifestation of the inborn error of immunity, several types of laboratory tests can yield a diagnosis. The specific type of infection suggests the effector arm of the immune system that may be dysfunctional, and the testing can be applied in a targeted fashion. Laboratory evaluation is noted in the light blue boxes. DHR, dihydrorhodamine, Ig, immunoglobulin; TRECs, T cell receptor excision circles.

Table 164.4 Recurrent Invasive Pneumococcal Infections

CONDITION	GENE/CONDITION SUBSET	INHERITANCE	OTHER FEATURES
Asplenia	*ATRX*	XL	Developmental delay, low-set ears, single palmar crease
Asplenia	*HMOX1*	AR	Hemolysis, nephritis
Asplenia	*NKX2-5*	AD	
Asplenia	*RPSA*	AD	
Asplenia	*ZEB2*	AD	Mowat-Wilson syndrome, microcephaly, Hirschsprung disease, defects in corpus callosum
Asplenia	Gene unknown/syndromic		Can occur in heterotaxy syndromes
Antibody deficiency	*BTK*	XL	
Antibody deficiency	Hypogammaglobulinemia	Various	
Antibody deficiency	Specific antibody deficiency	Various	
Antibody deficiency	IgG subclass deficiency	Various	
Antibody deficiency	CVID	Various	
Innate immune deficiency	*MYD88*	AR	Poor fever formation
Innate immune deficiency	*IRAK4*	AR	Poor fever formation
Innate immune deficiency	*IKBKG*	XL	Peg teeth, ectodermal dysplasia
Complement deficiency	C2	AR	Can have lupus
Complement deficiency	C1	AR	Can have lupus
Complement deficiency	C4	AR	Can have lupus
Complement deficiency	C3	AR	Glomerulonephritis

AD, Autosomal dominant; AR, autosomal recessive; CVID, common variable immunodeficiency; XL, X-linked.

the immune etiology is critical because of the substantial morbidity associated with continually spreading warts.

Herpes Simplex Virus Encephalitis

Several innate PIDDs uniquely present with recurrent herpes simplex virus (HSV) encephalitis (without mucosal HSV infections) due to disruption of the signaling pathways regulating antiviral cytokines interferon (IFN)-α and -β, which are critical for control of HSV infections (see Table 164.3). Examples of these PIDDs include TLR3 deficiency, UNC93b deficiency, and interferon regulatory factor 3 (IRF3) deficiency. The importance of recognition relates to the likelihood of recurrence, with the attendant central nervous system (CNS) dysfunction that can result.

Epstein-Barr Virus

Severe life-threatening infections with fulminant Epstein-Barr virus (EBV) are a hallmark of certain PIDDs, whereas typical outpatient infectious mononucleosis infections are not concerning (see Chapter 301) (see Table 164.3). Patients with **familial hemophagocytic lymphohistiocytosis** (HLH) have a block in the cytotoxic lymphocyte (NK and CD8 T cell) pathway necessary to control EBV infections (see Chapter 556). Patients develop uncontrolled immune hyperactivation (cytokine storm) from unchecked EBV infections resulting in life-threatening HLH. Clinical symptoms include fever, hepatosplenomegaly, pancytopenia, and multi-system organ failure. There may be evidence of hemophagocytosis activated by macrophages in a bone marrow biopsy. Patients with **X-linked lymphoproliferative syndrome (XLP)** are predisposed to fatal fulminant EBV with or without HLH, as well as lymphoma. Patients with XLP who survive acute EBV infections will often go on to develop hypogammaglobulinemia. Multiple PIDD disorders have an increased risk of HLH (Table 164.5). These conditions are more likely to require hematopoietic cell transplantation (see Chapter 176) than HLH occurring in the non-PIDD community.

Severe *Candida*

Severe oral thrush from *Candida albicans* (as well as other opportunistic infections such a *Pneumocystis jiroveci*) can be seen in patients with SCID who have very low CD3 T cells (classically <300) and poor T-cell function; this mirrors the clinical phenotype of infants with HIV who also have low T cells (see Table 164.3). Intact T-cell IL-17 immunity is essential for control of *Candida* infections and overall decrements in the entire T-cell population or selective defects in the Th17 population are strongly associated with *Candida*. Patients with specific gene pathogenic variants in IL-17 signaling (IL-17RA, IL-17RC, IL-17F, and ACT1) present with **chronic mucocutaneous candidiasis** (CMCC; *Candida* infections of the skin, nails, mucosa). ***STAT1*** gain-of-function pathogenic variants result in decreased IL-17 production that also predisposes patients to skin and mucosal *Candida* infections. Autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) is an autosomal recessive disease caused by mutations in the autoimmune regulator (AIRE) gene. Patients develop CMCC and autoimmune endocrine disorders such as hypoparathyroidism and adrenal insufficiency.

Aspergillus

Neutrophils are responsible for engulfing and killing fungal organisms. *Aspergillus* species are a major cause of infections in chronic granulomatous disease (CGD), a PIDD characterized by defective neutrophil function (see Table 164.3). CGD patients most commonly develop *Aspergillus* pneumonia or osteomyelitis, although all sites are susceptible to fungal infection. *Aspergillus nidulans* infections occur almost exclusively in CGD and result in a much higher rate of osteomyelitis and mortality than *A. fumigatus*. Exposure to *Aspergillus* through handling of mulch with gardening or exposure to hay can cause fulminant pneumonitis in CGD patients. Patients with **GATA2 deficiency** and ***STAT1*** gain-of-function pathogenic variants can develop fungal infections such as aspergillus and histoplasmosis as well as atypical mycobacteria. Patients with autosomal dominant **hyper-IgE syndrome**

Table 164.5 Primary Immune Deficiency Disease and Risk of Hemophagocytic Lymphohistiocytosis*

CONDITION	GENE/CONDITION SUBSET	INHERITANCE	RISK OF HLH	OTHER FEATURES
CD48 deficiency	*CD48*	AD	High	
Chédiak-Higashi syndrome	*LYST*	AR	High	Pigmentary dilution
NLRC4	*NLRC4*		High	IBD
Perforin deficiency (FHL2)	*PRF1*	AR	High	
Griscelli syndrome, type 2	*RAB27A*	AR	High	Pigmentary dilution
X-linked lymphoproliferative disease 1	*SH2D1A*	XL	High	
Syntaxin 11 deficiency (FHL4)	*STX11*	AR	High	
STXBP2/Munc18-2 deficiency (FHL5)	*STXBP2*	AR or AD	High	Hypogammaglobulinemia, IBD
UNC13D/Munc13-4 deficiency (FHL3)	*UNC13D*	AR	High	
X-linked lymphoproliferative disease 2	*XIAP*	XL	High	
CD27 deficiency	CD27	AR	Medium	Unable to control EBV
Chronic granulomatous disease	*All genetic types*	XL, AR	Low	Infections, granulomas
Hermansky-Pudlak syndrome, type 2	*AP3B1*	AR	Low	Pigmentary dilution
Hermansky-Pudlak syndrome, type 10	*AP3D1*	AR	Low	Pigmentary dilution
Lysinuric protein intolerance SLC7A7 deficiency	*SLC7A7*	AR	Low	Lung disease, feeding intolerance

*Other primary immune deficiency diseases, including most T-cell deficiencies have been associated with HLH in rare patients.
AD, Autosomal dominant; AR, autosomal recessive; HLH, Hemophagocytic lymphohistiocytosis; IBD, inflammatory bowel disease.

(STAT3 deficiency) commonly develop lung pneumatoceles (cavities), which can then become superinfected with *Aspergillus*.

Sentinel Bacterial Infections

Certain bacterial infections are considered *sentinel infections* because the pathogen is highly associated with specific PIDDs. The following bacteria are considered highly suspicious for CGD: *Burkholderia cepacia*, *Nocardia*, *Serratia marcescens*, *Chromobacterium violaceum*, and *Granulibacter bethesdensis*. Unlike patients with cystic fibrosis, *B. cepacia* in CGD can cause pneumonia but also rapidly fatal sepsis. Terminal complement (C5-C9) and alternative complement defects (properdin or factor D deficiency) have increased susceptibility to recurrent invasive *Neisseria* species (recurrent meningococcal and disseminated gonococcal infections). Complement deficiencies are also found more frequently in patients with meningitis due to unusual serotypes of *Neisseria*.

Mycobacterial Infections

Intact IL-12 and IFN-γ signaling is required to activate phagocytes such as macrophages to clear intracellular pathogens such as mycobacteria (see Table 164.3). Patients who have defects along this pathway such as IL-12 p40, IL-12 receptor, and **IFN-γ receptor deficiency** present with atypical mycobacterial infections; these infections can spread to bones and visceral organs (rather than isolated uncomplicated cervical lymphadenitis, which does not suggest a PIDD). STAT1 deficiency is associated with mycobacterial infections because STAT1 is required for IFN-γ signaling. Patients with NEMO deficiency due to pathogenic variants in *IKBKG* develop mycobacterial disease due to impaired IL-12 production in response to infection and impaired TLR signaling. Atypical mycobacteria also cause pulmonary disease in patients with CGD. Patients with the PIDDs mentioned previously born outside of the United States who receive the bacilli Calmette-Guérin (BCG) attenuated vaccine can present with disseminated BCG strain mycobacterial infection often complicating subsequent hematopoietic cell transplantation.

Severe Cryptosporidia

Cryptosporidium is a protozoan parasite that causes diarrheal disease in humans. Exposure occurs from contaminated drinking water sources as well as fresh water and public swimming pools. Patients with PIDD can develop infections outside of the GI tract such as the lungs, biliary tract, and pancreas. Intact T-cell immunity appears to play a critical role in resolution of *Cryptosporidium* infection as evidenced by the high incidence of this infection in patients with HIV. PIDDs with impaired T-cell immunity are characterized by increased risk for developing *Cryptosporidium*. In X-linked hyper-IgM syndrome, major histocompatibility complex (MHC) class II deficiency, DOCK8 deficiency, IL-21 receptor deficiency, sclerosing cholangitis, and cirrhosis from chronic *Cryptosporidium* infection can occur. The presence of liver disease from *Cryptosporidium* appears to increase the risk of mortality from curative hematopoietic cell transplantation.

SCHEMA FOR DIAGNOSIS

Clues to the diagnosis of a PIDD may be obtained by the past and current history and the physical exam (Tables 164.6 and 164.7)

Laboratory studies typically used in the diagnosis of PIDD are rudimentary. Typical laboratory studies measure the amount of antibody or count the numbers of a given cell type (T cells as an example). There is a relatively limited ability to test function. Figures 164.1 and 164.2 outline a strategy to approach the diagnostic testing for PIDDs.

NONINFECTIOUS PRESENTATIONS SUGGESTING PIDD

Autoimmunity and inflammation can be indicators of a possible PIDD. Infections may be falsely attributed to the medications used to control the autoimmunity or inflammation. Often the usual immunologic testing is normal. Many of the autoimmune or autoinflammatory disorders associated with PIDD may need to be identified through genetic sequencing.

Autoimmunity

Autoimmunity can be the presenting manifestation of a PIDD. Rather than having the more familiar infectious phenotype, these patients have defects in tolerance or lymphocyte function that compromise their homeostasis. HLH is a profound form of immune dysregulation (see Chapter 556.2). These conditions are important to recognize because *targeted* therapies can be beneficial and because they can evolve to complex phenotypes with severe morbidity. The typical laboratory

Table 164.6 Clinical Aids to the Diagnosis of Immunodeficiency

SUGGESTIVE OF B-CELL DEFECT (HUMORAL IMMUNODEFICIENCY)
Recurrent bacterial infections of the upper and lower respiratory tracts
Recurrent skin infections, meningitis, osteomyelitis secondary to encapsulated bacteria *(Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Neisseria meningitidis)*
Severe *Giardia lamblia* infections
Paralysis after vaccination with live attenuated poliovirus
Reduced levels of immunoglobulins
SUGGESTIVE OF T-CELL DEFECT (COMBINED IMMUNODEFICIENCY)
Systemic illness after vaccination with any live virus or BCG
Unusual life-threatening complication after infection with benign viruses (giant cell pneumonia with measles; varicella pneumonia)
Chronic oral candidiasis after 6 mo of age
Chronic mucocutaneous candidiasis
Graft versus host disease after blood transfusion
Reduced lymphocyte counts for age
Low level of immunoglobulins
Absence of lymph nodes and tonsils
Small thymus
Chronic diarrhea
Failure to thrive
Recurrent infections with opportunistic organisms
Generalized, recurrent, recalcitrant warts
SUGGESTIVE OF MACROPHAGE DYSFUNCTION
Disseminated atypical mycobacterial infection, recurrent *Salmonella* infection
Fatal infection after BCG vaccination
CONGENITAL SYNDROMES WITH IMMUNODEFICIENCY
Ataxia-telangiectasia: ataxia, telangiectasia
Autoimmune polyglandular syndrome: hypofunction of one or more endocrine organs, chronic mucocutaneous candidiasis
Cartilage-hair hypoplasia: short-limbed dwarfism, sparse hair, neutropenia
Wiskott-Aldrich syndrome: thrombocytopenia, male gender, eczema
Chédiak-Higashi syndrome: oculocutaneous albinism, nystagmus, recurrent bacterial infections, peripheral neuropathies
DiGeorge syndrome (22q deletion syndrome): unusual facies, heart defect, hypocalcemia
CHARGE syndrome: coloboma, heart defects, atresia choanae, retarded growth, genital hypoplasia, ear anomalies/deafness
Short-limb skeletal dysplasia with combined immune deficiency: metaphyseal dysplasia, ADA deficiency, or Omenn syndrome
X-linked agammaglobulinemia with growth hormone deficiency: hypogammaglobulinemia, growth hormone deficiency
Kabuki syndrome: long palpebral fissures, prominent eyelashes, congenital heart disease
Timothy syndrome: prolonged QT, congenital heart disease, developmental delay
PTEN tumor hamartoma syndrome: multiple hamartomas, cancer
SUGGESTIVE OF ASPLENIA
Heterotaxia, complex congenital heart disease, Howell-Jolly bodies on blood smear, sickle cell anemia

ADA, Adenosine deaminase; BCG, bacille Calmette-Guérin.
From Verbsky JW, Routes JM. Recurrent fever, immune deficiency, and autoinflammatory disorders. In: Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis.* 2nd ed. Philadelphia: Elsevier; 2023.Table 54.7, p. 1028.

evaluations used in the diagnosis of the PIDD are often unrevealing or minimally abnormal, leading to delay in diagnosis and implementation of appropriate therapy. The prognosis may be poor; hematopoietic cell transplantation is recommended.

Early-Onset Systemic Lupus Erythematosus

Prepubertal systemic lupus erythematosus (SLE) is uncommon and onset of SLE before 5 years of age is exceptionally unusual (Table 164.8); onset before 5 years of age suggests a monogenic condition such as early complement component deficiencies (see Chapter 173). Complement deficiencies also have an infection phenotype. SLE is the dominant phenotype for C1 and C4 deficiencies. The mechanism by which these complement deficiencies lead to susceptibility to SLE is through impaired clearance of apoptotic material and compromised tolerance. SLE may present in infancy in C1 and C4 deficiencies and it is typically severe. C2 deficiency, in contrast, is associated with a milder susceptibility to SLE and proportionally higher susceptibility to infection. Other gene defects associated with early-onset SLE include lymphocyte defects such as *PRKCD*, *FAS*, and *FASL*. Manifestations of the **interferonopathies** such as Aicardi Goutières can resemble SLE and may have a high rate of antinuclear antibodies (ANA). CNS involvement and a cutaneous vasculopathy are hallmarks of interferonopathies (see Chapter 205).

Early-Onset Enteropathy

Small bowel enteropathy in these conditions is defined as non–gluten sensitive and associated with villous blunting or atrophy (Table 164.9). A key component of the differential diagnosis is the congenital diarrheas associated with either solute carrier defects or altered epithelial function (see Chapter 385). However, many of the solute carrier defects do not have villous blunting or atrophy. The early-onset enteropathy conditions are most often related to T-cell defects in intolerance and are classically associated with dysfunctional regulatory T cells such as in **IPEX** (immune dysregulation enteropathy X-linked). Identical but milder enteropathy is also seen in patients with **STAT5B deficiency** and **IL2RA deficiency**. Both of these molecules are required for critical signal transduction in regulatory T cells. Although enteropathy is often the presenting manifestation in these regulatory T-cell deficiency states, many of these patients will develop additional autoimmune features. The progression of autoimmune involvement of different organ systems can only be altered through hematopoietic cell transplantation. Enteropathy can also be seen in older individuals with one of the immune dysregulation conditions associated with **CVID**. In these conditions, the enteropathy may appear in early childhood or as late as middle age. The key to suspecting a monogenic immune dysregulation condition is the finding of villous atrophy that is not gluten-restriction responsive. Expanded populations of intraepithelial lymphocytes are also common.

Pleomorphic Autoimmunity

Autoimmunity in children usually does not imply an inherited monogenic condition (Table 164.10). In a setting where there is a strong family history and a suspected autosomal dominant condition, the first onset of autoimmunity may prompt a genetic evaluation; a single organ autoimmune disease does not strongly suggest that there is a monogenic condition underlying that autoimmune disease.

Pleomorphic autoimmunity refers to autoimmune disease affecting multiple organs in a pattern that is not typical for either age of onset or evolution. SLE can affect a number of organs as can mixed connective tissue disease, but it would be unusual for those conditions to also be associated with diabetes mellitus or autoimmune hepatitis. When autoimmunity does not fall cleanly into a particular diagnosis, it is suggestive of pleomorphic autoimmunity.

There is a broad range of defects in T- and B-cell tolerance and conditions associated with impaired regulation of T-cell behavior that can lead to an array of autoimmune conditions. The organs affected by autoimmunity typically accrue over time and in a pattern that is not standard for the known sporadic systemic autoimmune conditions. In some cases, these conditions may also have peculiar pathologic features that represent a clue that the underlying diagnosis is something other than a standard autoimmune disease of childhood. Table 164.10 attempts to categorize conditions according to the pathway implicated. There is wide heterogeneity in the timing of the autoimmune disease, the penetrance of the disease, and the end organs affected. This combination makes this particular subset of PIDD extraordinarily difficult to conceptualize. Only a high index of suspicion and the use of genetic evaluations can identify these patients who will often benefit from targeted therapeutics.

Table 164.7 Special Physical Features Associated with Immunodeficiency Disorders

CLINICAL FEATURES	DISORDERS
DERMATOLOGIC	
Eczema	Wiskott-Aldrich syndrome, IPEX, hyper-IgE syndromes, hypereosinophilia syndromes, IgA deficiency
Sparse and/or hypopigmented hair	Cartilage-hair hypoplasia, Chédiak-Higashi syndrome, Griscelli syndrome
Ocular telangiectasia	Ataxia-telangiectasia
Oculocutaneous albinism	Chédiak-Higashi syndrome
Severe dermatitis	Omenn syndrome
Erythroderma	Omenn syndrome, SCID, graft versus host disease, Comèl-Netherton syndrome
Recurrent abscesses with pulmonary pneumatoceles	Hyper-IgE syndromes
Recurrent organ granulomas or abscesses, lung, liver, and rectum especially	CGD
Recurrent abscesses or cellulitis	CGD, hyper-IgE syndrome, leukocyte adhesion defect
Cutaneous granulomas	Ataxia telangiectasia, SCID, CVID, RAG deficiency
Oral ulcers	CGD, SCID, congenital neutropenia
Periodontitis, gingivitis, stomatitis	Neutrophil defects
Oral or nail candidiasis	T-cell immune defects, combined defects (SCIDs); mucocutaneous candidiasis; hyper-IgE syndromes; IL-12, IL-17, and IL-23 deficiencies; *CARD9* deficiency; STAT1 deficiency
Vitiligo	B-cell defects, mucocutaneous candidiasis
Alopecia	B-cell defects, mucocutaneous candidiasis
Chronic conjunctivitis	B-cell defects
EXTREMITIES	
Clubbing of nails	Chronic lung disease caused by antibody defects
Arthritis	Antibody defects, Wiskott-Aldrich syndrome, hyper-IgM syndrome
ENDOCRINOLOGIC	
Hypoparathyroidism	DiGeorge syndrome, mucocutaneous candidiasis
Endocrinopathies (autoimmune)	Mucocutaneous candidiasis
Diabetes, hypothyroid	IPEX and IPEX-like syndromes
Growth hormone deficiency	X-linked agammaglobulinemia
Gonadal dysgenesis	Mucocutaneous candidiasis
HEMATOLOGIC	
Hemolytic anemia	B- and T-cell immune defects, ALPS
Thrombocytopenia, small platelets	Wiskott-Aldrich syndrome
Neutropenia	Hyper-IgM syndrome, Wiskott-Aldrich variant, CGD
Immune thrombocytopenia	B-cell immune defects, ALPS
SKELETAL	
Short-limb dwarfism	Short-limb dwarfism with T-cell and/or B-cell immune defects
Bony dysplasia	ADA deficiency, cartilage-hair hypoplasia

ADA, Adenosine deaminase; ALPS, autoimmune lymphoproliferative syndrome; CGD, chronic granulomatous disease; CVID, common variable immunodeficiency; IPEX, X-linked immune dysfunction enteropathy polyendocrinopathy; SCID, severe combined immunodeficiency.
From Goldman L, Ausiello D, ed. *Cecil Textbook of Medicine.* 22nd ed. Philadelphia: Saunders; 2004. p 1599.

Inflammatory Diseases

Many of the recognized inflammatory diseases are the periodic fever (autoinflammatory) syndromes (see Chapter 204). Distinguishing fevers related to infection and those fevers that are driven by endogenous immune dysfunction is often initially difficult. The first contact with the healthcare system may be by a subspecialist who may only recognize the initial presenting manifestation. The inflammatory diseases are typically managed according to the pathway that is defective; therefore the distinction between these conditions and the autoimmune conditions is critically important.

Very Early Onset Inflammatory Bowel Disease

A key setting where a monogenic inflammatory condition should be considered is infantile-onset inflammatory bowel disease or early-onset inflammatory bowel disease with additional autoimmune features (see Chapter 382.1). Overall, approximately 20% of children who develop inflammatory bowel disease prior to 6 years of age will have a monogenic immune-based condition. The frequency increases with infantile onset or with panenteric disease. The diagnosis is most often established through genetic sequencing because the implicated genes are numerous and diverse (see Chapters 174 and 382.3). These conditions are managed with targeted biologic or small molecule agents with a few select patient subsets requiring hematopoietic cell transplantation.

Fever Syndromes

The central feature of the inherited fever syndromes is fever arising in the absence of infectious trigger (see Chapter 204). Infants and toddlers may have infections with a frequency of one per month and take as long as 2 weeks to recover. Nevertheless, the parents will often remark that the fevers "came out of the blue" or no one else in the household was ill at the time and express surprise at the frequency with which their child has been diagnosed with a viral infection with no viral symptoms. Some of the fever syndromes have fever that is typically isolated with no additional end-organ effects, whereas others have fever as a component of a much larger systemic inflammatory picture.

The most familiar inherited fever syndromes are those associated with inflammasome activation and typically treated with IL-1 inhibitors. A key consideration in the differential diagnosis for these conditions is the nongenetic condition called periodic fever aphthous stomatitis pharyngitis adenitis (PFAPA; see Chapter 204).

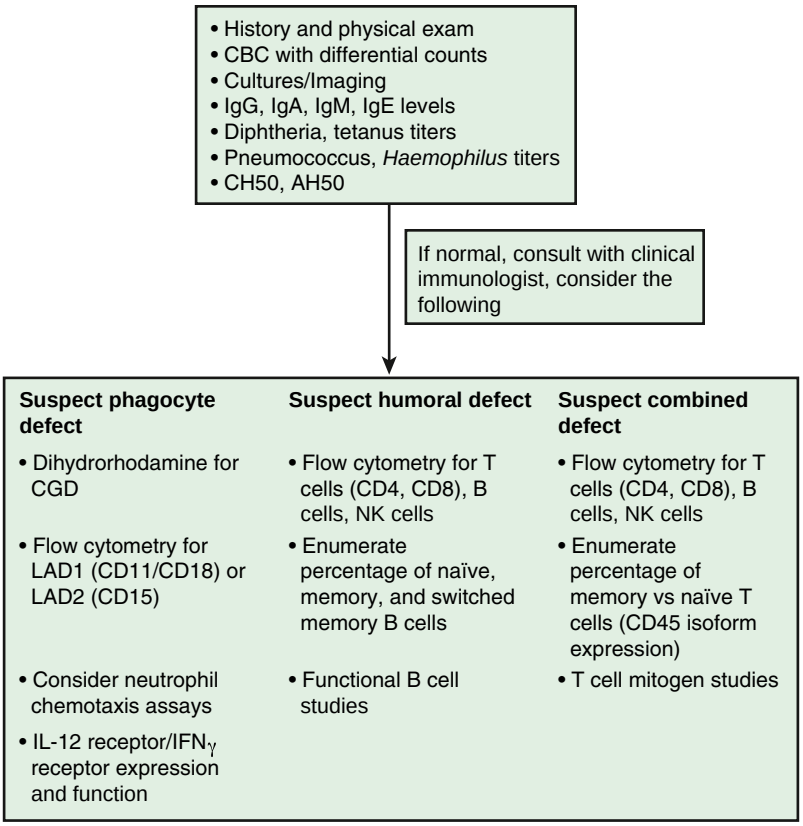

Fig. 164.2 Initial work-up and follow-up studies of patients with suspected immune deficiency. Consultation with a clinical immunologist is recommended to guide advanced testing and interpret results. CGD, Chronic granulomatous disease; Ig, immunoglobulin; LAD, leukocyte adhesion defect; NK, natural killer; IL, interleukin; IFN, interferon. *(From Verbsky JW, Routes JM. Recurrent fever, immune deficiency, and autoinflammatory disorders. In Kliegman RM, Toth H, Bordini BJ, Basel D, eds. Nelson Pediatric Symptom-Based Diagnosis. 2nd ed. Philadelphia: Elsevier; 2023. Although genetic fever syndromes may have a cutaneous component, abdominal pain, or nausea, fever is by far the dominant manifestation. There may be a family history or there may be an ethnic background that suggests the diagnosis (e.g., familial Mediterranean fever).

Other fever syndromes are related to proteasome dysfunction. These often have a very strong cutaneous component that can be a neutrophilic dermatosis or more of a vasculopathic picture with chilblains affecting the ears, fingers, and toes. Over time, these conditions may develop lipodystrophy. Fever is often seen in these conditions before 5 years of age. Treatment often includes a Jak inhibitor.

In their most severe form, interferonopathies present with the infantile-onset leukoencephalopathy called **Aicardi Goutières syndrome**. There are milder variants leading to interferon production that can be associated with later onset and a picture more typical for SLE. The earlier the onset the more likely there is to be significant brain involvement. These conditions are treated with Jak inhibitors.

Section 2

The T-, B-, and NK-Cell Systems

Chapter 165

T-Cell and Combined Deficiencies

Ramsay L. Fuleihan

T-CELL AND COMBINED DEFICIENCIES

T lymphocytes (T cells) play a central role in the orchestration and regulation of the adaptive immune response. CD4 T cells help B cells synthesize specific IgG, IgA, and IgE antibodies and develop into memory B cells, help macrophages kill intracellular pathogens, and regulate the immune response. CD8 T cells kill virus-infected or malignant cells. Immune deficiency diseases that disrupt T-cell development or function are usually severe, affecting multiple aspects of adaptive immunity, and are thus *combined immune deficiency diseases*. A hallmark of the adaptive immune response is specific recognition of pathogen proteins via antigen receptors, the T-cell receptor (TCR) in T cells and immunoglobulin in B cells. Antigen receptors have a variable region that is formed by random rearrangement of two to three gene segments, V(D)J, allowing a large variety of antigen recognition. TCRs recognize a fragment of a protein that is presented by the major histocompatibility complex (MHC) molecules; therefore the randomly generated variable region of the TCR needs to be able to interact with the individual's MHC molecules. During T-cell development in the thymus, only thymocytes with TCRs that recognize the individual's MHC molecules are selected to survive (positive selection) and all other thymocytes die (by neglect). Among the thymocytes that survive, those with self-reactive TCRs are eliminated (negative selection) or develop into regulatory T cells to prevent autoimmune disease (Fig. 165.1). There is a symbiotic relationship between the thymus and developing thymocytes, where the absence of a thymus affects T-cell development and the absence of thymocytes leads to disruption of the thymic architecture. Pathogenic gene variants affecting any of the signaling pathways, DNA recombination, and repair enzymes as well as the thymic environment can lead to T-cell and combined immune deficiency diseases.

165.1 Severe Combined Immunodeficiencies

Ramsay L. Fuleihan

Severe combined immunodeficiency (SCID) is caused by diverse pathogenic gene variants that lead to absence of T- and B-cell function. Patients with this group of disorders have the most severe immunodeficiency.

GENETICS AND PATHOGENESIS

SCID is caused by pathogenic variants in genes crucial for lymphoid cell development or function (Table 165.1 and Fig. 165.2). All patients with SCID have very small thymuses that contain no thymocytes and lack corticomedullary distinction and lack Hassall's corpuscles. The thymic epithelium appears histologically normal. Both the follicular and the paracortical areas of the spleen are depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped.

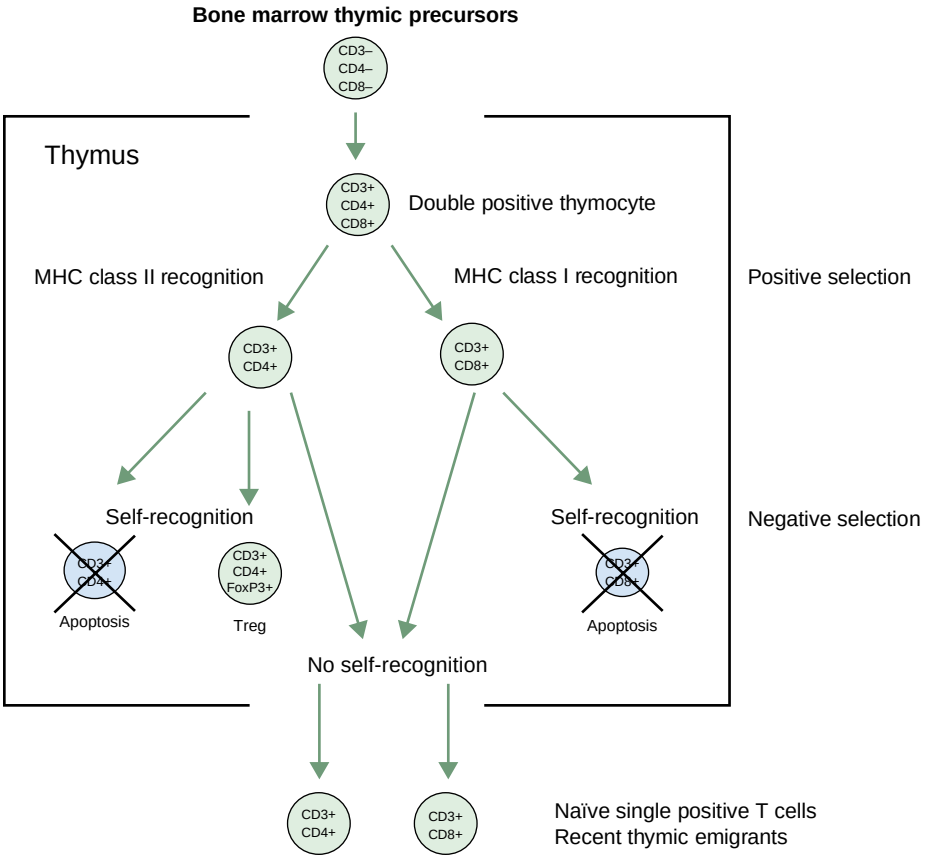

Fig. 165.1 Schematic representation of T-cell development in the thymus. Thymocyte precursors leave the bone marrow and enter the thymus with no expression of CD3, CD4, or CD8 (double negative T cells). Later the thymocytes express CD3 and both CD4 and CD8. If the newly formed T-cell receptor (TCR) recognizes major histocompatibility complex (MHC) class I or class II molecules, the thymocytes receive a positive selection signal and develop into CD8 or CD4 single positive thymocytes, respectively. Single positive thymocytes with TCR that recognize self-proteins will be killed by apoptosis or develop into regulatory T cells (Treg) to prevent autoimmune disease. Single positive thymocytes that are non–self-reactive leave the thymus as naïve single positive T cells ready to engage in the immune response when needed.

Table 165.1 Genetic Basis of Severe Combined Immunodeficiency and SCID Variants

DISEASE	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
T^-B^- SCID				
Reticular dysgenesis	AR	Impaired mitochondrial energy metabolism and leukocyte differentiation	Severe neutropenia, deafness Pathogenic variants in adenylate kinase 2	GCSF, HSCT
Reticular dysgenesis	AD	Impaired hematopoiesis	Severe neutropenia but no deafness, gain-of-function variant in RAC2	HSCT
Adenosine deaminase deficiency	AR	Accumulation of toxic purine nucleosides	Neurologic, hepatic, renal, lung, skeletal, bone marrow abnormalities	HSCT, PEG-ADA, gene therapy
RAG1 and RAG2 deficiency	AR	Defective V(D)J recombination	None	HSCT
Artemis deficiency	AR	Defective V(D)J recombination, radiation sensitivity	*DCLERE1C* pathogenic gene variants	HSCT
DNA-PK deficiency	AR	Defective V(D)J recombination	None	HSCT
DNA ligase IV deficiency	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay, microcephaly, bone marrow abnormalities, lymphoid malignancies	HSCT
Cernunnos-XLF	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay, microcephaly, birdlike facies, bone defects	HSCT
T^-B^+ SCID				
γ_c (CD132) deficiency	XL	Abnormal signaling via γ_c-ILRs (IL-2, 4, 7, 9, 15, 21)	None	HSCT, gene therapy
Jak3 deficiency	AR	Abnormal signaling downstream of γ_c	None	HSCT
IL-7Rα deficiency	AR	Abnormal IL-7R signaling	Thymus absent	HSCT
CD45 deficiency	AR		None	HSCT
CD3δ deficiency	AR	Arrest of thymocytes differentiation at $CD4^-CD8^-$ stage	Thymus size may be normal	HSCT
CD3ε deficiency	AR	Arrest of thymocytes differentiation at $CD4^-CD8^-$ stage	γ/δ T cells absent	HSCT
CD3ζ deficiency	AR	Abnormal signaling	None	HSCT
Coronin-1A deficiency	AR	Abnormal T-cell egress from thymus and lymph nodes	Normal thymus size Attention deficit disorder	HSCT
LAT deficiency	AR	Defective T-cell development in the thymus	Autoimmune disease	HSCT
SLP76	AR	Abnormal signaling	Neutrophil defect, skin abscesses, rash, autoimmunity	HSCT attempted

γ_c, Common gamma chain; AD, Autosomal dominant; AR, Autosomal recessive; GCSF, granulocyte colony-stimulating factor; HSCT, hematopoietic stem cell transplantation; IL, interleukin; Jak3, Janus kinase 3; PEG-ADA, polyethylene glycol-modified adenosine deaminase; R, receptor; RAG1, RAG2, recombinase-activating genes 1 and 2; SCID, severe combined immune deficiency; V(D)J, variable, diversity, joining domains; XL, X-linked.

Adapted from Roifman CM, Grunebaum E. Primary T-cell immunodeficiencies. In: Rich RR, Fleisher TA, Shearer WT, et al., eds. *Clinical Immunology*. 4th ed. Philadelphia: Saunders; 2013. pp. 440-441.

The 4 most common types of SCID are the X-linked forms caused by pathogenic variants in *CD132*, autosomal recessive *RAG1* and *RAG2* deficiencies, and adenosine deaminase (ADA) deficiency. Additional forms are listed in Table 165.1. For X-linked SCID and *ADA* deficiency, gene therapy exists, but genetic counseling is the most compelling reason for genetic sequencing to identify the pathogenic gene variant. Several specific pathogenic gene variants are associated with increased sensitivity to radiation and chemotherapy, and their early identification can lead to a better transplant experience by avoiding or reducing dosages of conditioning agents.

CLINICAL MANIFESTATIONS

SCID is included in the newborn screening program in all states in the United States and in several countries around the world. Thus infants can be identified and treated prior to development of symptoms, which has dramatically improved the survival of infants with SCID. A few genetic types of SCID are not detected by newborn screening, and there are many countries where newborn screening for SCID is not yet performed. Therefore an awareness of the clinical presentation of SCID remains important in the early diagnosis and treatment of patients.

When infants with SCID are not detected through newborn screening, they most often present with **infection** during infancy. Diarrhea, pneumonia, otitis media, sepsis, and cutaneous infections are common presentations. Infections with a variety of opportunistic organisms, either through direct exposure or immunization, can lead to death. Potential infectious threats include *Candida albicans, Pneumocystis jiroveci* (PJP), parainfluenza 3 virus, adenovirus, respiratory syncytial virus (RSV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus, measles virus, and attenuated organisms from the MMRV (measles, mumps, rubella, varicella), rotavirus, oral polio, nasal influenza, yellow fever, or bacille Calmette-Guérin (BCG) vaccines. Disseminated BCG infection may be the presenting feature of SCID in countries where the vaccine is given at birth. Infants with SCID also lack the ability to reject foreign tissue and are therefore at risk for severe or fatal **graft versus host disease (GVHD)** from T lymphocytes in nonirradiated blood products or maternal immunocompetent T cells

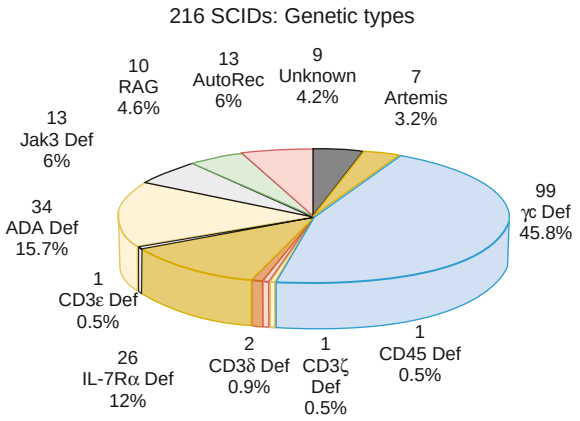

Fig. 165.2 Relative frequencies of the different genetic types of severe combined immunodeficiency (SCID) among 216 patients seen consecutively. *(From Buckley RH, Orange JS. Primary immunodeficiency diseases. In: Burks AW, Holgate ST, O'Hehir RE, et al., eds. Middleton's Allergy: Principles and Practice. 9th ed. Philadelphia: Elsevier; 2020. Fig. 69.2, p. 1126.)*

Fig. 165.3 Typical clinical features in an infant with Omenn syndrome. Note generalized erythroderma with scaly skin, alopecia, and edema. *(From Notarangelo LD. T cell immunodeficiencies. In: Leung DYM, Akdis CA, Bacharier LB, et al., eds. Pediatric Allergy Principles and Practice. 4th ed. Philadelphia: Elsevier; 2021. Fig 6.1.)*

that crossed the placenta during pregnancy. The latter is usually not fatal but can be severe. This devastating presentation is characterized by expansion of the allogeneic cells, rash, hepatosplenomegaly, and diarrhea. A third presentation is often called **Omenn syndrome**, caused by hypomorphic pathogenic variants in SCID-causing genes, which allow few T cells to be generated in the infant that then expand, unregulated, and cause a clinical picture similar to GVHD (Fig. 165.3) with a severe dermatitis, lymphadenopathy, and diarrhea. The difference in this case is that the cells are the infant's own cells. Dermatitis, especially if it is difficult to treat, failure to thrive, and infection in the first 6 months of life, particularly severe infections from commonly mild pathogens or opportunistic organisms, should raise the suspicion of SCID.

All genetic types of SCID are associated with profound immunodeficiency. A small number have other associated features or atypical features that are important to recognize. ADA deficiency can be associated with pulmonary alveolar proteinosis and chondroosseous dysplasia. Adenylate kinase 2 (AK2) deficiency causes a picture referred to as **reticular dysgenesis** where neutrophils, myeloid cells, and lymphocytes are all low. This condition is also often associated with deafness.

DIAGNOSIS

A high index of suspicion is very important in the diagnosis of SCID. A key feature of SCID is that almost all patients will have a low lymphocyte count. Some patients may have a normal lymphocyte count from proliferation of B cells and/or natural killer (NK) cells. A combination of infection and a persistently low lymphocyte count is an indication to test for SCID. The diagnostic strategy both for symptomatic infants and those detected by newborn screening or with a family history of SCID is to perform flow cytometry to quantitate the T, B, and NK cells in the infant (Fig. 165.4). The CD45RA (naïve T-cell) and CD45RO (memory T-cell) markers can be helpful to identify patients with maternal engraftment or Omenn syndrome with predominantly memory T cells. Identification of a limited TCR repertoire is also helpful in the diagnosis of Omenn syndrome. T-cell function is often assessed by measuring proliferative responses to stimulation with mitogens.

Gene sequencing is often done by requesting a SCID gene panel or a more extensive primary immunodeficiency (PID) gene panel. There are certain laboratory features that predict specific gene defects. When both T and B cells are low with normal numbers of NK cells, often a gene encoding a protein involved in V(D)J recombination is the cause such as *RAG1* and *2*. Similarly, certain cytokine receptor defects are associated with specific SCID lymphocyte phenotypes, such as absent T cells and NK cells, but normal or elevated numbers of B cells in X-SCID caused by pathogenic variants in the common gamma chain (CD132) of cytokine receptors. Pathogenic variants in Janus kinase *(JAK)3*, which signal downstream of CD132, cause an autosomal recessive form of SCID affecting both females and males, with an identical lymphocyte phenotype as X-SCID.

The diagnosis of SCID can be established by the presence of a known pathogenic gene variant, low T-cell counts with proliferative response to the mitogen phytohemagglutinin (PHA) less than 10% of a normal control, or the identification of maternal T cells in the child. In male infants, this can be determined by fluorescence in situ hybridization (FISH) for the X and Y chromosomes.

Newborn Screening

Newborn screening for SCID has allowed the early diagnosis and treatment of SCID, improving the outcome of therapy and changing the natural history of the disease. Newborn screening is based on quantitative polymerase chain reaction (PCR) of T-cell receptor excision circles (TRECs), which are formed during V(D)J rearrangement of the variable region of the TCR chains. These TRECs do not replicate during cell division; they are thus present in most or all recent thymic emigrants but get diluted out as T cells divide in the periphery. The TREC assay identifies low numbers of recent thymic emigrants, which is not diagnostic of SCID, but raises suspicion to proceed with an evaluation of lymphocyte subsets and function followed by confirmation with genetic testing. Other diseases with low T-cell counts may also be identified by newborn screening and include 22Q11.2 deletion syndrome, Rac2 deficiency, trisomy 21, and idiopathic lymphopenia, which was not well appreciated until newborn screening was implemented. In many countries, kappa excision circles (KRECs), generated during B-cell development, are assayed simultaneously with TRECs allowing a larger number of types of SCID to be identified as well as allowing identification of infants with agammaglobulinemia.

TREATMENT

SCID is a true pediatric immunologic emergency. Unless immunologic reconstitution is achieved through hematopoietic stem cell transplantation (HSCT) or gene therapy, death usually occurs during the first year of life and almost invariably before 2 years of age. HSCT in the first 100 days of life or in an infant prior to infection is associated with a 95% survival rate. In patients with SCID, 92% have survived after T-cell–depleted parental marrow is given soon after birth when the infant is healthy, without pretransplant chemotherapy or posttransplant GVHD prophylaxis, although T-cell reconstitution is improved with pretransplant conditioning including reduced-intensity protocols.

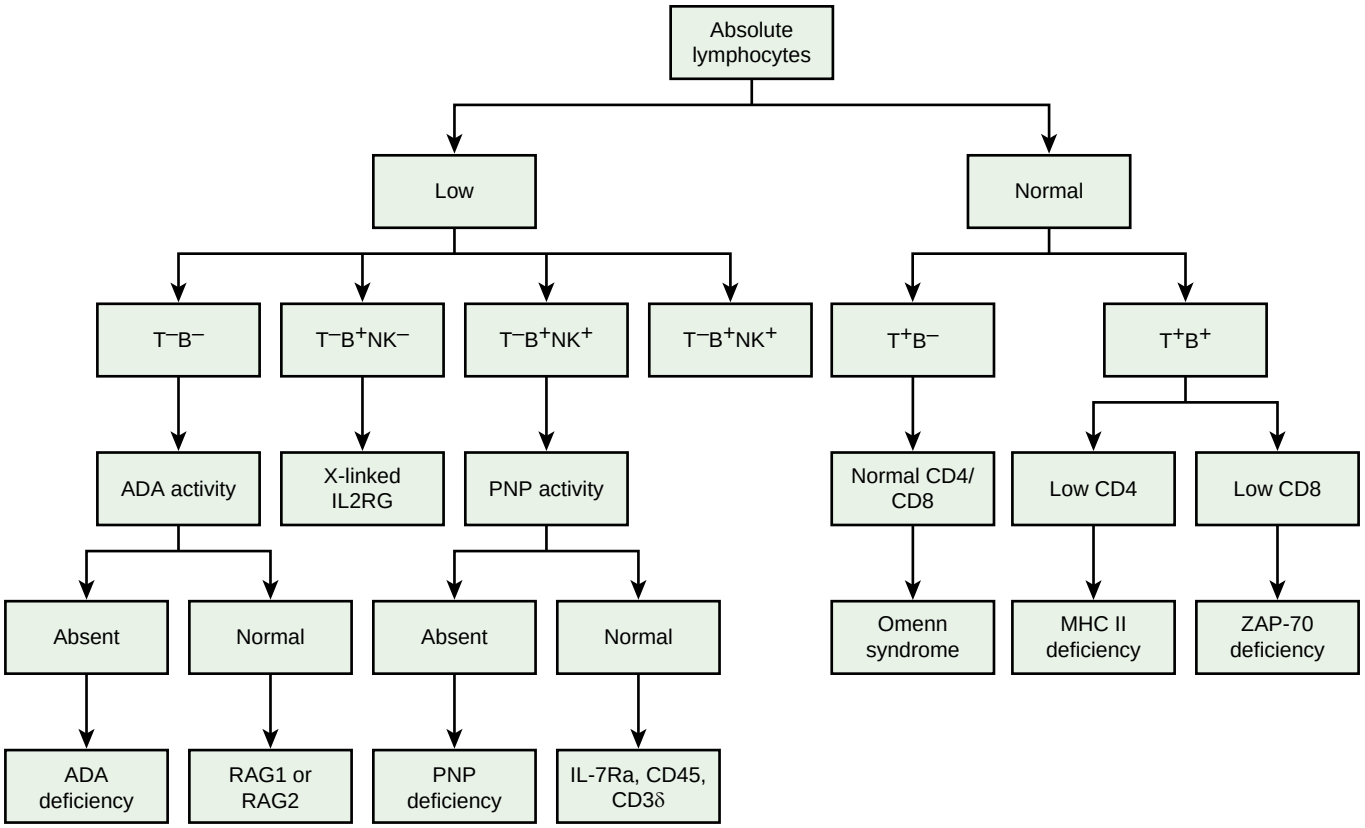

Fig. 165.4 Using the absolute lymphocytes count as a starting place to suggest the type of severe combined immunodeficiency (SCID) that may be present. ADA, Adenosine deaminase; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase. *(From Cunningham-Rundles C. Approach to the child with recurrent infections and molecular diagnosis. In: Leung DYM, Akdis CA, Bacharier LB, et al., eds. Pediatric Allergy Principles and Practice. 4th ed. Philadelphia: Elsevier; 2021. Fig. 4.2.)*

Bone marrow transplantation remains the most important and effective therapy for SCID. In ADA-deficient and X-linked SCID, there has been success in correcting the immune defects with ex vivo gene transfer to autologous hematopoietic stem cells. Initial protocols of gene therapy for X-linked SCID resulted in **insertional mutagenesis** with the development of leukemic-like clonal T cells or lymphoma in some patients. Modification of the gene therapy protocol has greatly reduced the risk of insertional mutagenesis. ADA-deficient SCID can also be treated with enzyme replacement by repeated injections of polyethylene glycol-ADA (PEG-ADA), although the immune reconstitution achieved is not as effective as with HSCT or gene therapy. Until definitive therapy can be achieved, SCID patients should be treated with supportive care for prevention and treatment of infections with immunoglobulin replacement and microbial prophylaxis starting at 4-6 weeks of age including PJP prophylaxis as well as viral and fungal prophylaxis. Breastfeeding should be avoided if the mother is CMV or EBV positive as infection can be transmitted via breast milk.

165.2 Combined Immunodeficiencies

Ramsay L. Fuleihan

Combined immunodeficiency (CID) is distinguished from SCID by the presence of low but not absent T-cell function. CID is a syndrome of diverse genetic causes and, therefore, diverse clinical and laboratory characteristics. Patients with CID may have recurrent or chronic pulmonary infections, opportunistic infections, failure to thrive, oral or cutaneous candidiasis, chronic diarrhea, recurrent skin infections, gram-negative bacterial sepsis, urinary tract infections, or severe varicella in infancy. Although they usually survive longer than infants with SCID, patients with CID fail to thrive and often die before reaching adulthood. Neutropenia and eosinophilia are common. Serum immunoglobulins may be normal or elevated for all classes; selective IgA deficiency, marked elevation of IgE, and elevated IgM levels occur in some cases. Although antibody-forming capacity is impaired in most patients, it may not be absent.

Studies of cellular immune function may show lymphopenia, deficiencies of T cells, specific T-cell subsets, or switched memory B cells, and extremely low but not absent lymphocyte proliferative responses to mitogens, antigens, or allogeneic cells in vitro. Peripheral lymphoid tissues may demonstrate paracortical lymphocyte depletion. The thymus is usually small, with a paucity of thymocytes and usually no Hassall's corpuscles.

There is a large number and variety of CIDs caused by pathogenic variants in many different genes. A list of known causes of CID with some of their characteristic features can be found in Tables 165.2 to 165.7.

COMBINED IMMUNODEFICIENCIES THAT ARE GENERALLY LESS PROFOUND THAN SCID

Several types of CID are characterized by a severe immunodeficiency but affected patients tend to survive longer than patients with SCID (see Table 165.2). These patients are susceptible to severe viral, opportunistic, and/or fungal infections. Their laboratory features are variable from normal lymphocyte subsets to a severe deficiency of CD4, CD8, or both cell types. Invariably, T-cell function is decreased but proliferative responses to mitogens and, in some cases, to antigens may be normal, making it difficult to have unifying laboratory characteristics for this group of diseases. The severity of clinical infection and/or the presence of a family history of CID should raise suspicion and initiate a laboratory evaluation for these diseases.

COMBINED IMMUNODEFICIENCY FROM DEFICIENCY IN CD4 T-CELL HELPER FUNCTION

CD4 T cells play an important role in orchestrating the immune response. Helper function from CD4 T cells is critical for immunoglobulin isotype switching, somatic hypermutation, and B-cell memory

Table 165.2 Combined Immunodeficiencies Generally Less Profound Than SCID

DISEASE (DEFICIENCY)	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
CD40 Ligand (CD154)	XL	Defective CD40 ligand:CD40 signaling	Opportunistic infections, neutropenia, biliary tract and liver disease/cancer, neuroectodermal cancer	HSCT
CD40	AR	Defective CD40 ligand:CD40 signaling	Opportunistic infections, neutropenia, biliary tract and liver disease	HSCT
ICOS	AR		Autoimmunity, gastroenteritis, granulomas	
ICOS Ligand	AR	Decreased T and B cells	Neutropenia	
CD3γ	AR	Low TCR expression	Autoimmunity of variable severity	
CD8	AR	Absent CD8 T cells	May be asymptomatic	
ZAP-70 LOF	AR	Low CD8 T cells, poor CD4 T-cell function	May have immune dysregulation, autoimmunity	HSCT
ZAP-70 LOF/GOF	AR	Low CD8 T cells	Severe autoimmunity, bullous pemphigoid, inflammatory colitis	HSCT
MHC class I (TAP1, TAP2, TAPBP, β_2-microglobulin)	AR	Low CD8 T cells, absent MHC I on lymphocytes and thymic epithelium	Vasculitis, pyoderma gangrenosum	
MHC class II (CIITA, RFX5, RFXANK, RFXAP)	AR	Low CD4 T cells absent MHC II on lymphocytes and thymic epithelium	Failure to thrive, liver biliary tract disease	HSCT
IKAROS	AD	No memory T cells or B cells	Opportunistic infections, early CID onset	
DOCK2	AR	Low T cells and poor NK cell function	Invasive herpesvirus infections, poor interferon responses	
Polymerase and (POLD1, POLD2)	AR	Low CD4 T cells	Skin infections, warts and molluscum, short stature, intellectual disability	
RHOH	AR	Restricted TCR repertoire	HPV infection, lung granulomas, molluscum, lymphoma	
STK4	AR	Low CD4 T cells	Intermittent neutropenia, viral and *Candida* infection, lymphoproliferation, autoimmune cytopenias, lymphoma, congenital heart disease	
TCRα	AR	Absent TCRαβ	Immune dysregulation, autoimmunity, diarrhea	
LCK	AR	Poor TCR signaling, low CD4 T cells and low regulatory T cells, restricted TCR repertoire	Immune dysregulation, autoimmunity	
ITK	AR	Decreased T-cell activation, progressive decline in CD4 T cells	EBV-associated B-cell lymphoproliferation, immune dysregulation	
MALT1	AR	Poor T-cell proliferation		
CARD11 LOF	AR	Poor T-cell proliferation	Opportunistic infections	
BCL10	AR	Poor T-cell antigen or anti-CD3 proliferation, few memory T cells and Tregs	Candidiasis, gastroenteritis	
IL-21	AR	Low T-cell function, low memory/switched B cells	Opportunistic infections, liver disease	
IL-21R	AR	Low cytokine production, low T-cell antigen proliferation		
OX40	AR	Low Ag-specific memory CD4 T cells	Impaired immunity to HHV8, Kaposi's sarcoma	
IKBKB	AR	Impaired TCR activation, absent Treg and γ/δ T cells	Opportunistic infections	HSCT
NIK	AR	Poor T-cell antigen proliferation, low switched memory B cells	*Cryptosporidium* infection	
RelB	AR	Reduced TCR diversity with poor proliferation to mitogens and absent to antigens

Table 165.2 Combined Immunodeficiencies Generally Less Profound Than SCID—cont'd

DISEASE (DEFICIENCY)	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
RelA haploinsufficiency	AD	Impaired NFκB activation with decreased inflammatory cytokines	Chronic mucocutaneous ulceration	
Moesin	XL	Defective T-cell migration and proliferation	Varicella infections, neutropenia	
TFRC	AR	Poor T-cell proliferation, low memory B cells	Neutropenia, thrombocytopenia	
c-Rel	AR	Poor T- and B-cell proliferation, low memory CD4 and low memory B cells	*Mycobacteria* and *Salmonella* infections, opportunistic infections, defective innate immunity	
FCHO1	AR	Poor T-cell proliferation	Mycobacterial infections, lymphoproliferation, failure to thrive	

Ag, antigen; AD, Autosomal dominant; AR, autosomal recessive; CID, combined immune deficiency; EBV, Epstein-Barr virus; HHV8, human herpesvirus-8; HPV, human papillomavirus; HSCT, hematopoietic stem cell transplantation; IL, interleukin; GOF, gain of function; LOF, loss of function; MHC, major histocompatibility complex; NK, natural killer; R, receptor; TCR, T-cell receptor; Treg, regulatory T cell; XL, X-linked.

Table 165.3 DNA Repair Defects Other Than Causing SCID

DISEASE	GENE	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
Ataxia-telangiectasia	*ATM*	AR	Progressive decrease in T cells, poor T-cell proliferation	Ataxia, telangiectasia, elevated IgM, lymphoreticular malignancy, increased radiosensitivity, chromosomal instability and translocations	Ig replacement, supportive care, avoid ionizing radiation
Nijmegen breakage syndrome	*NBS1*	AR	Progressive decrease in T cells	Microcephaly, dysmorphic features, lymphomas and solid tumors, hyper-IgM	Ig replacement, supportive care, avoid ionizing radiation
Bloom syndrome	*BLM*	AR	Marrow failure, low Ig	Short stature, dysmorphic facies, sun-sensitive erythema, leukemia, lymphoma, chromosomal instability	Ig replacement, supportive care, avoid ionizing radiation
Immunodeficiency with centromeric instability and facial anomalies (ICF types 1, 2, 3, 4)	*DNMT3B* *ZBTB24* *CDCA7* *HELLS*	AR	Decreased T cells, decreased response to PHA, hypogammaglobulinemia with variable antibody deficiency	Facial dysmorphism, developmental delay, macroglossia, opportunistic infections, malabsorption, cytopenias, malignancies, multiradial configurations of chromosomes 1, 9, 16	Ig replacement, supportive care, avoid ionizing radiation
PMS2 deficiency	*PMS2*	AR	Low B cells, abnormal antibody responses	Café-au-lait spots, hyper-IgM, lymphoma, colorectal carcinoma, brain tumors	Ig replacement, supportive care, avoid ionizing radiation
Radiosensitivity, immune deficiency, dysmorphic features, learning difficulties (RIDDLE) syndrome	*RNF168*	AR	Low IgG or IgA	Short stature, mild defects of motor control to ataxia, may have learning difficulties	Ig replacement, supportive care, avoid ionizing radiation
MCM4 deficiency	*MCM4*	AR	Low number and function of NK cells	Short stature, B-cell lymphoma, adrenal failure	Supportive care, avoid ionizing radiation
Polymerase ε subunit 1 deficiency (FILS syndrome)	*POLE1*	AR	Decreased T-cell proliferation	Short stature, facial dysmorphism, livedo	Ig replacement, supportive care, avoid ionizing radiation

Table 165.5 Other Combined Immunodeficiencies

DISEASE	GENE	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
PNP deficiency	*PNP*	AR	Progressive decrease in T cells	Autoimmune hemolytic anemia, neurologic impairment	HSCT
Immunodeficiency with multiple intestinal atresias	*TTC7A*	AR	Variable T-cell counts but may be as low as SCID with low TRECs at NBS	Multiple intestinal atresias, intrauterine polyhydramnios, early demise, bacterial (sepsis), viral and fungal infections	HSCT for severe T-cell deficiency
Trichohepatoenteric syndrome (THES)	*TTC37* *SKIV2L*	AR	Impaired IFNγ production, variably low switched memory B cells, hypogammaglobulinemia, may have low antibody responses	Respiratory infections; IUGR; facial dysmorphic features, wooly hair; early-onset intractable diarrhea, liver cirrhosis; platelet abnormalities	
Hepatic venoocclusive disease with immunodeficiency (VODI)	*SP110*	AR	Decreased memory T and B cells; low IgG, IgA, and IgM; absent germinal centers and tissue plasma cells	Hepatic venoocclusive disease Susceptibility to opportunistic infections: PJP, CMV, *Candida* Thrombocytopenia, hepatosplenomegaly, cerebrospinal leukodystrophy	
BCL11B deficiency	*BCL11B*	AD	Decreased T-cell counts with poor proliferation	Congenital abnormalities, neonatal teeth, dysmorphic facies; absent corpus callosum, neurocognitive deficits	
EPG5 deficiency (Vici syndrome)	*EPG5*	AR	Very low CD4 T cells, decreased Ig levels especially IgG2, defective B cells	Chronic mucocutaneous candidiasis, recurrent infections, agenesis of the corpus callosum, microcephaly, cataracts; cardiomyopathy, skin hypopigmentation, intellectual disability	
HOIL1 deficiency	*RBCK1*	AR	Decreased memory B cells with poor antibody response to polysaccharide antigens	Bacterial infections, autoinflammation, amylopectinosis	
HOIP deficiency	*RNF31*	AR	Decreased memory B cells with decreased Ig levels	Bacterial infections, autoinflammation, amylopectinosis, lymphangiectasia	
Hennekam lymphangiectasia-lymphedema syndrome	*CCBE1 FAT4*	AR	Variably decreased T- and B-cell counts, decreased Ig levels	Facial anomalies and other dysmorphic features, lymphangiectasia and lymphedema	
Activating de novo mutations in nuclear factor, erythroid 2-like (NFE2L2)	*NFE2L2*	AD	Decreased switched memory B cells, hypogammaglobulinemia and decreased antibody responses	Recurrent respiratory and skin infections; growth restriction, developmental delay; white matter cerebral lesions; increased level of homocysteine; increased expression of stress response genes	
STAT5b deficiency	*STAT5B*	AR	Slightly decreased T cells, decreased Treg number and function, hypogammaglobulinemia with elevated IgE	Growth-hormone insensitive dwarfism, dysmorphic features, eczema, lymphocytic interstitial pneumonitis, autoimmunity	
STAT5b deficiency	*STAT5B*	AD (dominant negative variants)	Increased IgE	Growth failure, eczema, lack immune defects of AR STAT5b deficiency	
Kabuki syndrome (type 1 and 2)	*KMT2D* *KDM6A*	AD XL (females may be affected)	Low IgA, occasionally low IgG	Typical facial abnormalities, cleft or high arched palate, skeletal abnormalities, short stature; intellectual disability; congenital heart defects; recurrent infections (otitis media, pneumonia); autoimmunity

Table 165.6 Thymic Disorders

DISEASE	GENE	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
DiGeorge/Velocardio-facial syndrome/ chromosome 22Q11.2 deletion syndrome *TBX1* deficiency	22Q11.2del including *TBX1, TBX1* Unknown	AD (Unknown defects are sporadic)	Variable T-cell counts, may have low TRECs at NBS, may have hypogammaglobulinemia	Conotruncal cardiac defects, hypoparathyroidism, abnormal facies, velopalatal insufficiency, intellectual disability, autoimmunity	Thymic transplant for severe T-cell deficiency
CHARGE syndrome	*CHD7* *SEMA3E* Unknown	AD AD	Variable T-cell counts, may have low TRECs at NBS, may have hypogammaglobulinemia	Coloboma of eye; heart anomaly; choanal atresia; intellectual disability; genital and ear anomalies (CHARGE), CNS malformation	Thymic transplant for severe T-cell deficiency
Winged helix nude *FOXN1* deficiency	*FOXN1*	AR	Very low T cells, decreased Ig levels	Severe infections, abnormal thymic epithelium, congenital alopecia, nail dystrophy, neural tube defect	Thymic transplant attempted
FOXN1 haploinsufficiency	*FOXN1*	AD	Severe T-cell lymphopenia at birth, normal by adulthood	Recurrent, viral and bacterial respiratory tract infections; (eczema, dermatitis), nail dystrophy	
Chromosome 10p13-p14 deletion syndrome (10p13-p14DS)	10p13-p14del	AD	T-cell lymphopenia rarely with decreased proliferation to mitogens and antigens, may have hypoplastic thymus	Hypoparathyroidism, renal disease, deafness, growth retardation, facial dysmorphism, cardiac defects may be present, may have recurrent infections	
Chromosome 11q deletion syndrome (Jacobsen syndrome)	11q23del	AD	T-, B-, and NK cell lymphopenia, low switched memory B cells, variable Ig levels and antibody responses	Recurrent respiratory infections; multiple warts; facial dysmorphism, growth retardation	Ig replacement for antibody deficiency
PAX1	*PAX1*	AR	Absent thymus	Omenn-like syndrome	HSCT attempted, thymic transplantation attempted

AD, Autosomal dominant; AR, Autosomal recessive; del, deletion; CNS, central nervous system; HSCT, hematopoietic stem cell transplantation; TREC, T-cell receptor excision circle; NBS, newborn screening; Ig, immunoglobulin.

Table 165.7 Hyper IgE Syndromes

DISEASE	GENE	INHERITANCE	PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
HIE (Job syndrome)	*STAT3*	AD (DN LOF)	Decreased response to *STAT3*-activating cytokines; decreased Th17, T follicular helper, MAIT, NKT cells, reduced memory B cells, elevated IgE	Coarse facial features, broad nasal bridge; staphylococcal abscesses, eczema, pneumatoceles, pulmonary *Aspergillus,* PJP, mucocutaneous candidiasis; hyperextensible joints, osteoporosis and bone fractures, scoliosis, retained primary teeth; coronary and cerebral aneurysms	Bacterial and fungal prophylaxis
DOCK8 deficiency	*DOCK8*	AR	T-cell lymphopenia with poor proliferation, few Tregs with poor function, reduced MAIT and NKT cells, very high IgE	Low NK cells with poor function Eosinophilia, recurrent infections, cutaneous viral, fungal and staphylococcal infections, severe atopy/allergic disease, cancer diathesis	HSCT
IL-6 receptor deficiency	*IL6R*	AR	Decreased switched memory B cells, very high IgE	Recurrent pyogenic infections, cold abscesses, elevated IL-6 levels	Bacterial prophylaxis
IL-6 signal transducer (IL6ST) deficiency	*IL6ST*	AR	Decreased Th17 cells, reduced memory B cells, high IgE, variable antibody responses	Bacterial infections, abscesses, eczema, pulmonary abscesses, pneumatoceles; bone fractures; scoliosis; retention of primary teeth; craniosynostosis	Bacterial prophylaxis
IL6ST	*IL6ST*	AD (DN)	Increased Th2, naïve T cells, low memory T and B cells, low to normal NK cell counts, elevated IgE with normal or low IgG	Similar to AD HIE syndrome: dermatitis/eczema, eosinophilia, recurrent skin infections, pneumonia, bronchiectasis, pneumatoceles, pulmonary aspergillosis, connective tissue defects (scoliosis, face, joints, fractures, palate, tooth retention)	Bacterial and fungal prophylaxis
IL6ST	*IL6ST*	AR (LOF)	Death in utero or in neonatal period	Fatal Stuve-Wiedemann-like syndrome; skeletal dysplasia, lung dysfunction, renal abnormalities, thrombocytopenia, dermatitis, eczema, defective acute phase response, complete unresponsiveness to IL-6 family cytokines	None
ZNF341 deficiency	*ZNF341*	AR	Decreased Th17 and NK cells, reduced memory B cells, decreased response to *STAT3*-activating cytokines	Similar to AD-HIE: mild facial dysmorphism; early-onset eczema, mucocutaneous candidiasis, bacterial skin infections, *Staphylococcus aureus* abscesses, recurrent bacterial respiratory infections, pneumatoceles; hyperextensible joints; bone fractures and retention of primary teeth	Bacterial and fungal prophylaxis
ERBIN deficiency	*ERBB2IP*	AD	Increased Treg, moderate increased IgE	Susceptibility to *S. aureus,* eczema, recurrent respiratory infections, hyperextensible joints, scoliosis, arterial dilatation in some patients	Bacterial prophylaxis
Loeys-Dietz syndrome	*TGFBR1, TGFBR2*	AD	Elevated IgE	Recurrent respiratory infections; eczema, food allergies; hyperextensible joints, scoliosis, retention of primary teeth; aortic aneurysms	Bacterial prophylaxis
Comèl-Netherton syndrome	*SPINK5*	AR	Low memory B cells, elevated IgE and IgA, variable antibody responses	Congenital ichthyosis, bamboo hair, atopic diathesis, bacterial infections, failure to thrive	Bacterial prophylaxis; Ig replacement for antibody deficiency
PGM3 deficiency	*PGM3*	AR	May have low T cells, B cells, memory B cells, normal or elevated IgG, IgA, and high IgE, eosinophilia	Severe atopy; autoimmunity; bacterial and viral infections; short stature, brachydactyly, dysmorphic facial features; intellectual disability and cognitive impairment, delayed CNS myelination in some patients	
CARD11 deficiency	*CARD11 DN LOF*	AD	Defective T-cell activation and proliferation, high IgE, Th2 skewing, poor specific antibody production, impaired activation of the NF-κB and mTORC1 pathways	Variable atopy, eczema, food allergy, eosinophilia; cutaneous viral infections, recurrent respiratory infections; lymphoma; CID	Ig replacement for antibody deficiency

AD, Autosomal dominant; AR, Autosomal recessive; CID, combined immunodeficiency; CNS, central nervous system; DN, dominant negative; HIE, hyper-IgE; Ig, immunoglobulin; IL, interleukin; IL6ST, gp130 common signal transducer of the IL-6 cytokine family; LOF, loss of function; MAIT, mucosal-associated invariant T cells; NKT, natural killer T cells; PJP, *Pneumocystis jiroveci*; Th, T helper; Treg, regulatory T cells.

Adapted from Tangye SG, Al-Herz W, Bousfiha A, et al. Human inborn errors of immunity: 2022 update on the classification from the International Union of Immunological Societies Expert Committee. *J Clin Immunol* 2022;42:1473–1507.

formation as well as helping macrophages kill intracellular pathogens. In addition, patients with poor or absent CD4 T-cell helper function are susceptible to opportunistic infection. The consequences of defects in CD40 ligand and CD40 highlight the role CD4 T-cell–dependent helper function plays in immunity.

CD40 LIGAND AND CD40 DEFICIENCY

CD40 ligand (CD154) deficiency (X-linked) and similarly, CD40 deficiency (autosomal recessive), cause a severe form of **hyper-IgM syndrome** that is a CID.

Genetics and Pathogenesis

Pathogenic variants in the CD40 ligand or CD40 genes, disrupt the interaction between CD4 T cells and antigen-presenting cells (APCs): dendritic cells, monocytes/macrophages, and B cells. CD40 ligand is expressed on activated CD4 T cells and delivers signals to APC via CD40 to stimulate expression of co-stimulatory molecules that help T-cell activation and differentiation, immunoglobulin isotype switching and somatic hypermutation in B cells as well as memory B-cell development, and signals to macrophages to kill intracellular pathogens. Therefore disruption of the CD40 signaling pathway affects several key elements of the adaptive immune response leading to a CID disease characterized by failure of immunoglobulin isotype switching, a process important for synthesis of IgG, IgA, and IgE antibodies; failure of somatic hypermutation, a process by which B cells generate antibodies of higher affinity; and absent B-cell memory, susceptibility to opportunistic infections including PJP, and *Cryptosporidium* and enhanced susceptibility to some cancers especially of the liver or of neuroectodermal origin.

Clinical Manifestations

Recurrent and opportunistic infections usually develop in the first year of life. About half the patients present with PJP pneumonia. Recurrent bacterial sinopulmonary infections are also common as well as *Cryptosporidium* infection and sclerosing cholangitis. Chronic or recurrent neutropenia is also a feature of this disease, although the pathogenesis of neutropenia is not well known. Patients have a higher susceptibility to cancer of the liver or biliary tree as well as primitive neuroectodermal carcinoma, which usually develop after the first 10 years of life. Few patients survive beyond 30 years of age. Some patients with milder genetic variations present in adolescence with parvovirus-induced aplastic anemia.

Diagnosis

Serum immunoglobulin levels show very low or absent IgG, IgA, and IgE, with normal or elevated IgM. Some patients have normal serum IgA levels, likely the result of a non–CD40-dependent isotype switching mechanism. The term hyper-IgM is a misnomer because most patients are identified before they have elevation of serum IgM levels. Lymphocyte subsets as well as lymphocyte proliferation to mitogens are usually normal. Characteristically, there is an absence or paucity of switched memory B cells. Patients may or may not have neutropenia, which can be severe. Flow cytometry for expression of CD40 on resting B cells or CD40 ligand on activated T cells can identify patients with these defects. Staining for CD40 ligand expression with soluble CD40 will identify all CD40 ligand variants that prevent binding to CD40. Gene sequencing of CD40 and CD40 ligand can be done separately or within a larger PID gene panel with known pathogenic variants confirming the disease.

Treatment

Patients should be treated with immunoglobulin replacement therapy and PJP prophylaxis as soon as the diagnosis is suspected. Attention to hygiene and clean drinking water as well as avoiding swimming in lakes will help prevent exposure to opportunistic organisms such as *Cryptosporidium*. HSCT can be curative and is recommended if the patient has a matched related or unrelated donor. Outcomes after stem cell transplantation have a trend toward improved survival and a reduced risk for cancer and improved quality of life.

MHC CLASS II DEFICIENCY AND OTHER CAUSES OF CD4 T-CELL DEFICIENCY

MHC class I and II molecules play an important role in T-cell development and function by presenting a peptide fragment from a pathogen-derived protein to the TCR of CD8 or CD4 T cells, respectively. MHC class II molecules are required for processing and presentation of peptides derived from exogenous antigens to CD4 T cells and for positive selection of CD4 T cells in the thymus. Therefore MHC class II deficiency is a severe form of **bare lymphocyte syndrome** resulting in decreased CD4 T cells and impairment in their function.

Clinical Manifestations

Patients with low, or occasionally normal, CD4 T-cell numbers from MHC class II deficiency are susceptible to bacterial, viral, fungal, and opportunistic infections. Patients usually present in the first year of life with respiratory infections, chronic diarrhea, and failure to thrive. *Cryptosporidium* infections may be associated with sclerosing cholangitis and liver failure.

Genetics and Pathogenesis

MHC class II deficiency results from defects in genes encoding for transcription factors necessary for expression of MHC class II molecules from the HLA-DR, HLA-DP, and HLA-DQ loci including CIITA, RFXANK, RFX5, and RFXAP, which explains the concomitant loss of expression from all three loci.

Diagnosis

Immunodeficiencies with MHC class II deficiency can be identified by absent or low CD4 T cells on lymphocyte phenotyping by flow cytometry and absent MHC class II molecules. In some cases, CD8 T-cell numbers are also decreased. Lymphocyte proliferation to mitogens is normal but absent in response to antigens.

Treatment

The prognosis for MHC class II deficiency is poor with most patients dying in the first decade of life. HSCT has been performed and improves CD4 T-cell proliferation but not numbers because it does not correct the expression of MHC class II molecules on thymic epithelial cells. The outcome of HSCT in MHC class II deficiency is not as good as in SCID and other severe immunodeficiency diseases.

MHC CLASS I DEFICIENCY AND OTHER CAUSES OF CD8 T-CELL DEFICIENCY

MHC class I molecules play an important role in T-cell development and function by presenting a peptide fragment from an intracellular pathogen, such as viruses, or cancer-derived proteins to the TCR of CD8 T cells. In the thymus, MHC class I molecules provide the positive selection signal for thymocytes to develop into CD8 T cells. Therefore the absence of MHC class I molecules in the thymus (and on all nucleated cells) is associated with very low or absent CD8 T cells. There are several other pathogenic gene variants that cause a deficiency in CD8 T cells.

Genetics and Pathogenesis

MHC class I deficiency results from pathogenic variants in the transporter associated with antigen processing (TAP) 1 or 2, TAP binding protein, or β_2-microglobulin genes. The TAP proteins play an important role in allowing the expression of MHC class I molecules on the surface of all nucleated cells and β_2-microglobulin associates with MHC class I molecules on the surface of cells.

Clinical Manifestations

Patients with low CD8 T cells from MHC class I deficiency may be asymptomatic in some cases but may present with chronic respiratory infections including bronchiectasis and granulomatous skin ulcers.

Diagnosis

Immunodeficiency patients with MHC class I deficiency can be identified by absent or low CD8 T cells on lymphocyte phenotyping by flow

cytometry and absent MHC class I molecules. Lymphocyte proliferation is normal.

Treatment
MHC class I deficiency is treated with supportive therapy and avoidance of immunosuppression if possible.

OTHER FORMS OF CD8 DEFICIENCY
CD8 α Gene Defects
CD8 deficiency also results from pathogenic variants in the CD8 α gene. Patients are susceptible to bacterial and viral respiratory infections. CD8 T-cell numbers are low and there is an increase in CD4-CD8- T cells. Lymphocyte proliferation is normal. CD8 α deficiency is also treated with supportive therapy and avoidance of immunosuppression if possible.

Defects in the Zeta-Associated Protein 70
The zeta-associated protein (ZAP-70) is a severe immunodeficiency similar to SCID with absent or very low numbers of CD8 T cells. Although CD4 T cells develop in adequate numbers, they are defective in proliferation and function. Patients with ZAP-70 deficiency are susceptible to all types of infection including opportunistic infections, disseminated varicella, and mucocutaneous candidiasis with failure to thrive and diarrhea. The diagnosis of ZAP-70 deficiency can be made by low CD8 T-cell counts and deficient T-cell proliferation to mitogens that can be rescued by bypassing ZAP-70 signaling with phorbol ester and ionomycin, helping confirm that the defect is in the proximal signaling pathway in T cells. The diagnosis is confirmed by identification of a homozygous or combined heterozygous pathogenic variant in the ZAP-70 gene. Treatment of ZAP-70 deficiency requires HSCT. Immunoglobulin replacement and microbial prophylaxis should be initiated until immune reconstitution after HSCT is achieved.

COMBINED IMMUNODEFICIENCIES WITH CONGENITAL THROMBOCYTOPENIA
Wiskott-Aldrich Syndrome
Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder characterized by atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and susceptibility to infection.

Genetics and Pathogenesis
The Wiskott-Aldrich syndrome protein (WASP) controls the assembly of actin filaments required for cell migration and cell-cell interactions. Specific pathogenic variants in the WASP gene cause X-linked thrombocytopenia (XLT) without immunodeficiency and gain-of-function variants cause X-linked severe congenital neutropenia. A similar phenotype to WAS occurs with pathogenic variants in the WASP interactive Protein (WIP) that is an autosomal recessive disease affecting both females and males.

Clinical Manifestations
Patients often have prolonged bleeding from the circumcision site or bloody diarrhea during infancy. The thrombocytopenia is not caused initially by antiplatelet antibodies, although autoimmunity may develop later in life. **Atopic dermatitis** and **recurrent infections** usually develop during the first year of life. *Streptococcus pneumoniae* and other bacteria having polysaccharide capsules cause otitis media, pneumonia, meningitis, and sepsis. Later, infections with agents such as *P. jiroveci* and the herpesviruses become more frequent. Infections, bleeding, and EBV-associated malignancies are major causes of death.

Diagnosis
The predominant immunoglobulin pattern is a low serum level of IgM, elevated IgA and IgE, and a normal or slightly low IgG. Percentages of T cells are moderately reduced, and lymphocyte responses to mitogens are variably depressed. The presence of low numbers of platelets that are small in size is typical. Immunologically, patients with this defect uniformly have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or greatly diminished isohemagglutinins, and poor or absent antibody responses after immunization with polysaccharide vaccines. In addition, antibody responses to protein and conjugate vaccines may also be diminished.

Treatment
Good supportive care includes appropriate nutrition, immunoglobulin replacement, use of killed vaccines, and aggressive management of eczema and associated cutaneous infections. Because of their profound antibody deficiency, these patients should be given immunoglobulin replacement regardless of their serum levels of the different immunoglobulin isotypes. HSCT is the treatment of choice when a high-quality matched donor is available and is usually curative. Gene therapy has resulted in sustained benefits in several patients. As in X-SCID, early trials of gene therapy were associated with the development of malignancy.

In addition to WAS and WIP deficiency, there is a third cause of immunodeficiency with thrombocytopenia from pathogenic variants in the *ARPC1B* gene affecting Arp2/3-mediated filament branching presenting with mild thrombocytopenia but normal-sized platelets and recurrent infections. Patients have high IgA and IgE as in WAS.

DNA REPAIR DEFECTS OTHER THAN THOSE CAUSING SCID
DNA repair plays an important role during lymphocyte development and differentiation including V(D)J recombination and immunoglobulin isotype switching. Therefore defects in DNA repair enzyme are frequently associated with CID and many have other characteristic features to identify them (see Table 165.3).

ATAXIA-TELANGIECTASIA
Ataxia-telangiectasia is a complex syndrome with immunologic, neurologic, endocrinologic, hepatic, and cutaneous abnormalities.

Genetics and Pathogenesis
The ataxia-telangiectasia pathogenic variant *(ATM)* gene encodes a protein critical for responses to DNA damage. Cells from patients, as well as from heterozygous carriers, have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.

In vitro tests of lymphocyte function have generally shown moderately depressed proliferative responses to T- and B-cell mitogens. Percentages of CD3 and CD4 T cells are moderately reduced, with normal or increased percentages of CD8 T cells and elevated numbers of γ/δ T cells. The thymus is very hypoplastic, exhibits poor organization, and lacks Hassall's corpuscles.

Clinical Manifestations
The most prominent clinical features are progressive cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary disease, a high incidence of malignancy, and variable humoral and cellular immunodeficiency. Ataxia typically becomes evident soon after these children begin to walk and progresses until they are confined to a wheelchair, usually by age 10-12 years. The telangiectasias begin to develop at 3-6 years of age, contributing to a delay in diagnosis. Recurrent sinopulmonary infections occur in approximately 80% of patients. Although common viral infections have not usually resulted in untoward sequelae, fatal varicella has occurred. The malignancies associated with ataxia-telangiectasia are usually of the lymphoreticular type, but adenocarcinomas also occur. Carriers of pathogenic variants have an increased incidence of malignancy.

Diagnosis
Patients have elevated serum α-fetoprotein levels. The most frequent humoral immunologic abnormality is the selective absence of IgA, which occurs in 50–80% of these patients. IgG2 or total IgG levels may be decreased, and specific antibody levels may be decreased or normal. Some patients have an elevated serum IgM level. Identification of homozygous or compound heterozygous pathogenic variants in the *ATM* gene confirms the diagnosis.

Treatment
Therapy in ataxia-telangiectasia is supportive but includes immunoglobulin replacement and avoidance of ionizing radiation unless absolutely necessary to establish a clinical diagnosis and initiate appropriate treatment.

Immunoosseous Dysplasias
Immunoosseous dysplasias are a group of combined immune deficiency diseases affecting bone development as well as T-cell development or function. They are characterized by skeletal abnormalities and recurrent infections (see Table 165.4).

CARTILAGE-HAIR HYPOPLASIA
Cartilage-hair hypoplasia (CHH) is an unusual form of **metaphyseal dysplasia** with frequent and severe infections. It occurs with a high frequency among the Amish and Finnish people (Chapter 741).

Genetics and Pathogenesis
CHH is an autosomal recessive condition. Numerous pathogenic variants that cosegregate with the CHH phenotype have been identified in the untranslated RNase MRP *(RMRP)* gene. The RMRP endoribonuclease consists of an RNA molecule bound to several proteins and has at least two functions: cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-RNA. Defects in *RMRP* cause CHH by disrupting a function of *RMRP* RNA that affects multiple organ systems. In vitro studies show decreased numbers of T cells and defective T-cell proliferation because of an intrinsic defect related to the G1 phase, resulting in a longer cell cycle for individual cells. NK cells are increased in number and function.

Clinical Manifestations
Clinical features include short, pudgy hands; redundant skin; hyperextensible joints of hands and feet but an inability to extend the elbows completely; and fine, sparse, light hair and eyebrows. Infections range from mild to severe (Fig. 165.5). Associated conditions include deficient erythrogenesis, Hirschsprung disease, and an increased risk of malignancies. The bones radiographically show scalloping and sclerotic or cystic changes in the metaphysis and flaring of the costochondral junctions of the ribs.

Diagnosis
The diagnosis of CHH is suspected by the clinical constellation of skeletal dysplasia and immune deficiency and supporting laboratory findings. Homozygous or compound heterozygous pathogenic variants in the *RMRP* gene confirms the diagnosis.

Treatment
Treatment of CHH is supportive. Some patients have been treated with HSCT, which will correct the T-cell immunodeficiency and erythrogenesis but will not affect other organ systems.

ANHIDROTIC ECTODERMAL DYSPLASIA WITH IMMUNODEFICIENCY
Anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) is a CID characterized by susceptibility to infection, thin sparse hair, abnormal dentition (conical teeth), and absence of salivary gland (Chapter 690).

Genetics and Pathogenesis
X-linked EDA-ID results from hypomorphic gene variants in the *IKKγ* gene that encodes the NF-κB essential modulator **(NEMO)**. Complete loss-of-function (LOF) variants are deleterious early in embryogenesis. Carriers of LOF variants have features of incontinentia pigmenti. NEMO is a member of the IKK complex that phosphorylates the inhibitor of NF-κB (IκB), which then allows NF-κB to translocate to the nucleus and turn on gene expression. In lymphocytes, NF-κB is involved in signaling via the antigen receptors, the tumor necrosis factor (TNF) receptor family, and toll-like receptors as well as the interleukin (IL)-1 receptor. Defects in NEMO affect both the innate and adaptive immune systems and can be severe. Autosomal dominant gain-of-function variants in IκBα also result in a similar phenotype

Fig. 165.5 Metaphyseal dysplasia, McKusick type. Note the fine, sparse hair and short limbs. *(From Jones KL, Jones MC, Del Campo M. Smith's Recognizable Patterns of Human Malformation. 8th ed. Philadelphia: Elsevier; 2022. Fig.1, p. 529.)*

that affects both females and males as well as gain-of-function variants in IKBKB. The latter is also associated with recurrent bacterial, viral, and fungal infections, but the ectodermal defects are variable.

Clinical Manifestations
Patients with EDA-ID suffer from recurrent and severe infections from gram-positive and gram-negative bacteria, mycobacteria, viruses, and fungi. Patients have thin sparse hair and conical teeth and may have colitis. More severe variants may be associated with osteopetrosis and lymphedema; their disease is termed OL-EDA-ID (osteopetrosis, lymphedema, EDA-ID).

Diagnosis
The diagnosis can be suspected from the clinical features of anhidrosis, ectodermal dysplasia, and recurrent infections. Patients frequently present with hypogammaglobulinemia as in the hyper-IgM syndrome because CD40 signaling involves NF-κB, with elevated IgM in some patients. Most if not all patients have poor NK cell function. The diagnosis can be confirmed by identification of hypomorphic variants in the *IKKγ* gene or gain-of-function variants in the *IκBα* gene.

Treatment
Patients are usually treated with immunoglobulin replacement and close monitoring. The outcome is dependent on the severity of the phenotype. HSCT has been successful in some patients, but it may not correct the colitis or other features of the disease.

Calcium Channel Defects
Calcium signaling plays an important role in T-cell activation, where initially calcium is released from the endoplasmic reticulum into the cytoplasm, which is sensed by STIM1 that in turn activates calcium release activated channels (CRACs), which are made up of the pore-forming subunit ORAI-1, to bring in additional calcium from outside the cell. Intracellular calcium activates calcium-dependent enzymes including calcineurin, which activates the nuclear factor of activated T cells (NFAT), which

translocates to the nucleus and activates gene transcription including IL-2 and the CD40 ligand. Pathogenic variants in *ORAI-1* or *STIM1* result in a CID associated with hypotonia because calcium is also important for muscle function.

Clinical Manifestations

Patients with calcium channel defects have recurrent and severe infections with bacteria, viruses, and fungi. They typically have pneumonia but may present with a variety of infections including BCG lymphadenitis, chronic rotavirus diarrhea, and mucocutaneous candidiasis. They may also present with failure to thrive, ectodermal dysplasia defective dental enamel, and mydriasis. Patients also have a nonprogressive hypotonia.

Diagnosis

Patients have normal numbers of T cells, but the T cells have decreased or have absent proliferation to mitogens, antigens, or anti-CD3. Although serum immunoglobulins are normal or increased, specific antibody levels are diminished and NK cell function may also be decreased as B cells and NK cells also depend on calcium signaling for their activation. The clinical features and laboratory test results are similar for both *ORA-1* and *STIM1* deficiency. Therefore genetic testing is required to identify the specific pathogenic variants, which will aid in genetic counseling and prenatal diagnosis.

Treatment

HSCT is the optimal treatment for the immunodeficiency; however, it does not correct the hypotonia, which may contribute to recurrent pneumonia.

165.3 Thymic Disorders

Ramsay L. Fuleihan

The thymus is the organ where T-cell development occurs and central T-cell tolerance to self-proteins develops by negative selection of self-reactive thymocytes or development of regulatory T cells. Defects in thymic development affect T-cell development causing a variable degree of T-cell immunodeficiency and are associated with higher risk for the development of autoimmunity.

DIGEORGE/VELOCARDIOFACIAL SYNDROME/ CHROMOSOME 22Q11.2 DELETION SYNDROME (22Q11.2DS)

Chromosome 22q11.2 deletion syndrome is the most common of the T-cell disorders, occurring in about 1 in 3,000 births in the United States. Chromosome 22q11.2 deletions disrupt development of the third and fourth pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands. Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal, atrial, and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and posteriorly rotated ears (see Chapter 99) (Fig. 165.6). With advanced fetal ultrasound and fetal echocardiography, the diagnosis is often identified prenatally. Other patients may be identified by low TREC counts on newborn screening for SCID or sometimes by the development of hypocalcemic seizures during the neonatal period.

Genetics and Pathogenesis

Chromosome 22q11.2 deletions occur with high frequency because complex repeat sequences that flank the region represent a challenge for DNA polymerase. This condition is inherited in an autosomal dominant fashion and occurs with comparable frequency in all populations. Within the deleted region, haplosufficiency for the TBX1 transcription factor appears to underlie the majority of the phenotype. The phenotype is highly variable; a subset of patients has a phenotype that has also been called **DiGeorge syndrome**, **velocardiofacial syndrome**, or **conotruncal anomaly face syndrome**.

Fig. 165.6 Typical facial appearance of a child with DiGeorge syndrome. Notice the microstomia, hypertelorism, upturned nose, and posteriorly rotated and small, low-set ears. *(From Chinn IK, Chinen J, Shearer WT. Primary immunodeficiency diseases. In: Cherry JD, Harrison GJ, Kaplan SL, et al., eds. Feigin and Cherry's Textbook of Pediatric Infectious Diseases. 8th ed. Philadelphia: Elsevier; 2019. Fig. 67.1, p. 641.)*

Variable hypoplasia of the thymus occurs in 75% of the patients with the deletion, which is more frequent than total aplasia; aplasia is present in <1% of patients with 22q11.2 deletion syndrome. Slightly less than half of patients with complete thymic aplasia are hemizygous at chromosome 22q11.2. Approximately 15% are born to diabetic mothers. Another 15% of infants have no identified risk factors. Approximately 30% of infants with complete DiGeorge syndrome have **CHARGE association** (*c*oloboma, *h*eart defect, choanal *a*tresia, growth or developmental *r*etardation, *g*enital hypoplasia, and *e*ar anomalies including deafness). Pathogenic variants in the chromodomain helicase DNA-binding protein 7 *(CHD7)* gene on chromosome 8q12.2 are found in approximately 60–65% of individuals with CHARGE syndrome; some have pathogenic variants in *SEMA3E*.

Clinical Manifestations

Children with partial thymic *hypoplasia* may have little trouble with infections and grow normally. Patients with thymic *aplasia* (complete DiGeorge syndrome) resemble patients with SCID in their susceptibility to infections with low-grade or opportunistic pathogens, including fungi, viruses, and *P. jiroveci*, and to GVHD from nonirradiated blood transfusions. Patients with thymic aplasia can develop an atypical phenotype in which oligoclonal T-cell populations appear in the blood associated with rash and lymphadenopathy. These atypical patients appear phenotypically similar to patients with **Omenn syndrome** or maternal T-lymphocyte engraftment.

It is critical to ascertain in a timely manner whether an infant has thymic aplasia, because this disease is fatal without treatment. A T-cell count should be obtained on all infants born with primary hypoparathyroidism, CHARGE syndrome, and conotruncal cardiac anomalies with syndromic features. Some but not all infants are identified by newborn screening for SCID and when 22q11.2 deletion is suspected, a calcium level should be obtained at the time of T-cell evaluation. The three manifestations with the highest morbidity in early infancy are profound immunodeficiency, severe cardiac anomaly, and seizures from hypocalcemia. Thus an early focus on these concerns is warranted even before the diagnosis is confirmed. Affected patients may also develop autoimmune cytopenias, juvenile idiopathic arthritis, atopy, and malignancies (lymphomas).

Diagnosis

The clinical features of DiGeorge/CHARGE/22Q11.2DS will help in establishing the diagnosis, but there is a wide variety of clinical phenotypes. In most patients, absolute lymphocyte counts are usually only moderately low for age. The CD3 T-cell counts are variably decreased in number, corresponding to the degree of thymic hypoplasia. Lymphocyte responses to mitogen stimulation are absent, reduced, or normal, depending on the degree of thymic deficiency. Immunoglobulin levels are often normal, but there is an increased frequency of IgA deficiency, low IgM levels, and some patients develop progressive hypogammaglobulinemia. FISH for 22Q11.2 may identify patients with 22Q11.2DS as well as the more sensitive DNA microarray. Pathogenic variants in *TBX1* may be found in DiGeorge syndrome, and pathogenic variants in *CHD7* or *SEMA3E* in CHARGE syndrome.

Treatment

The immunodeficiency in thymic aplasia is correctable by cultured allogenic (donor derived) thymic tissue transplants. Following thymic tissue transplantation, a cytokine release syndrome may develop. Some infants with thymic aplasia have been given nonirradiated unfractionated bone marrow or peripheral blood transplants from a human leukocyte antigen–identical sibling, with subsequent improved immune function because of adoptively transferred T cells. Infants and children with low T-cell counts but not low enough to consider transplantation should be monitored for evolution of immunoglobulin defects as well as autoimmunity. Infections in these patients are multifactorial. Their anatomy may not favor drainage of secretions; they have a higher rate of atopy, which may complicate infections; and their host defense may allow persistence of infections. Interventions range from hand hygiene, probiotics, prophylactic antibiotics, and risk management to immunoglobulin replacement for those who have demonstrated defective humoral immunity. Live-viral vaccines should be avoided until adequate CD4 and CD8 T-cell counts are confirmed and normal response to antigens is documented with T-cell proliferation to antigens or a protective antibody response to a protein vaccine such as tetanus.

165.4 Inborn Errors of Immunity with a Strong Atopic Diathesis

Ramsay L. Fuleihan

AUTOSOMAL DOMINANT HYPER-IgE SYNDROME *STAT3* DEFICIENCY (JOB SYNDROME)

This syndrome is associated with early-onset atopy and recurrent skin and lung infections.

Genetics and Pathogenesis

The autosomal dominant hyper-IgE syndrome is caused by heterozygous pathogenic variants in the gene encoding signal transducer and activator of transcription 3 *(STAT3)*. These pathogenic variants result in a dominant negative effect. The many clinical features are caused by compromised signaling downstream of the IL-6, type I interferon, IL-22, IL-10, and epidermal growth factor (EGF) receptors.

Clinical Manifestations

The characteristic clinical features are staphylococcal abscesses, pneumatoceles, osteopenia, and unusual facial features. There is a history from infancy of recurrent staphylococcal abscesses involving the skin, lungs, joints, viscera, and other sites. Persistent pneumatoceles develop as a result of recurrent pneumonia. Patients often have a history of sinusitis and mastoiditis. *C. albicans* is the second most common pathogen. Allergic respiratory symptoms are usually absent. The pruritic dermatitis that occurs is not typical of atopic eczema and does not always persist. There can be a prominent forehead, deep-set wide-spaced eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy, although these are most evident in adulthood. In older children, delay in shedding primary teeth, recurrent fractures, and scoliosis occur.

Fig. 165.7 Mucocutaneous inflammation and infections in DOCK8-HIES. Severe eczema, molluscum contagiosum and fungal skin infections, and benign tumorous mucosa proliferations progressing from the inner eyelid and from oral mucosa are clinical signs of DOCK8-HIES. *(From Hagl B, Heinz V, Schlesinger A, et al. Key findings to expedite the diagnosis of hyper-IgE syndromes in infants and young children. Pediatr Allergy Immunol. 2016;27[2]:177-184. Fig. 1)*

These patients demonstrate an *exceptionally high serum IgE concentration*; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; and poor antibody and cell-mediated responses to neoantigens. Although IgE levels >2,000 IU/mL are characteristic, IgE levels may fluctuate and even decrease in adulthood. In neonates and infants with the pruritic pustular dermatosis, IgE levels will be elevated *for age* and are usually in the 100s. In vitro studies show normal percentages of blood T, B, and NK lymphocytes, except for a decreased percentage of T cells with the memory (CD45RO) phenotype and an absence or deficiency of T-helper type 17 (Th17) cells. Most patients have normal T-lymphocyte proliferative responses to mitogens but very low or absent responses to antigens or allogeneic cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall's corpuscles and thymic architecture are normal.

Treatment

Therapy is generally directed at prevention of infection using antimicrobials including antibiotics and antifungals as well as immunoglobulin replacement.

DOCK8 DEFICIENCY

Deficiency of DOCK8 (dedicator of cytokinesis 8) is an autosomal recessive severe immunodeficiency that most often presents with impressively severe eczema in infancy and toddlerhood, food allergy, and eosinophilic esophagitis. Patients commonly have cutaneous viral infections with herpes simplex virus (HSV), varicella, or molluscum contagiosum; susceptibility to infection by CMV and EBV; recurrent pneumonia leading to bronchiectasis; and opportunistic infections with PJP. In some patients, cryptosporidia causes sclerosing cholangitis (Fig. 165.7). The infectious susceptibility tends to worsen over time, as do the laboratory features of immune dysfunction, most often low T-cell counts and poor proliferative function. Serum IgE levels tend to be elevated with eosinophilia, whereas other immunoglobulin levels may be decreased, especially IgM. Specific antibody levels are variably decreased. Patients are also susceptible to autoimmune disease as well as cancer. Although these patients can survive to adulthood without transplantation, they suffer many complications and their quality of life is often poor. For this reason, most patients are now transplanted early in life to avoid the later complications.

Chapter 166

B-Cell and Antibody Deficiencies

Vivian P. Hernandez-Trujillo and Camile Ortega

Of the primary immunodeficiency diseases (PIDDs), those affecting antibody production are the most prevalent. Selective absence of IgA is the most common defect, with rates ranging from 1 in 333 to 1 in 18,000 persons among different races and ethnicities. Patients with antibody deficiency are usually recognized because they have recurrent infections with encapsulated bacteria, predominantly in the upper and lower respiratory tracts. Some individuals with selective IgA deficiency or infants with transient hypogammaglobulinemia may have few or no infections. These conditions have a complex and likely polygenic inheritance, as do the common variable immunodeficiency (CVID) syndromes. The gene defects for many primary antibody deficiency disorders have been identified (Table 166.1). Sometimes the defect is not in the B cell itself but in T cells, which are required for complete B-cell function. Some disorders are caused by unknown factors or are secondary to an underlying disease or its treatment.

166.1 Agammaglobulinemia

Vivian P. Hernandez-Trujillo and Camile Ortega

X-LINKED AGAMMAGLOBULINEMIA

Patients with X-linked agammaglobulinemia (XLA), or **Bruton agammaglobulinemia**, have a profound defect in B-lymphocyte development resulting in severe hypogammaglobulinemia, an absence of circulating B cells, small to absent tonsils, and no palpable lymph nodes. These patients present with an increased susceptibility to infection (Fig. 166.1) and have increased risk of neutropenia and autoimmunity, particularly presenting as colitis.

Genetics and Pathogenesis

The variant gene in XLA maps to q22 on the long arm of the X chromosome and encodes the B-cell protein tyrosine kinase Btk (Bruton tyrosine kinase). Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases and is expressed at high levels in all B-lineage cells, including pre-B cells. Some pre-B cells are found in the bone marrow, but the percentage of peripheral blood B lymphocytes is <1%. The percentage of T cells is increased, ratios of T-cell subsets are normal, and T-cell function is intact. The thymus is normal.

Several autosomal recessive defects have also been shown to result in agammaglobulinemia with an absence of circulating B cells (see Table 166.1; Table 166.2), including pathogenic variants in the genes encoding the (1) μ heavy chain gene; (2) Igα and (3) Igβ signaling molecules; (4) B-cell linker adaptor protein (BLNK); (5) surrogate light chain, λ5/14.1; (6) leucine-rich repeat-containing 8 (LRRC8); (7) p85α subunit of phosphatidylinositol-3 kinase; (8) p110 δ subunit of phosphatidylinositol-3 kinase; (9) TCF3; (10) SLC39A7; and (11) TOP2B. These are rare but are clinically indistinguishable from the X-linked form (see Fig. 166.1).

Clinical Manifestations/Complications

Most males afflicted with XLA remain well during the first 6-9 months of life by virtue of maternally transmitted IgG antibodies. Thereafter they acquire infections with extracellular pyogenic organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* unless they are given prophylactic antibiotics or immunoglobulin therapy. Infections include sinusitis, otitis media, pneumonia, or, less often, sepsis or meningitis (Fig. 166.2). Infections with *Mycoplasma* are also particularly problematic, specifically as they can affect the joints. Chronic fungal infections are seen; *Pneumocystis jirovecii* pneumonia rarely occurs. Viral infections are usually handled normally, with the exceptions of hepatitis viruses and enteroviruses. There are examples of paralysis when live polio vaccine was administered to these patients, and chronic, eventually fatal, central nervous system (CNS) infections with various echoviruses and coxsackieviruses have occurred in a significant number of patients. An enterovirus-associated myositis resembling dermatomyositis has also been observed. Enteroviral encephalitis can also be life-threatening in patients with XLA. **Neutropenia**, typically seen at diagnosis when infected, can be associated with *Pseudomonas* or staphylococcal infections. In addition, *Pseudomonas* can lead to severe and life-threatening invasive infections. *Giardia* can also lead to diarrhea and weight loss. A sudden decrease in serum IgG level should prompt an evaluation for *Giardia*.

Long-term complications include bronchiectasis and colitis, presenting like an inflammatory bowel disease. Gastrointestinal (GI) disease has been increasingly reported in patients with XLA. Although immune globulin replacement decreased severe infectious complications, the chronic lung disease persisted in a recent cohort study. In addition, in a separate cohort, infections were highest before initiation of antibody replacement; however, patients continued to have infections despite adequate IgG levels.

Diagnosis

The diagnosis of XLA should be suspected if lymphoid hypoplasia is found on physical examination (minimal or no tonsillar tissue and no palpable lymph nodes), and serum concentrations of IgG, IgA, IgM, and IgE are far below the 95% confidence limits for appropriate age- and race-matched controls; total immunoglobulins are usually <100 mg/dL. Levels of natural antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) and antibodies to antigens given during routine immunizations are abnormally low in XLA, whereas they are typically normal in transient hypogammaglobulinemia of infancy. In infants below the age of 6 months, care should be taken when interpreting normal IgG, which can represent maternal IgG passed in utero. In this case, flow cytometry is essential in making the diagnosis of XLA. Flow cytometry is an important test to demonstrate the absence of circulating B cells, which will distinguish XLA from most types of **CVID**, the hyper-IgM syndrome, and transient **hypogammaglobulinemia** of infancy (Fig. 166.3). Genetic testing is also available to detect absence of Btk.

AUTOSOMAL RECESSIVE AGAMMAGLOBULINEMIA

Autosomal recessive agammaglobulinemia (ARA) is a clinically indistinguishable disorder from XLA presenting in males and females. The successful assembly and subsequent signaling capacity of the pre-B cell receptor complex (pre-BCR) in the bone marrow is central to the production of B cells and antibody-secreting plasma cells. A pathogenic variant in any of the components of the pre-BCR, or in the downstream signaling cascade, results in these rare forms of agammaglobulinemia (see Fig. 166.1).

Genetics and Pathogenesis

Hematopoietic stem cells develop into B cells in the bone marrow. The maturation into antibody-secreting plasma cells occurs in peripheral lymphoid tissues. B-cell development relies on a tightly regulated sequence of events from the pro-B cell stage to the formation of the pre-BCR and onward (see Fig. 166.1).

The pre-BCR is composed of the membrane form of the μ heavy chain, the surrogate light chain composed of VpreB and λ5/14.1 and the immunoglobulin-associated signal transducing chains, Igα and Igβ. An autosomal pattern of inheritance occurs in approximately 10% of agammaglobulinemic syndromes, and, in some affected families, there is known consanguinity. Approximately half of these pathogenic variants are in μ heavy (IGHM) and have a clinical picture that

Table 166.1 Genetic Basis of the Most Common Primary Antibody Deficiency Disorders

GENE	PHENOTYPE	DISORDER
BAFFR	CVID	Hypogammaglobulinemia
CD19	CVID	Hypogammaglobulinemia
CD20	CVID	Hypogammaglobulinemia
CD21	CVID	Hypogammaglobulinemia
CD81	CVID	Hypogammaglobulinemia
CTLA4	CVID	Hypogammaglobulinemia, pronounced lymphoproliferation and autoimmunity
ICOS	CVID	Hypogammaglobulinemia, autoimmunity, neoplasia
LRBA	CVID	Hypogammaglobulinemia, pronounced lymphoproliferation and autoimmunity
NFKB2	CVID	Hypogammaglobulinemia, autoimmunity
NFKB1	CVID	Hypogammaglobulinemia, autoimmunity
PIK3CD (AD)	CVID	Hypogammaglobulinemia, adenopathy
PI3KR1 (AD)	CVID	Hypogammaglobulinemia
TNFRSF13B	CVID	Hypogammaglobulinemia, low penetrance of disease
Unknown	CVID	Hypogammaglobulinemia, autoimmunity Majority of patients with CVID have no known gene variant
Unknown	IgG subclass deficiency	Variable association with infection
Unknown	Specific antibody deficiency	Normal immunoglobulin levels with poor vaccine responses
Unknown	Transient hypogammaglobulinemia of infancy	Vaccine responses are usually preserved, and most children outgrow this by age 3yr
Unknown	Selective IgA deficiency	Low or absent IgA; low concentrations of all immunoglobulins and of switched memory B cells in CVID
BLNK	Agammaglobulinemia	Absence of antibody production, lack of B cells
BTK	Agammaglobulinemia	Absence of antibody production, lack of B cells, X-linked agammaglobulinemia
CD79A	Agammaglobulinemia	Loss of the Igα required for signal transduction, absence of antibody production, lack of B cells
CD79B	Agammaglobulinemia	Loss of the Igβ required for signal transduction, absence of antibody production, lack of B cells
IGHM	Agammaglobulinemia	Loss of the Ig heavy chain, absence of antibody production, lack of B cells
IGLL1	Agammaglobulinemia	Loss of the surrogate light chain, absence of antibody production, lack of B cells
PI3KR1 (AR)	Agammaglobulinemia	Loss of signal transduction through the B-cell receptor, absence of antibody production, lack of B cells
PIK3CD δ (AR)	Agammaglobulinemia	Severely impaired signal transduction through B-cell receptor, absence of antibody production, lack of B cells
SLC39A7	Agammaglobulinemia	Impaired signal transduction through the B-cell receptor, absence of antibody production, lack of B cells
TCF3	Agammaglobulinemia	Loss of a key transcription factor for B-cell development, absence of antibody production, lack of B cells
AID	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
CD40	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, *Pneumocystis* and *Cryptosporidium* susceptibility
CD154	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, *Pneumocystis* and *Cryptosporidium* susceptibility
INO80	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
MSH6	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, malignancy
UNG	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
CD27	EBV lymphoproliferation	Memory B-cell deficiency Hypogammaglobulinemia
NEMO	Anhidrotic ectodermal dysplasia with immunodeficiency	Phenotype highly variable but includes specific antibody deficiency and CVID

AD, autosomal dominant; AR, autosomal recessive; CVID, common variable immunodeficiency; EBV, Epstein-Barr virus.

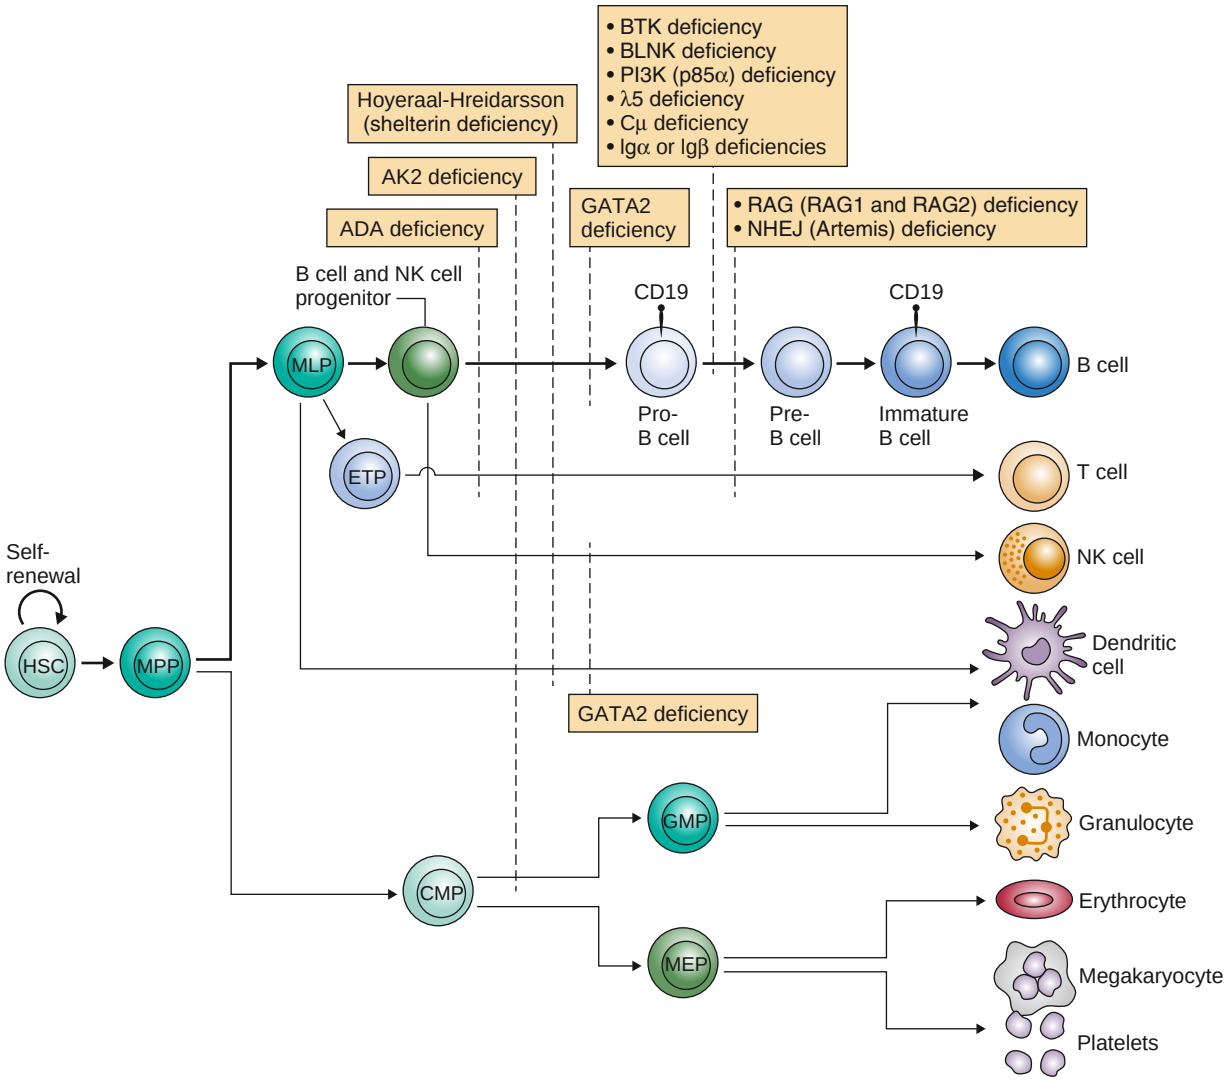

Fig. 166.1 B-cell development defects in primary antibody deficiencies (PADs) result from developmental defects that are either B-cell specific or affect several hematopoietic cell lineages. B-cell development occurs in the bone marrow, where hematopoietic stem cells (HSCs) undergo B-cell lineage specification. Some autosomal-recessive forms of severe combined immunodeficiency (SCID) are associated with an early defect in both B and T cells and are diagnosed in the first few months or years of life. For example, adenosine deaminase (ADA) deficiency leads to an accumulation of adenosines and thus the death of the lymphocytes. Moreover, adenylate kinase 2 (AK2) deficiency (also known as reticular dysgenesis) is a metabolic defect that mostly affects T cells, natural killer (NK) cells, neutrophils, and (in some cases) B cells. It is associated with very early onset hypogammaglobulinaemia or even agammaglobulinaemia. Dyskeratosis congenita is caused by mutations in genes encoding components of the telomerase or shelterin complexes; it is a rare inherited bone-marrow failure syndrome that leads to progressive B- and T-cell lymphopenia and hypogammaglobulinaemia. Finally, mutations in GATA2 (which encodes a transcription factor required for early differentiation of hematopoietic cells in the bone marrow) also lead to B-cell, dendritic cell, monocyte, and NK cell deficiencies. Successive B-cell differentiation stages are characterized by ordered gene expression and stochastic immunoglobulin gene rearrangements. The V(D)J recombination of the immunoglobulin locus is achieved by the lymphocyte-specific RAG molecules and the non–lymphocyte-specific nonhomologous end joining (NHEJ) complex and leads to the expression of the pre-B cell receptor (BCR). Defects in V(D)J recombination (as observed in RAG deficiency and NHEJ deficiency) typically result in the absence of mature B and T cells. The pre-BCR is affected in these cases, leading to PADs as V(D)J recombination is required for heavy chain expression. The dashed lines indicate a block of differentiation. BLNK, B-cell linker; Btk, Bruton tyrosine kinase; CMP, common myeloid progenitor; ETP, early T-cell precursor; GMP, granulocyte/macrophage progenitor; MEP, megakaryocyte/erythrocyte progenitor; MLP, multi-lymphoid progenitor; MPP, multipotent progenitor; PI3K, phosphoinositide 3-kinase. *(From Durandy A, Kracker S, Fischer A. Primary antibody deficiencies.* Nat Rev Immunol. *2013;13:519-533. Box 1, p. 520.)*

is similar to XLA. Variants in the genes encoding for Igα (CD79a), Igβ (CD79b), λ5 (IGLL1), BLNK, and p85α (PI3KR1) have been identified as other, more rare, causes for ARA in humans (see Fig. 166.1). Autosomal dominant forms of agammaglobulinemia have also been identified in patients with an unusual phenotype characterized by an increased expression of CD19, but with the absence of the BCR. Genetic studies demonstrated a de novo variant in the broadly expressed transcription factor E47, which functions as a quality control mechanism of enforcing a block to prevent cells that lack a pre-BCR from further development.

Clinical Manifestations

Absent peripheral B cells and severe hypogammaglobulinemia due to a developmental arrest at the pro-B stage to pre-B stage is characteristic of ARA. Although these patients generally have clinical findings that are indistinguishable from Btk mutations, patients with the pathogenic variants in any of the components of the BCR leading to ARA tend to have a more severe phenotype. ARA is diagnosed at a mean age of 11 months, rather than 35 months in patients with XLA. There is also a higher incidence of enteroviral infections and *Pseudomonas* sepsis with neutropenia. These differences suggest there is protective value in

Table 166.2 Patterns of Inheritance for Different Forms of Agammaglobulinemia

DISEASE	GENE/PROTEIN AFFECTED	PATTERN OF INHERITANCE
XLA	Btk	X-linked
IGHM	μ heavy chain	Autosomal recessive

the small amount of immunoglobulins produced by patients with XLA. Treatment using immunoglobulin and aggressive use of antibiotics is identical to that for patients with XLA.

Diagnosis

Due to the early B-cell developmental arrest, ARA variants have been associated with the complete absence of $CD19^+$ B cells in the peripheral circulation and profound hypogammaglobulinemia. Identifying a genetic cause of ARA is challenging, and there is a need for a better understanding of susceptibility genes and modifying genetic factors. The goal of further areas of investigation should include the identification of variant genes in patients who do not appear to have defects in the genes already associated with immunodeficiency.

Whole genome sequencing will greatly facilitate the molecular diagnosis of abnormalities in additional genes that can cause ARA.

Inheritance Patterns

XLA affects males, as it is an X-linked disorder. The inheritance patterns include all female offspring as carriers, and none of the male offspring will be affected. Autosomal recessive forms of agammaglobulinemia result in both males and females affected, as each parent passes on the affected gene. Patients with agammaglobulinemia tend to have more severe disease, often presenting earlier in life compared with patients with hypogammaglobulinemia, specific antibody deficiency (SAD), or CVID.

Treatment with antibody replacement and prophylactic antibiotics for patients with any form of agammaglobulinemia is essential in preventing infections and will be further reviewed later.

166.2 Hypogammaglobulinemia, Transient Hypogammaglobulinemia of Infancy, Specific Antibody Deficiency, and Common Variable Immunodeficiency

Vivian P. Hernandez-Trujillo and Camile Ortega

Patients with low IgG may present at different ages. Hypogammaglobulinemia results from low, but not absent, levels of serum immunoglobulins. If a patient is diagnosed with a specific pathologic genetic variant, this aids in making a specific diagnosis. Otherwise, in patients with a low IgG, the diagnosis may be arbitrary when considering the differential of hypogammaglobulinemia, SAD, and CVID (Tables 166.3 and 166.4).

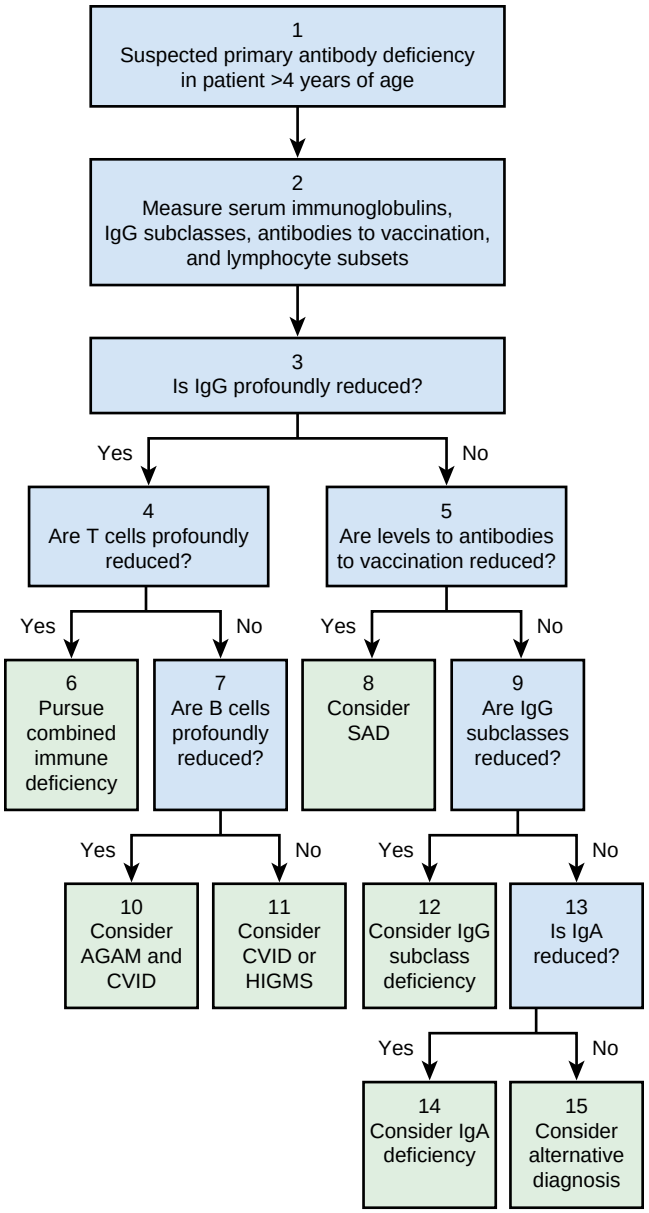

Fig. 166.3 Algorithm for evaluation of a patient with suspected primary antibody deficiency. AGAM, Congenital agammaglobulinemia; CVID, common variable immunodeficiency; HIGMS, hyperIgM syndrome; SAD, specific antibody deficiency. *(From Maglione PJ. Primary antibody deficiency. In: Leung DYM, Akdis CA, Bacharier LB, et al., eds.* Pediatric Allergy Principles and Practice. *4th ed. Philadelphia: Elsevier, 2021. Fig. 5.1.)*

HYPOGAMMAGLOBULINEMIA

The most common types of PIDD are antibody deficiencies characterized by hypogammaglobulinemia and recurrent infections and are usually present in childhood. Primary hypogammaglobulinemia represents a spectrum of disease, with more severe phenotypes characterized by profound hypogammaglobulinemia or agammaglobulinemic states, as was described in the previous section. SAD and CVID are presented in the following sections, and onset may occur later in childhood and adolescence. This is in contrast to transient hypogammaglobulinemia of infancy, which presents in the first few months of life.

The secondary forms are more common in adults and are a result of decreased production or increased loss. Decreased production can be drug induced (rituximab, glucocorticoids, and antiepileptics), from malignancy or premalignant disorders (chronic lymphocytic leukemia, lymphoma, multiple myeloma, or Waldenström macroglobulinemia), and from Good syndrome (thymoma with hypogammaglobulinemia). Increased loss can result from protein-losing enteropathies, intestinal lymphangiectasia, nephrotic syndrome, burns, and trauma.

Specific Antibody Deficiency

SAD is defined as patients, 2 years old and older, with recurrent infections and normal immunoglobulin isotypes who lack antibody response to purified *S. pneumoniae* capsular polysaccharide antigens, while responding normally to protein antigens.

Genetics and Pathogenesis

Infants demonstrate robust antibody responses to protein antigens through T-cell–dependent activation. Response to purified polysaccharide vaccines (PPVs) does not involve T-cell activation, and is only considered to be fully developed by 2 years of age. The response to protein antigens, including those contained in the protein conjugated vaccines (PCVs), typically remains intact in patients with SAD. In SAD, some patients' lack of response to PPV may represent physiologic immaturity of the immune system, and may resolve over time. In SAD patients with recurrent infections requiring antibiotics, there is likely an underlying immunologic abnormality. The cause for this delay in maturation remains unknown. Abnormalities in a specific pathogen-associated molecular pathway may be responsible for the variability in which individuals respond to specific protein or polysaccharide antigens despite normal total immunoglobulin levels. A number of cellular pathways produce antibodies against purified or conjugate polysaccharides and are likely to be altered by different defects. The response seen to PPV, which can occur in patients who lack a response to PCV, demonstrates how conjugate and purified polysaccharides induce antibodies through different activation pathways. The variation in phenotypes of SAD also supports the likelihood of different pathogenic mechanisms resulting in polysaccharide antibody deficiencies. The use of large-scale DNA studies, along with IgM memory and class-switched memory B cells as immunologic markers, is expected to provide useful information for the evaluation and management of patients with SAD in the future.

Clinical Manifestations

Patients with SAD present in a manner consistent with those with defects of humoral immunity. Frequent, severe, or prolonged sinopulmonary infections are most common. Rapid recurrence of infection on discontinuation of antibiotics, following initial improvement, is also common. Invasive and life-threatening infections are not frequent. Approximately half of children show resolution of SAD in 3 years and treatment may be temporary. A new diagnosis of SAD during adolescence or adulthood could indicate a previously missed diagnosis or progression of a mild phenotype. Pathogen susceptibility is not specific and not limited to *S. pneumoniae.* Other encapsulated bacteria, (*H. influenzae* and *Moraxella catarrhalis*), *Staphylococcus aureus* and respiratory viruses cause significant disease in SAD.

SAD patients with allergic disease are among the most challenging to identify due to increased risk of sinopulmonary infections resulting from persistent inflammation and anatomic dysfunction associated with asthma and rhinitis. It is important to consider underlying SAD in this population, as IgE-mediated sensitization is only present in some of these patients. Mucociliary or anatomic defects should also be considered in those who have developed high titers in response to natural infection, but maintain an abnormal pattern of infections.

Although lack of antibody response to polysaccharide antigens is found frequently in patients without any associated immune deficiency, selective antibody deficiencies are also common in patients with known PIDDs with normal total immunoglobulin levels such as ataxia telangiectasia, asplenia, hyper-IgE syndrome, selective IgA deficiency, IgG subclass deficiencies, Wiskott-Aldrich syndrome, and partial DiGeorge syndrome. A subset of adolescents and adults with SAD may progress to more severe forms of PIDD, including other forms of hypogammaglobulinemia and CVID.

Diagnosis

The gold standard for the diagnosis of SAD involves evaluating the response to the 23-valent pneumococcal polysaccharide vaccine (PPV23). In patients immunized with protein conjugated

Table 166.3 Main Phenotypes of Primary Antibody Deficiencies

PHENOTYPE	MAIN CLINICAL FEATURES	MAIN B-CELL FEATURES
Agammaglobulinemia	Bacterial infections (in respiratory tract) and enterovirus infections	Absence of CD19 B cells
Common variable immunodeficiency	Bacterial infections (in respiratory tract and gut), autoimmunity, cancer, and increased risk of granuloma	Highly variable; may see decreased memory B cells
Class switch defects	Bacterial and opportunistic infections	Decreased frequency of memory B cells
Selective IgA deficiency	Most often asymptomatic	Normal
IgG subclass deficiency	Frequent bacterial infections; diagnosis after age 2 yr	B-cell subsets normal
Selective polysaccharide antibody deficiency	Bacterial infections (after age 2 yr)	Normal IgG (including IgG2 and IgG4) levels, normal B-cell subsets

Table 166.4 Antibody Deficiency Disorders with Laboratory Evaluation

LABORATORY VALUES	XLA/AR AGAMMA	SELECTIVE IgA	SPECIFIC ANTIBODY DEFICIENCY	COMMON VARIABLE IMMUNODEFICIENCY	TRANSIENT HYPOGAMMA-GLOBULINEMIA
IgG	Decreased	Normal	Normal	Decreased to normal	Decreased
IgA	Decreased	Decreased	Normal	Decreased to normal	Normal
IgM	Decreased	Normal	Normal	Varies	Normal
LYMPHOCYTES					
B $CD19^+$	Decreased to absent	Normal	Normal	Decreased to normal memory B cells	Normal

pneumococcal vaccines (PCV-7, PCV-13, PCV-10, PCV-15, PCV-20), the evaluation must be based on the serotypes not present in conjugate vaccines. In unimmunized patients, a complete absence of protective titers to all serotypes is unusual, as most individuals would be expected to have developed some in response to natural infection by 2 years of age. The standard and reproducible method used for analysis is the third-generation World Health Organization enzyme-linked immunosorbent assay (ELISA) and the antigens are individual serotype specific capsular polysaccharides of pneumococci. Antibody titers are expressed as mg/mL and although titers as low as 0.35 mg/mL have been considered protective against invasive infections, a titer of 1.3 mg/mL is used as the threshold of response to PPV23 and generally considered protective against mucosal infections. **Four different phenotypes of SAD** have been described based on the response to the available pneumococcal vaccines: mild, moderate, severe, and memory. Although all phenotypes presume an abnormal pattern of infection, severity or susceptibility to infection may or may not correlate clinically. The severe phenotype is defined as nearly absent protective titers to ≤2 serotypes following PPV23. The moderate phenotype is based on age: for those less than 6 years old, less than 50% protective serotypes and those age 6 years old and greater, less than 70% protective serotypes. Many patients fall in the mild phenotype, which is less well defined as a failure of response to multiple phenotypes. The memory phenotype, also dependent on age, is defined as an adequate initial response and subsequent loss of protective titers within 6 months. The evaluation of specific antibodies against *S. pneumoniae* polysaccharides provides guidance in determining the need for additional immunization, antibiotic therapy, or IgG replacement therapy in SAD patients. Children and adults who have not been immunized and have not developed protective titers in response to natural infection should be immunized with PCV followed by PPV23, as they have been shown to respond both clinically and serologically. Patients who fail to respond to the initial challenge with PPV23 may respond to the conjugated vaccine, when given ≥1 year after PPV23. Most patients have an excellent prognosis with appropriate treatment.

COMMON VARIABLE IMMUNODEFICIENCY

CVID is a syndrome characterized by hypogammaglobulinemia after an initial period of apparent normal immune function. Serum IgG must be <2 standard deviations below the *age-adjusted* norms, with low IgA and/or IgM levels. CVID patients may appear similar clinically to those with XLA in the types of infections experienced and bacterial etiologic agents involved, except that enterovirus meningoencephalitis is rare in patients with CVID. In contrast to XLA, the sex distribution in CVID is almost equal, the age at onset is later, and infections may be less severe. CVID is the most common of the antibody defects.

Genetics and Pathogenesis

CVID is a phenotypic diagnosis with a polygenic inheritance in most cases. Genes known to produce the **CVID** phenotype when pathogenic variants occur include *ICOS* (inducible co-stimulator) deficiency, *SH2DIA* (responsible for X-linked lymphoproliferative disease [XLP]), *CD19, CD20, CD21, CD81, BAFF-R* (B-cell–activating factor of the tumor necrosis factor family of receptors), *NFKB1* and *NFKB2*, *IKZF1*, *ATP6AP1*, *MOGS*, *TACI*, and *TRNT1* (Fig. 166.4). With rare exceptions, management of CVID does not depend on a genetic diagnosis. In the setting of atypical infections or autoimmunity, pursuing a genetic diagnosis can be useful because some genetic etiologies can have a poor prognosis and transplantation should be considered. Targeted treatment options may also be available to treat some forms of CVID related to *LRBA* or *CTLA4* pathogenic variants.

Despite normal numbers of circulating B cells in many patients and the presence of lymphoid cortical follicles, blood B cells from CVID patients do not differentiate normally into immunoglobulin-producing cells. They may have a deficiency of switched memory B cells.

Clinical Manifestations

The serum immunoglobulin and antibody deficiencies in CVID are associated with recurrent sinopulmonary infections (sinusitis, otitis, pneumonia). Most patients present before age 20. Close monitoring for the development of chronic lung disease is needed. Repeated pulmonary infections may produce bronchiectasis; interstitial lung disease is common (Fig. 166.5). Sepsis and meningitis with encapsulated bacteria occur more frequently than in the general population. Patients with recurrent infections as their only manifestation typically have a normal life expectancy and do well with immunoglobulin replacement. The presence of autoimmune disease or lymphoproliferation confers a poor prognosis, as antibody replacement does not improve these conditions. Patients with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes; about 25% of patients have splenomegaly. CVID has also been associated with a spruelike enteropathy with or without nodular lymphoid hyperplasia of the intestine. Other autoimmune diseases include alopecia areata, hemolytic anemia, thrombocytopenia, gastric atrophy, achlorhydria, and pernicious anemia. Lymphoid interstitial pneumonia, intestinal lung disease, pseudolymphoma, B-cell lymphomas, amyloidosis, and noncaseating sarcoid-like granulomas of the lungs (**granulomatous and lymphocytic interstitial lung disease [GLILD]**), spleen, skin, and liver also occur. Patients should be monitored closely over time for symptoms involving multiple tissues.

166.3 Class Switch Defects

Vivian P. Hernandez-Trujillo and Camile Ortega

The **hyper-IgM syndrome** is genetically heterogeneous and characterized by normal or elevated serum IgM levels associated with low or absent IgG, IgA, and IgE serum levels, indicating a defect in the class switch recombination (CSR) process. Causative pathogenic variants have been identified in the CD40 ligand gene on the X chromosome and three genes on autosomal chromosomes: the activation-induced cytidine deaminase (AID) gene, the uracil DNA glycosylase gene (UNG), and the CD40 gene on chromosome 20. Distinctive clinical features permit presumptive recognition of the type of pathogenic variants in these patients, thereby aiding proper choice of therapy. All such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and decisions regarding definitive therapy.

X-LINKED HYPER-IgM CAUSED BY MUTATIONS IN CD40 LIGAND GENE

X-linked hyper-IgM is caused by pathogenic variants in the gene that encodes the CD40 ligand (CD154, CD40L), which is expressed on activated T-helper (Th) cells. Males with this syndrome have very low serum concentrations of IgG and IgA, with a usually normal or sometimes elevated concentration of polyclonal IgM; may or may not have small tonsils; usually have no palpable lymph nodes; and often have profound neutropenia. This disease, unlike the autosomal recessive forms of hyper-IgM, affects both B and T cells.

Genetics and Pathogenesis

The B cells are normal in this condition; the defect is in the T cells. CD40L is the ligand for CD40, which is present on B cells and monocytes. CD40L is upregulated on activated T cells. Mutations result in an inability to signal B cells to undergo isotype switching, and thus the B cells produce only IgM. The failure of T cells to interact with B cells through this receptor-ligand pair also causes a failure of upregulation of the B-cell and monocyte surface molecules CD80 and CD86 that

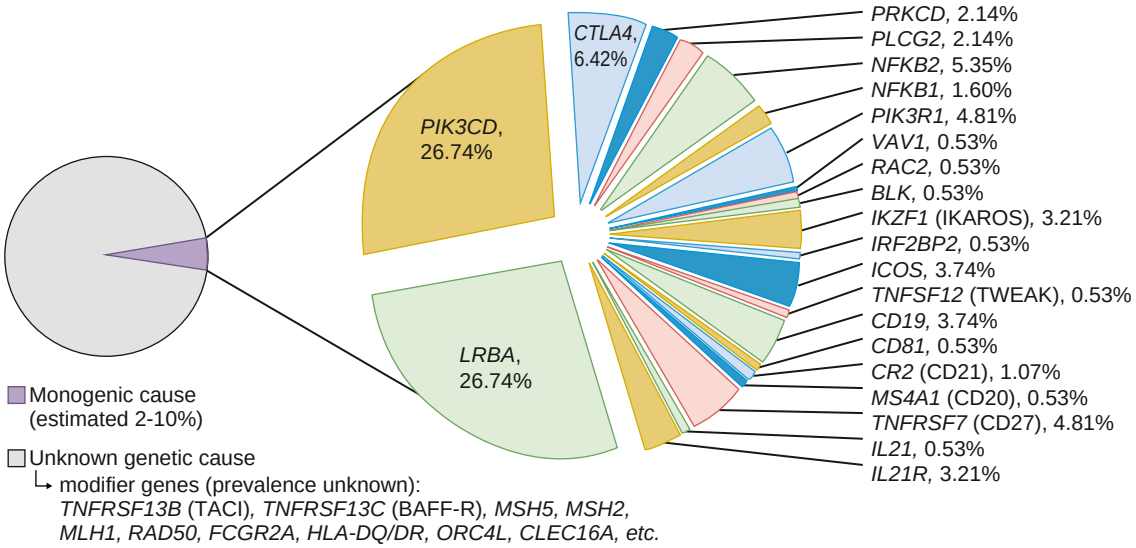

Fig. 166.4 Known genetic etiology of common variable immunodeficiency (CVID). **The majority of cases of CVID do not have a defined genetic cause.** Many of these are likely to be multifactorial, and the genomic duplication and deletion burden in CVID suggests this to be the case; 115 of the mutations have been identified. The colored pie chart represents their breakdown and relative frequency. *(From Bogaert DJ, Dullaers M, Lambrecht BN, et al. Genes associated with common variable immunodeficiency: One diagnosis to rule them all?* J Med Genet. *2016;53[9]:575-590. Fig 1.)*

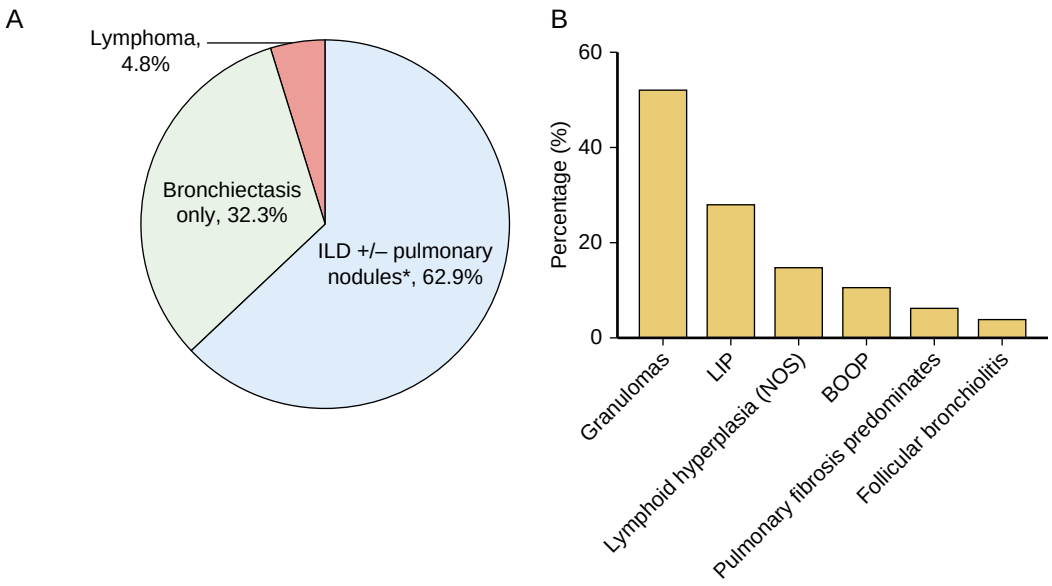

Fig. 166.5 Chronic lung disease in common variable immunodeficiency. **A,** Lung disease types by radiographs and/or pathology reports (n = 124). **B,** Interstitial lung disease pathologies (n = 46). *Thirteen of 65 subjects with ILD had concurrent bronchiectasis. BOOP, bronchiolitis obliterans organizing pneumonia; ILD, interstitial lung disease; LIP, lymphoid interstitial pneumonia. *(From Ho HE, Cunningham-Rundles C. Non-infectious complications of common variable immunodeficiency: Updated clinical spectrum, sequelae, and insights to pathogenesis.* Front Immunol. *2020;11:149. Fig. 1)*

interact with CD28/CTLA4 on T cells, resulting in failure of "crosstalk" between immune system cells.

Clinical Manifestations

Males with the CD40 ligand defect become symptomatic during the first or second year of life with recurrent pyogenic infections, including otitis media, sinusitis, pneumonia, and tonsillitis. They have marked susceptibility to *P. jirovecii* pneumonia and can be neutropenic. Lymph node histology shows only abortive germinal center formation with severe depletion and phenotypic abnormalities of follicular dendritic cells. These patients have normal numbers of circulating B lymphocytes, but a decreased frequency of $CD27^+$ memory B cells. Circulating T cells are also present in normal numbers and in vitro responses to mitogens are normal, but there is decreased antigen-specific T-cell function. In addition to opportunistic infections such as *P. jirovecii* pneumonia, there is an increased incidence of extensive verruca vulgaris lesions, *Cryptosporidium* enteritis, subsequent liver disease, and an increased risk of malignancy.

Treatment

Because of the poor prognosis, the treatment of choice is an HLA-identical hematopoietic stem cell transplant at an early age. Alternative treatment for this condition is lifelong infusions of immune globulin. In patients with severe neutropenia, the use of granulocyte colony-stimulating factor has been beneficial.

AUTOSOMAL RECESSIVE HYPER-IgM

Genetics and Pathogenesis

In contrast to patients with the CD40L defect, B cells from these patients are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when co-cultured with normal T cells. The defects are all B-cell intrinsic. The most common autosomal recessive defect is in a gene that encodes AID. AID deaminates cytosine into uracil in targeted DNA, which is followed by uracil removal by UNG. Severely impaired CSR was found in three hyper-IgM patients reported to have UNG deficiency. Their clinical characteristics were similar to those with AID deficiency, with increased susceptibility to bacterial infections and lymphoid hyperplasia. Histologic examination of the enlarged lymph nodes reveals the presence of giant germinal centers (5-10 times > normal) filled with highly proliferating B cells. Autosomal recessive hyper-IgM can be caused by defects in CD40. Clinical manifestations included recurrent sinopulmonary infections, *P. jirovecii* pneumonia, and *Cryptosporidium parvum* infections, very similar to the manifestations seen in X-linked hyper-IgM syndrome. Patients with *INO80* deficiency may present with severe bacterial infections; whereas in *MSH6* deficiency patients may have increased IgM, family or personal history of cancer, and low switch memory B cells.

Clinical Manifestations

Concentrations of serum IgG, IgA, and IgE are very low in AID, UNG, and CD40 deficiencies. In contrast to the CD40 ligand defect, however, the serum IgM concentration in patients with AID deficiency is usually markedly elevated and polyclonal. Patients with AID and UNG mutations have lymphoid hyperplasia, are generally older at age at onset, do not have susceptibility to *P. jirovecii* pneumonia, often do have isohemagglutinins, and are much less likely to have neutropenia unless it occurs on an autoimmune basis. The lymphoid hyperplasia distinguishes these patients from many others with antibody deficiency, particularly agammaglobulinemia, which leads to a paucity of lymphoid tissue. They have a tendency, however, to develop autoimmune and inflammatory disorders, including diabetes mellitus, polyarthritis, autoimmune hepatitis, hemolytic anemia, immune thrombocytopenia, Crohn disease, and chronic uveitis.

Treatment and Prognosis

With early diagnosis and antibody replacement, as well as good management of infections with antibiotics, patients with AID and UNG mutations generally have a more benign course than do those with the CD40L or CD40 defects. CD40 deficiency is rare but appears to mimic the manifestations of CD40L quite closely.

Treatment of Antibody Deficiency

Except for the CD40 ligand defect, for which stem cell transplantation is recommended, judicious use of antibiotics to treat documented infections and regular administration of immunoglobulin are the only effective treatments for primary B-cell disorders. The most common forms of replacement therapy are either intravenous or subcutaneous immune globulin (IVIG or SCIg). Broad antibody deficiency should be carefully documented before such therapy is initiated. The rationale for the use of IVIG or SCIg is to provide missing antibodies, not to raise the serum IgG or IgG subclass level. The development of safe and effective immunoglobulin preparations is a major advancement in the treatment of patients with severe antibody deficiencies, although it is expensive and there have been national shortages.

Almost all commercial preparations are isolated from normal plasma by the Cohn alcohol fractionation method or a modification of it. Cohn fraction II is then further treated to remove aggregated IgG. Additional stabilizing agents such as sugars, glycine, and albumin are added to prevent reaggregation and protect the IgG molecule during lyophilization. The ethanol used in preparation of immunoglobulin inactivates

HIV, and an organic solvent/detergent step inactivates hepatitis B and C viruses. Some preparations are also nanofiltered to remove infectious agents. Most commercial lots are produced from plasma pooled from 10,000 to 60,000 donors and therefore contain a broad spectrum of antibodies. Each pool must contain adequate levels of antibody to antigens in various vaccines, such as tetanus and measles. However, there is no standardization based on titers of antibodies to more clinically relevant organisms, such as *S. pneumoniae* and *H. influenzae* type b.

The IVIG and SCIg preparations available in the United States have similar efficacy and safety. Rare transmission of hepatitis C virus has occurred in the past, but this has been resolved by the additional treatment step. There has been no documented transmission of HIV by any of these preparations. IVIG or SCIg at a dose of 400-600 mg/kg per month achieves trough IgG levels close to the normal range. Higher doses are indicated in patients with chronic or severe respiratory infections. Systemic reactions may occur, but rarely are these true anaphylactic reactions. Neutropenia associated with B-cell defects has responded to granulocyte colony-stimulating factor. Treatment of inflammatory bowel disease is essential in maintaining adequate IgG levels.

166.4 Isotype Defects

Vivian P. Hernandez-Trujillo and Camile Ortega

SELECTIVE IgA DEFICIENCY

An isolated absence or near absence (<5 mg/dL) of serum and secretory IgA is the most common well-defined immunodeficiency disorder, with a disease frequency as high as 0.33% in some populations. Patients may be asymptomatic or may develop sinopulmonary or gastrointestinal (GI) infections (especially *Giardia*). IgA deficiency is also associated with celiac disease and other autoimmune disorders. The diagnosis cannot be made until about 4 years of age, when IgA levels should be matured to adult levels.

The basic defect resulting in IgA deficiency is unknown. Phenotypically normal blood B cells are present. In these patients, normal levels of other isotypes and normal specific antibody levels are seen. This defect also often occurs in pedigrees containing individuals with CVID. Indeed, IgA deficiency may evolve into CVID over time. IgA deficiency is noted in patients treated with the same drugs associated with producing CVID (phenytoin, D-penicillamine, gold, and sulfasalazine), suggesting that environmental factors may trigger this disease in a genetically susceptible person.

Clinical Manifestations

Infections occur predominantly in the respiratory, GI, and urogenital tracts. Bacterial agents responsible are the same as in other antibody deficiency syndromes. Intestinal giardiasis is common. Serum concentrations of other immunoglobulins are usually normal in patients with selective IgA deficiency, although IgG2 (and other) subclass deficiency has been reported.

Serum antibodies to IgA are reported in as many as 44% of patients with selective IgA deficiency. These antibodies can cause nonhemolytic transfusion reactions. Washed erythrocytes (frozen blood would have this done routinely) or blood products from other IgA-deficient individuals should be administered to patients with IgA deficiency. Many immune globulin preparations contain sufficient IgA to cause reactions. It is important to note that administration of immune globulin, which is >99% IgG, is not indicated because most IgA-deficient patients make IgG antibodies normally.

IgG Subclass Deficiencies

Some patients have deficiencies of one or more of the four subclasses of IgG despite normal or elevated total IgG serum concentration. Most patients may be asymptomatic. Some patients with absent or very low concentrations of IgG2 also have IgA deficiency. They may present with bacterial infections. Other patients with IgG subclass deficiency have gone on to develop CVID, suggesting that the presence of IgG subclass deficiency may be a marker for more generalized immune dysfunction. The biologic significance of the numerous moderate deficiencies of IgG subclasses that have been reported is difficult to assess. IgG subclass measurement is not cost-effective in evaluating immune function in the child with recurrent infections. The more relevant issue is a patient's capacity to make specific antibodies to protein and polysaccharide antigens, because profound deficiencies of antipolysaccharide antibodies have been noted even in the presence of normal concentrations of IgG2. For this reason, immune globulin should not be administered to patients with IgG subclass deficiency unless they are shown to have a deficiency of antibodies to a broad array of antigens.

Immunoglobulin Heavy- and Light-Chain Deletions

Some completely asymptomatic individuals have been documented to have a total absence of IgG1, IgG2, IgG4, and/or IgA1 as a result of gene deletions. These patients illustrate the importance of assessing specific antibody formation before deciding to initiate immune globulin therapy in IgG subclass–deficient patients. Low or undetectable levels of IgG subclasses alone is, therefore, not an indication for antibody replacement.

166.5 Transient Hypogammaglobulinemia of Infancy

Vivian P. Hernandez-Trujillo and Camile Ortega

A common laboratory finding in infants, transient hypogammaglobulinemia represents developmental delay in the production of immunoglobulin. It is thought to occur in as many as 1:1,000 children. Most infants begin to produce IgG in the first 3 months of life, and the quantity produced increases throughout infancy. For reasons incompletely understood, a small number of infants either begin late or do not increase their production as expected. This condition will resolve with no intervention, but represents a source of diagnostic confusion. A key distinction is that responses to vaccines are usually preserved in this condition, whereas in the others, including SAD, antibody responses will be low to absent.

Chapter 167

Natural Killer Cells

Jessica M. Palmieri, Vibha A. Szafron*, and Lisa Forbes Satter*

Natural killer (NK) cells are lymphocytes that have a critical role in the innate immune response to pathogenic challenge and cellular stress. NK cells are capable of rapid target cell killing and can quickly secrete large amounts of preformed granzymes and perforins in response to viral infections, especially those of the herpesvirus family. They are also crucial in tumor surveillance. NK cells are found in the circulating blood as approximately 3–15% of lymphocytes and are also found in both primary and secondary lymphoid tissues where they are in a constant state of surveillance for cellular abnormalities. NK cells use a detection system composed of a wide range of germline-encoded cell surface receptors that contribute to simultaneous NK activating and inhibitory signals. NK cells are constantly receiving both activating and inhibitory signals with the balance of signals tilted toward inactivation until NK cell recognition of a target cell occurs. With target cell recognition, the balance between inhibitory and activating signals leans in favor of activation and NK cell killing is initiated.

NK cells are defined as *innate immune lymphocytes* because unlike B and T lymphocytes, they do utilize recombination-activating gene (RAG) proteins required for DNA rearrangement and assemblage of diverse antigen-specific receptors in response to antigen exposure. However, they can develop long-lived and highly antigen-specific immunologic memory responses to different antigens through *RAG-independent adaptive immunity,* which provides lifelong immune memory responses. This means that despite a lack of receptor diversity accrued via DNA rearrangement like B cells and T cells, NK cells do have characteristics associated with the adaptive immune system; distinguishing healthy from diseased cells, producing robust antiviral responses, and maintaining a collection of long-lived cells that expand during cellular stress responses.

NK CELL MARKERS, SUBSETS, AND MATURATION

Mature NK cells are traditionally defined as non-T, non-B lymphocytes that can rapidly produce interferon gamma (IFN-γ) and can mediate cellular cytotoxicity. Like all lymphocytes, they express cluster of differentiation (CD) markers that identify their cell type and stage of development that are also upregulated or downregulated for cell homing purposes. However, there are no surface markers that are unique and specific for NK cells. NK cells have been traditionally identified by using flow cytometry to exclude the cellular surface presence of leukocyte expressing markers specific to other leukocytes, such as CD3 and CD5 (T cells), CD19 and CD20 (B cells), and CD13 and CD14 (myelomonocytic cells). Further identification of NK cells follows via their expression of CD56 (neural cell adhesion molecule-1) and/or CD16, their low-affinity Fc gamma receptor that mediates **antibody-dependent cellular cytotoxicity** (ADCC). Neither CD56 nor CD16 is specific or unique to the NK cell lineage; however, these CD markers are functionally important and thus used to characterize major subsets of NK cells.

NK cells develop from CD34 hematopoietic stem cells (HSCs) in the bone marrow and then undergo maturation in secondary lymphoid tissues. NK cell development occurs through a series of six functionally distinct developmental stages distinguishable by cellular expression of cell surface markers including CD34, CD117, CD94/NKG2A (surface inhibitory receptor), NKp80 (surface activating receptor), CD16, and CD57. Once mature, NK cells then circulate through the peripheral blood (PB) or are found in organ tissues such as the secondary lymphoid tissues, liver, lungs, uterus, kidneys, or gut. For example, stage 1 cells found in the bone marrow are marked by the presence of only CD34, and subsequent stages occur through the upregulation and downregulation of previously mentioned cell surface markers; whereas, stage 6 mature NK cells in the PB express Nkp80, CD16, and CD57 (Fig. 167.1).

NK cells express CD56 at different levels of development. $CD56^{bright}$ NK cells that express high levels of CD56, without expressing much CD16, are considered stage 4b and are approximately 3–10% of circulating PB NK cells. Most PB NK cells express CD16 and low levels of CD56 and are referred to as $CD56^{dim}$ NK cells. Distinguishing cells as $CD56^{bright}$ and $CD56^{dim}$ refers to the increased fluorescent intensity for $CD56^{+}$ cells seen in comparison to cells negative for CD56. $CD56^{bright}$ and $CD56^{dim}$ cells are functionally different. $CD56^{bright}$ NK cells are considered to be developmentally immature and produce higher levels of cytokines such as IFN-γ with less cytotoxic capacity. They can rapidly produce large amounts of cytokines and chemokines; however, they contain low levels of perforin and granzymes and have low or absent CD16, making them poor mediators of direct cytotoxicity and ADCC. In contrast, $CD56^{dim}$ cells are developmentally more mature, contain high levels of perforin, are cytotoxic, and recognize antibody-coated cells through CD16. $CD56^{dim}$ cells are able to produce large amounts of cytokines but not to the degree of $CD56^{bright}$ cells.

The cell surface marker expression for NK cells in the PB and tissues are phenotypically distinct due to the influence of each tissue's unique microenvironment. Similarly, the ratio of $CD56^{bright}$ and $CD56^{dim}$ NK subsets in the tissues is not the same as the ratios found in the PB. In the bone marrow, lung, spleen, subcutaneous adipose tissue, and breast tissue, $CD56^{dim}$ NK cells predominate, whereas $CD56^{bright}$ NK cells predominate in the mucosa-associated lymphoid tissues (MALTs; e.g., gastric and intestinal mucosa), liver, uterus, visceral adipose tissue, adrenal gland, and kidney.

NK Cell Functions

NK cells have a critical role in the control of tumor growth and metastasis and are vital for the innate immune response against infections, particularly certain viruses. Additionally, there is increasing recognition of the importance of NK cells in immunoregulation, coordination of immunity, and modulation of autoreactivity.

NK cell activity is a balance between inhibitory and activating signals. NK cell surfaces contain a wide range of receptors that affect NK cell expression. Healthy host cells express high amounts of major histocompatibility complex class I (MHC I) molecules that ligate NK cell inhibitory receptors and prevent unwanted killing of healthy cells. Infected or malignant host cells downregulate their MHC I expression and express ligands for NK cell activating receptors, which triggers NK cell killing of the diseased cell. The balance of signals for NK cell inhibition by MHC I expression in healthy cells and NK cell activation by MHC I downregulation during cellular stress allows NK cells to defend against viruses and tumors and have protective roles in fungal, extracellular bacterial, intracellular bacterial, and parasitic infections. Many viruses have evolved to specifically downregulate MHC I in cells they infect to prevent the host cell from presenting antigenic peptides to virus-specific cytotoxic T lymphocytes (CTLs). Although this strategy does allow virus-infected cell evasion from CTLs, it makes the infected cell more susceptible to recognition by NK cells.

The three main functions of NK cells include cytokine/chemokine production, contact-dependent co-stimulation, and cytotoxicity. Additionally, NK cells are capable of interfacing with the adaptive immune system through their IgG Fc receptor, CD16, which allows them to engage in antibody-dependent killing.

Cytokine/Chemokine Production

Activated NK cells secrete a wide variety of cytokines and chemokines in response to stimulation by interleukin (IL)-12, IL-15, and IL-18. IFN-γ is one of the most potent cytokines released by

*These authors contributed equally to this work.

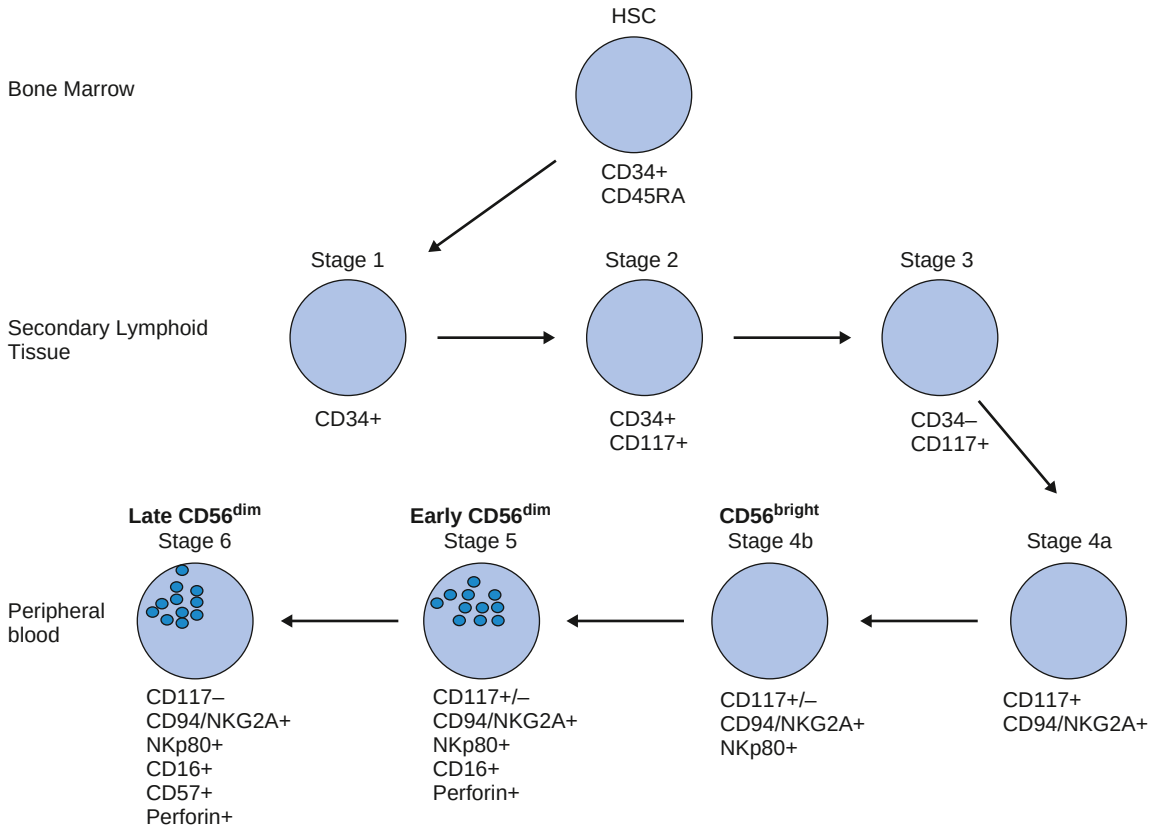

Fig. 167.1 Stages of NK cell development. HSC, Hematopoietic stem cell.

NK cells. It is crucial for the antiviral, antibacterial, and antitumor activity of NK cells through modulating death ligand expression of caspase, FasL, and TRAIL. NK cells are thus able to target cells for death through expression of these death ligands. Death ligand killing is not as rapid as lytic granule killing. Additional NK cell–released cytokines include TNF-α, IL-10, IL-5, and IL-13. NK cells also produce chemokines (chemotactic agents) such as MIP-1α, MIP-1β, IL-8, and RANTES. It is important to note that cytokines and chemokines in NK cells are compartmentalized separately from the lytic granules allowing them to be accessed separately from their cytotoxicity function.

Contact-Dependent Co-Stimulation

NK cells can promote and regulate immunity through direct receptor-ligand interactions with other cells, or contact-dependent co-stimulation. NK cells express or can be induced to express a variety of co-stimulatory and inhibitory ligands including the CD40 ligand, CD28, and PD-1, which can then interact with other types of immune cells to alter immune responses.

NK CELL SPONTANEOUS CYTOTOXICITY

Similar to cytotoxic T cells, NK cells secrete specialized lysosome-related organelles known as **lytic granules**. However, unlike CTLs, the lytic granules inside NK cells are preformed and abundant while the cell is at rest, which allows for their rapid killing response on recognition of cellular distress/disease. Lytic granule contents include **perforin** (pore-forming molecule) and pro-apoptotic enzymes such as **granzymes**. Once an NK cell recognizes an activation signal from a distressed cell, the NK cell will polarize its lytic granules toward the portion of the NK cell membrane in contact with the target cell where the lytic granules will then dock. This is followed by fusion of the secretory lysosome with the plasma membrane of the target cells. The site of NK cell connection with the target cell is called the **lytic immunologic synapse.**

Once a stable connection is formed at the lytic immunologic synapse, cellular killing by the lytic granules will be completed in less than 2 hours. Perforin will insert into the target cell membrane, which will allow for pro-apoptotic granzymes to travel to the target cell and initiate cellular killing.

NK CELL ANTIBODY-DEPENDENT KILLING

NK cells are also able to kill target cells via ADCC. NK cells have an IgG Fc receptor, CD16, expressed on their cell surfaces that allows them to recognize IgG-opsonized targets to promote killing without priming via lysing of the target cell. ADCC also causes NK cell secretion of cytokines like INF-γ for recruitment of adaptive immune cells.

Etiologies of NK Cell Deficiency

NK cells are lymphocytes that are critical for the immune response to viral infections. Patients with recurrent severe and refractory cutaneous viral and herpes viral infections should be evaluated for **NK cell deficiency (NKD)** with both enumeration and functional studies. However, ultimate evaluation should be completed with immunogenetic analysis as patients with diagnosed NKD may benefit from antiviral prophylaxis and eventual HSC transplant.

NKD accounts for a small subset of primary immunodeficiencies (PIDs) that often present as clinical and diagnostic challenges. In general, NKD is suspected in patients who appear to have increased susceptibility to herpesvirus infections as well as select other viral pathogens such a human papillomavirus (HPV).

NK cells can be decreased in number or function for many reasons. More commonly, severe illness and emotional stress can cause decreases of these cells. In addition, immunosuppressive medications such as corticosteroids, mycophenolate, cyclosporine, azathioprine, and 6-mercaptopurine can depress NK cells. Given many factors are known to affect the stability of NK cells, repetition of the test is required to document true deficiency. If a patient is found to have abnormal NK cell studies 3 times, drawn at least 1 month

apart, inborn errors in immunity should be also considered, as described next.

More than 50 PIDs include abnormalities in NK cells as part of their immunophenotypes. This occurs secondary to disruption in maturation, proliferation, or survival of NK cells. Forms of **severe combined immune deficiency (SCID)** including *IL2RG, JAK3,* and *AK2* deficiency are known to present with low or absent NK cell numbers. In addition, given the importance of lytic granule secretion to NK cytotoxicity, conditions with abnormal granule secretion, such as primary **hemophagocytic lymphohistiocytosis**, or abnormal cytoskeletal function, such as **Wiskott-Aldrich syndrome**, also can lead to NK cell aberrations.

NKDs are classified as classical or functional. In **classical NKD**, there is a significantly decreased or absent number of $CD3^{-}CD56^{+}$ cells, making up less than 1% of the total peripheral lymphocytes. Alternatively, although the number of NK cells can be normal in **functional NKD**, these cells are functionally impaired.

Classical NK Cell Deficiency

Classical NKDs include pathogenic variants in *MCM4*, *MCM10*, *GINS1*, *GATA2, RTEL1,* and *IRF8.*

MCM4 and *MCM10*

MCM (mini-chromosome maintenance complex member) 4 and 10 are a part of the MCM replisome progression complex important for DNA replication. *MCM4* is part of the *Cdc45-MCM2-7-GINS1* (CMG) helicase complex and *MCM10* is a replication factor associated with this complex. In times of cellular stress, variant complexes have resulted in abnormal DNA breakage (Fig. 167.2). These patients have a decreased number of NK cells, specifically $CD56^{dim}$ NK cells. $CD56^{dim}$ NK cells are mature NK cells that express CD16 (Fc receptor) and are important for ADCC. It is possible that $CD56^{dim}$ NK cells are particularly reliant on the MCM complex for survival. Alternatively, the pathogenic variant may cause an interruption along development before mature NK cell expansion. Patients with biallelic pathogenic variants in *MCM4* have Epstein-Barr virus (EBV)-driven lymphoproliferation and viral pneumonitis. As *MCM4* is widely expressed in many cells, these patients can also have adrenal insufficiency, short stature, and development delay.

MCM10-deficient patients have a similar immunologic phenotype related to their NK cell abnormalities and the patients reported were found to have severe cytomegalovirus (CMV) infection.

GINS1

Go-Ichi-Ni-San complex subunit 1 (GINS1) is a protein involved in the CMG helicase complex that is important for DNA replication. Biallelic pathogenic variants in *GINS* have been seen to cause growth retardation, neutropenia, and NKD. It is important to note that both $CD56^{dim}$ and $CD56^{bright}$ cells are affected in this disorder. *MCM4, MCM10,* and *GINS1* defects causing classical NKD suggests that chromosomal maintenance is critical to NK cell development and function.

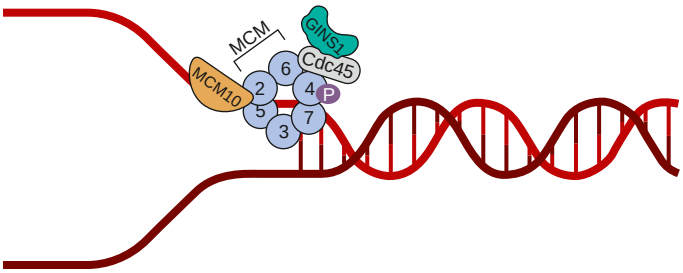

Fig. 167.2 Cell division cycle complex pathogenic variants associated with NK cell deficiency: *MCM4, MCM10, and GINS1*. Schematic illustration of the cell division cycle complex including the CMG (Cdc45, mini-chromosome maintenance [MCM 2-7], GINS1) helicase complex and *MCM10.*

GATA2

Pathogenic variants in *GATA2* (GATA-binding protein-2), inherited in an autosomal dominant manner, can cause immune aberrations affecting many different cell lines. The pathogenic variant prevents appropriate NK cell development with specific deficiency of immature $CD56^{bright}$ NK cells causing an absence of the $CD56^{bright}$ population, leaving a functionally impaired $CD56^{dim}$ population. These patients are known to have refractory HPV infections, among other cutaneous viral infections, myelodysplasias, cytopenias, and a risk of acute and chronic myeloid leukemias.

RTEL1

Biallelic pathogenic variants in regulator of telomerase elongation (*RTEL1)*, a DNA helicase, cause a form of **dyskeratosis congenita**, bone marrow failure, and immunodeficiency known as **Hoyeraal-Hreidarsson syndrome**. One patient reported with a history of disseminated varicella infection was found to have abnormal NK cells in number and function.

IRF8

Interferon regulatory factor 8 *(IRF8)* is a transcription factor involved in B-cell, dendritic cell, granulocyte, monocyte, and NK cell production. *IRF8* is vital for the NK cell response to viral infections and patients have been found to have severe EBV infections. Terminal NK cell maturation is disrupted and $CD56^{dim}$ cells are decreased in patients with biallelic *IRF8* pathogenic variants.

FUNCTIONAL NK CELL DEFICIENCY (FNKCD)

CD16 Deficiency

Patients with CD16 deficiency have severe infections with herpes viral pathogens such as varicella-zoster virus (VZV), herpes simplex virus (HSV) and EBV. One patient was reported to have EBV-driven Castleman disease. The deficiency is caused by a homozygous pathogenic variant in the *FCGR3A* gene, which encodes CD16. CD16 is the Fc receptor on NK cells required for ADCC. As CD16 deficiency is an FNKCD, patients have normal levels of NK cells, but abnormal function. Although CD16's main function is to facilitate ADCC, patients with CD16 deficiency have been found to have abnormal spontaneous cytotoxicity with normal antibody-dependent cytotoxicity (Fig. 167.3). Further analysis helped uncover a new function of the CD16 protein related to spontaneous cytotoxicity, which clarifies this unexpected finding. The variant sequence in CD16 deficiency encodes for the distal B73.1 domain of the CD16 molecule. Studies from patients with this pathogenic variant revealed that this region is needed for co-activation of the NK cell CD2 stimulatory receptor, which is required for spontaneous cytotoxicity. Alternatively, immunoglobulin binding, which is integral to ADCC, occurs at the proximal 3G8 domain of CD16, which is not affected by the variant. For diagnostic purposes, two anti-CD16 monoclonal antibodies are utilized against the distal B73.1 and proximal 3G8 domains. Therefore patients with CD16 deficiency will have absent B73.1 expression and normal 3G8 expression. These diagnostic tests can help identify patients with CD16 deficiency in addition to genetic analysis of *FCGR3A*.

ELF4

E74-like ETS transcription factor 4 (ELF4) is a protein involved in transactivation of gene promoters through DNA binding. Perforin expression, an important component of NK cell activity, has been shown to be dependent on ELF4-regulated promoters. Pathogenic variants in ELF4 can result in poor terminal NK cell maturation

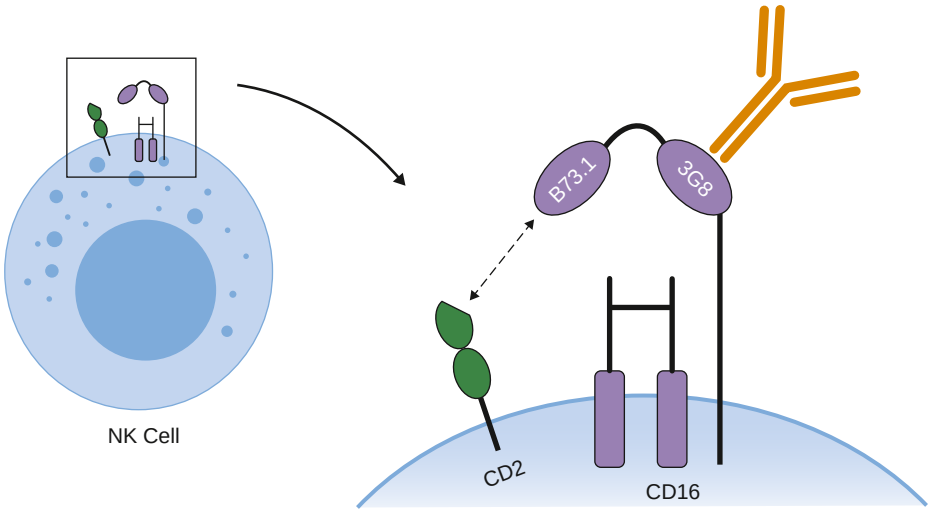

Fig. 167.3 Functional natural killer (NK) cell deficiency secondary to CD16 pathologic variants. Schematic of the CD16 (Fc) NK cell receptor. The proximal domain of the CD16 receptor, 3G8, binds the Fc portion of immunoglobulin, which is important for antibody-depending cytotoxicity. The distal domain of the CD16 receptor, B73.1, co-localizes with the CD2 stimulatory receptor facilitating spontaneous cytotoxicity. In *CD16* deficiency, the B73.1 domain of the CD16 receptor is not adequately expressed causing impaired spontaneous cytotoxicity.

from CD56^{bright} to CD56dim (cytotoxic) NK cells. A rare, hemizygous variant in ELF4, located on the X chromosome, has been described as a novel cause of NK cell deficiency. Patients with this variant can present with recurrent sinopulmonary and varicella zoster infections, as well as lymphoproliferative and malignant disease. Laboratory analysis has shown decreased number and function of NK cells, specifically with an abnormal immature NK cell CD56^{bright} to mature CD56dim NK cell ratio. Because these patients also can present with decreased B cells and hypogammaglobinemia, further work is needed to elucidate the role of ELF4 in B cell development and function.

NK Cell Diagnostic Tests

When evaluating for possible NK cell defects, it is important to examine the total NK cell count and percentage, the distribution of NK cell subsets, and NK cell function.

NK Cell Count and Percentage

The absolute NK cell count and NK cell percentage of total lymphocytes is often calculated using a lymphocyte subset analysis or enumeration assay. This test is performed using flow cytometry and will identify the CD16 and CD56 markers of NK cells. The majority of lymphocyte enumeration assays use a combined CD56/16 antibody and cannot distinguish between CD56^{bright} and CD56^{dim} NK cells. Further delineation of NK cell subsets (CD56^{dim}, CD56^{bright}, etc.) can be obtained with further flow cytometry for additional NK cell markers. Evaluation of NK cell phenotypes and ratios such as the CD56 bright to dim ratio becomes important in evaluating for NK cell defects such as *GATA2* deficiency.

FUNCTIONAL ASSAYS AVAILABLE FOR CLINICAL EVALUATION

NK Cell Cytotoxicity Assay

NK cytotoxic killing ability can be evaluated using a flow cytometry–based assay to quantify NK cell cytotoxic activity or a chromium release (^{51}CR) cytotoxicity assay. The ^{51}CR is technician dependent and requires the use of radioactive material. Many laboratories are doing the flow cytometry-based assay.

Individual clinical laboratories have normal ranges that are particular to their specific assay; however, the values for this assay are dependent on the percentage of NK cells present in the sample. A peripheral blood mononuclear cell (PBMC) sample with lower numbers of NK cells may not identify as much NK cell cytotoxicity as a sample with higher levels of NK cells, thus it is essential to take the percentage of NK cells into account when interpreting these assays.

CD107a Degranulation

Lysosomal-associated membrane protein-1 (LAMP-1) or CD107a is contained in NK cell lytic granules. CD107a is significantly upregulated on the surface of NK cells following lytic granule fusion with the NK cell membrane after activation by MHC I downregulated target cells. CD107a is thus often used as a way to evaluate activation-induced NK cell degranulation. In this test, NK cells are stimulated and the upregulation of CD107a is measured using flow cytometry.

CD107a degranulation has advantages and disadvantages when compared to the NK cell cytotoxicity assay. The main advantage is that CD107a degranulation can be measured in individual cells and is therefore independent of the NK cells percentage. The disadvantage is that it does not directly measure NK cell killing ability. NK cell killing can be impaired despite appropriate degranulation for reasons such as abnormal lytic effector molecules. Ten to 30% of resting NK cells can be induced to degranulate when measured by flow cytometry, and in normal individuals CD107a degranulation reasonably correlates with killing ability.

NK CELL DEFICIENCY TREATMENT

Primarily, treatment of NKD targets the infectious complications that occur in these patients. Specifically, HSV infections should be treated with antiviral therapy such as acyclovir. Long-term prophylaxis should be considered after completion of treatment. HPV infections can be significant and recurrent, and patients should be referred to dermatology for medical and surgical management.

Additional therapies such as immunoglobulin replacement and antimycobacterial prophylaxis can be utilized depending on the genetic cause of NKD. The only curative therapy for classical NKDs at this time is HSC transplantation.

Section 3

The Phagocytic System

Chapter 168

Neutrophils

Thomas D. Coates

THE PHAGOCYTIC INFLAMMATORY RESPONSE

The phagocyte system includes both granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Neutrophils and mononuclear phagocytes share primary functions, including the defining properties of large-particle ingestion and microbial killing. Phagocytes participate primarily in the innate immune response but also help initiate acquired immunity.

Neutrophils provide the rapid effector arm of the innate immune system. They circulate in the bloodstream for only about 6 hours (Table 168.1), but on encountering specific chemotactic signals, they adhere to the vascular endothelium and transmigrate into tissues. There they ingest and kill microbes and release chemotactic signals to recruit more neutrophils and to attract dendritic cells and other initiators of the acquired immune response.

HEMATOPOIESIS

The hematopoietic progenitor system can be viewed as a continuum of functional compartments, with the most primitive compartment composed of very rare **pluripotential stem cells**, which have high self-renewal capacity and give rise to more mature stem cells, including cells that are committed to either lymphoid or myeloid development (Fig. 168.1). Common lymphoid progenitor cells give rise to T- and B-cell precursors and their mature progeny. Common myeloid progenitor cells eventually give rise to committed single-lineage progenitors of the recognizable precursors through a random process of lineage restriction in a stepwise process (see Chapter 495). The capacity of lineage-specific committed progenitors to proliferate and differentiate in response to demand provides the hematopoietic system with a remarkable range of response to changing requirements for mature blood cell production.

Table 168.1 Neutrophil and Monocyte Kinetics

NEUTROPHILS	
Average time in mitosis (myeloblast to myelocyte)	7-9 days
Average time in postmitosis and storage (metamyelocyte to neutrophil)	3-7 days
Average half-life in the circulation	6 hr
Average total body pool	6.5×10^8 cells/kg
Average circulating pool	3.2×10^8 cells/kg
Average marginating pool	3.3×10^8 cells/kg
Average daily turnover rate	1.8×10^8 cells/kg
MONONUCLEAR PHAGOCYTES	
Average time in mitosis	30-48 hr
Average half-life in the circulation	36-104 hr
Average circulating pool (monocytes)	1.8×10^7 cells/kg
Average daily turnover rate	1.8×10^9 cells/kg
Average survival in tissues (macrophages)	Months

From Boxer LA. Function of neutrophils and mononuclear phagocytes. In: Bennett JC, Plum F, eds. *Cecil Textbook of Medicine*. 20th ed. Philadelphia: Saunders; 1996.

The proliferation, differentiation, and survival of immature hematopoietic progenitor cells are governed by hematopoietic growth factors, a family of glycoproteins (see Chapter 495). Along with regulating proliferation and differentiation of progenitors, these factors influence the survival and function of mature blood cells. During granulopoiesis and monopoiesis, multiple cytokines regulate the cells at each stage of differentiation from pluripotent stem cells to nondividing, terminally differentiated cells (monocytes, neutrophils, eosinophils, and basophils). As cells mature, they lose receptors for most cytokines, especially those that influence early cell development; however, they retain receptors for cytokines that affect their mobilization and function, such as granulocyte and macrophage colony-stimulating factors. Mature phagocytes also express receptors for chemokines, which help direct the cells to sites of inflammation. Chemokine receptors such as CXCR4 and its ligand SDF-1 play a key role in retention of developing myeloid cells within bone marrow.

NEUTROPHIL MATURATION AND KINETICS

The process of intramedullary granulocyte maturation involves changes in nuclear configuration and accumulation of specific intracytoplasmic granules. The bone marrow microenvironment supports the normal steady-state renewal of peripheral blood neutrophils through the generation of growth and differentiation factors by stromal cells. Growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) not only stimulate cell division, but also induce the expression of transcription factors that regulate the biosynthesis of functional components of the neutrophil, such as granule proteins. The transcription factor PU.1 is essential for myelopoiesis, both as a positive regulatory element and as a suppressor of GATA1, a transcription factor that directs nonmyeloid differentiation. Other transcription factors, such as Runx1 (AML1), c-myb, CDP, C/EBPα, C/EBPγ, and MEF, are expressed in the myeloblast and promyelocyte, and some of these are required for azurophil granule protein expression. As cells enter the myelocyte stage, Runx1 and myb are downregulated, whereas PU.1 and C/EBPε expression rise to initiate terminal differentiation.

Granulocytes survive for only 6-12 hours in the circulation; therefore daily production of 2×10^4 granulocytes/μL of blood is required to maintain a level of circulating granulocytes of 5×10^3/μL (see Table 168.1). The relatively small peripheral blood pool includes the rapidly interchanging circulating and marginating pools; the latter provides entrance into the tissue phase, where neutrophils may survive for hours or days. The circulating pool is fed and buffered by a much larger marrow population of mature neutrophils and myeloid precursors, representing the marrow reserve and proliferating pools, respectively. Proliferation of myeloid cells, encompassing approximately five mitotic divisions, takes place only during the first three stages of neutrophil development, in myeloblasts, promyelocytes, and myelocytes. After the myelocyte stage, the cells terminally differentiate into nondividing, maturing metamyelocytes, bands, and neutrophils.

Neutrophil maturation is associated with nuclear condensation and lobulation and the sequential production of characteristic granule populations. A **myeloblast** is a relatively undifferentiated cell with a large oval nucleus, a sizable nucleolus, and a deficiency of granules. **Promyelocytes** acquire peroxidase-positive azurophilic (primary) granules, and then **myelocytes** and **metamyelocytes** acquire specific (secondary) granules; tertiary granules and secretory vesicles develop in the final stage of neutrophil maturation.

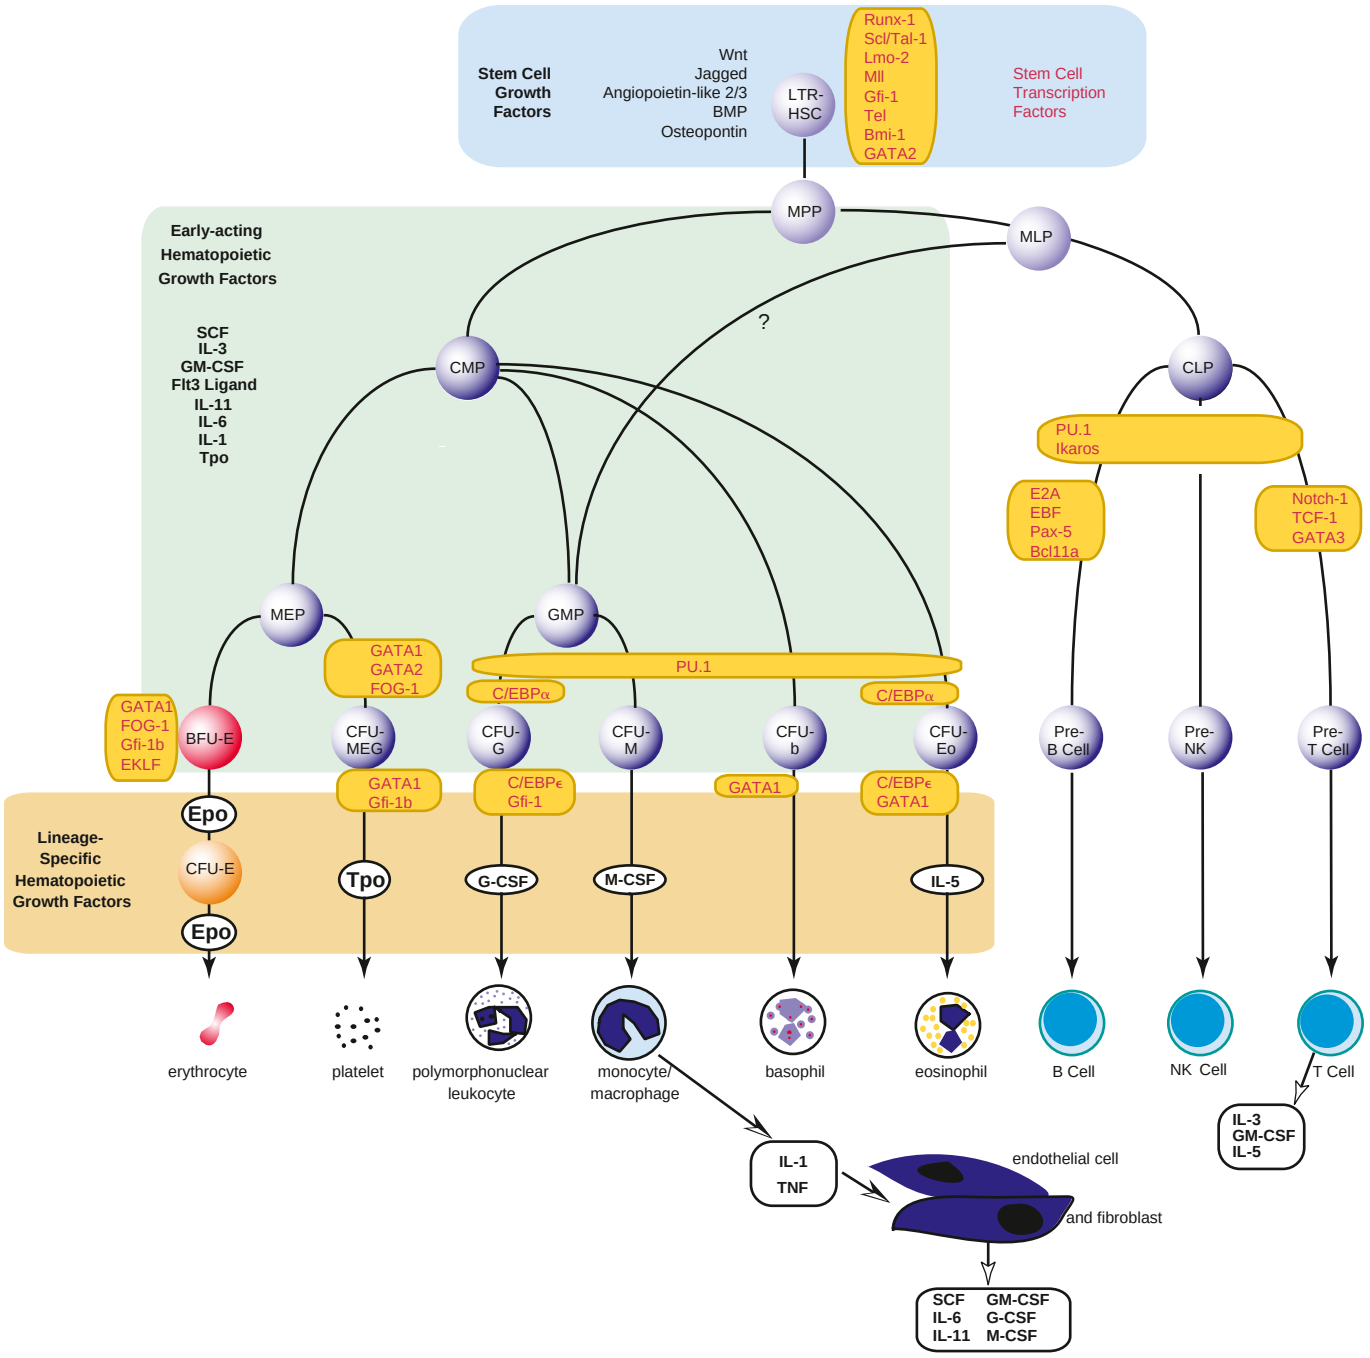

Fig. 168.1 Major cytokine sources and actions and transcription factor requirements for hematopoietic cells. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce macrophage, granulocyte-macrophage, and granulocyte colony-stimulating factors (M-CSF, GM-CSF, G-CSF), interleukin-6 (IL-6), and probably stem cell factor (SCF) (cellular sources not precisely determined) after induction with endotoxin (macrophage) or IL-1/tumor necrosis factor (TNF) (endothelial cells and fibroblasts). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages, optimal development requires a combination of early-acting and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown in *red* at the *top*, whereas stages of hematopoiesis blocked after the depletion of indicated transcription factors are shown in *red* for multipotent and committed progenitors. *(From Sieff CA, Daley GQ, Zon LI. Anatomy and physiology of hematopoiesis. In: Orkin SH, Fisher DE, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood. 8th ed. Philadelphia: Elsevier; 2015. Fig 1.7.)*

NEUTROPHIL FUNCTION

Neutrophil responses are initiated as circulating neutrophils flowing through the postcapillary venules detect low levels of chemokines and other chemotactic substances released from a site of infection. The sequence of events as the neutrophil moves from circulating in the blood to the encounter and destruction of bacteria is carefully orchestrated by a series of biochemical events, defects of which are associated with genetic disorders of neutrophil function (Fig. 168.2). In fact, these disorders of neutrophil function lead to our understanding of the cell biology of phagocyte function. A subset of circulating neutrophils loosely adheres to the endothelium through low-affinity receptors called **selectins** and rolls along the endothelium, forming the marginated pool. Soluble effectors of inflammation trigger subtle changes in surface adhesion molecules

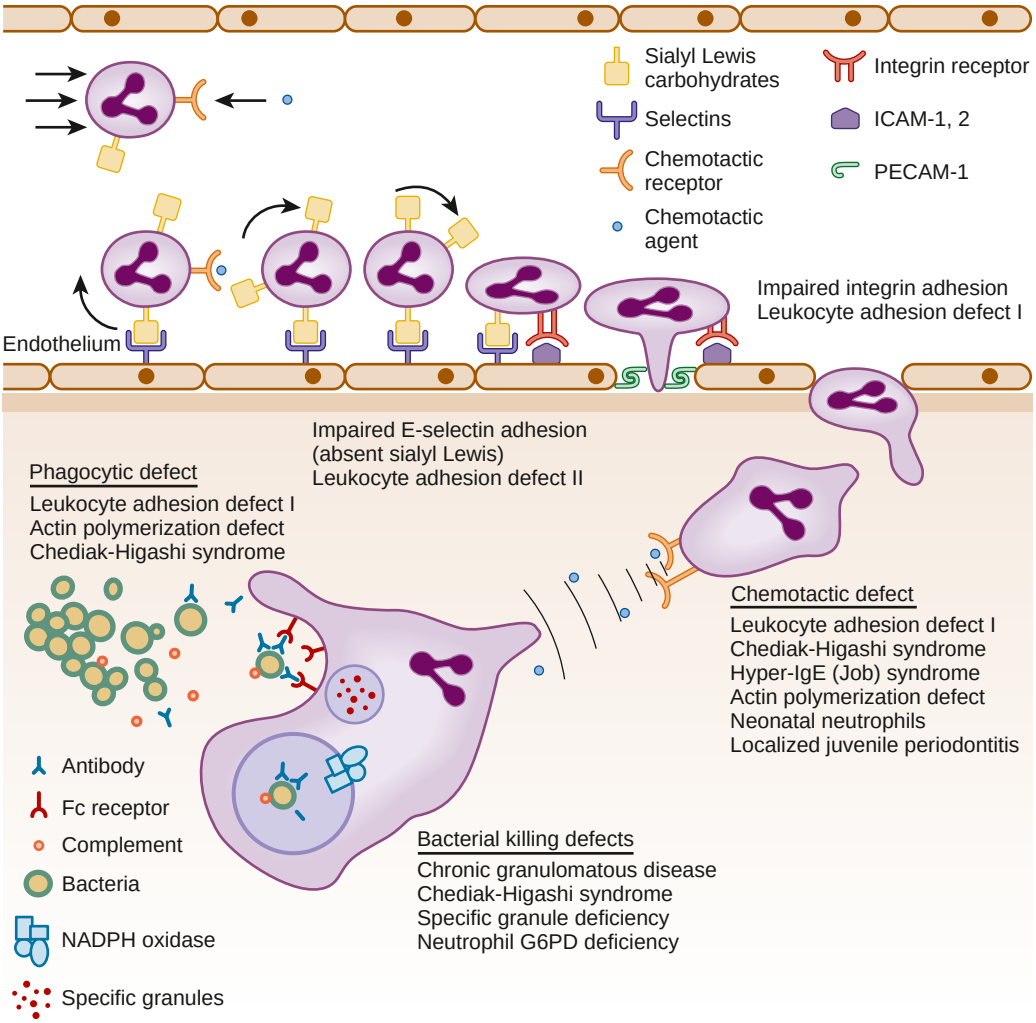

Fig. 168.2 The neutrophil-mediated inflammatory response and associated neutrophil dysfunction syndromes. Circulating neutrophils loosely attach to endothelium via selectins and roll along the vessel wall until they arrive at the site of infection. Inflammatory monokines, interleukin-1 (IL-1), and tumor necrosis factor (TNF) activate endothelial cells to express E- and P-selectins. E- and P-selectins serve as counter-receptors for neutrophils sialyl Lewis X and Lewis X to cause low-avidity neutrophil rolling. Activated endothelial cells express intracellular adhesion molecule (ICAM)-1, which serves as a counter-receptor for neutrophil β_2-integrin molecules, leading to high-avidity leukocyte spreading and the start of transendothelial migration at the infection site. Neutrophils invade through the vascular basement membrane with the release of proteases and reactive oxidative intermediates, causing local destruction of surrounding tissue at sites of high concentrations of chemotactic factors, and migrate to the site of infection, where they ingest and kill the bacteria. NADPH, Nicotinamide-adenine dinucleotide phosphate; PECAM, platelet endothelial cell adhesion molecule. *(Modified from Kyono W, Coates TD. A practical approach to neutrophil disorders. Pediatr Clin North Am. 2002;49:929.)*

on endothelial cells at the site of infection. The rolling of neutrophils allows more intense exposure of neutrophils to activating factors such as tumor necrosis factor or interleukin-1 (see Fig. 168.2). Exposure of neutrophils to these same activating factors induces qualitative and quantitative changes in the family of β_2-integrin adhesion receptors (the CD11/CD18 group of surface molecules), leading to tight adhesion between neutrophils and endothelial cells at the site of inflammation and ultimately to transmigration of the neutrophil into the tissue.

Once through the endothelium, the neutrophil senses the gradient of chemokines or other chemoattractants and migrates to sites of infection. **Neutrophil migration** is a complex process involving rounds of receptor engagement, signal transduction, and remodeling of the actin microfilaments composing in part the cytoskeleton. Actin polymerization-depolymerization occurs in approximately 8-second cycles and drives cyclic extension and retraction of the actin-rich lamella at the front of the neutrophil. Receptors at the leading edge of the lamella detect the gradient of attractant and follow microorganisms, then ingest and destroy them. When the neutrophil reaches the site of infection, it recognizes pathogens by means of Fc immunoglobulin and complement receptors, toll-like receptors, fibronectin receptors, and other adhesion molecules.

The neutrophil ingests microbes that are coated by **opsonins**, serum proteins such as immunoglobulin and complement component **C3**. The pathogens are engulfed into a closed vacuole, the **phagosome** (Fig. 168.3), where two cellular responses essential for optimal microbicidal activity occur concomitantly: degranulation and activation of nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent oxidase. Fusion of neutrophil granule membranes with the phagosome membrane delivers potent antimicrobial proteins and small peptides into the phagosome.

Assembly and activation of NADPH oxidase occur at the phagosome membrane as well (see Fig. 168.3), generating large amounts of superoxide (O_2^-) from molecular oxygen, which in turn decomposes to produce hydrogen peroxide (H_2O_2) and singlet oxygen. **Myeloperoxidase,** a major azurophil granule component, catalyzes the reaction

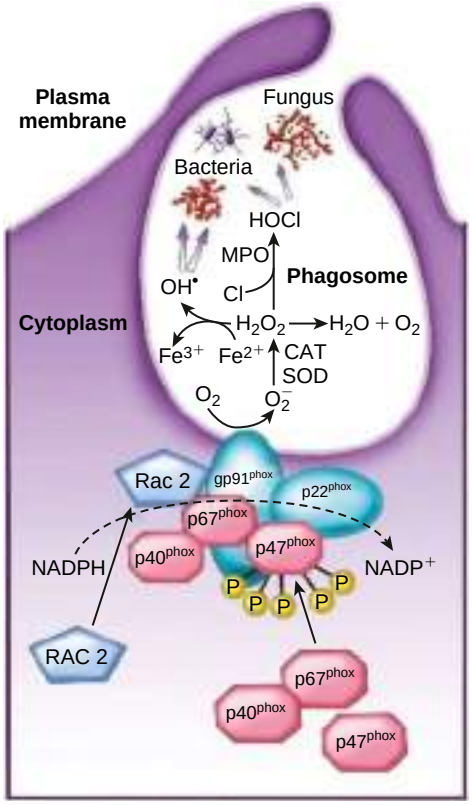

Fig. 168.3 Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase components and activation. On activation of phagocytic cells, the 3 cytosolic components *(red)* of the NADPH oxidase (p67^{phox}, p47^{phox}, and p40^{phox}), plus the small guanosine triphosphatase (GTPase) protein Rac2, are translocated to the membrane of the phagocytic vacuole. The p47^{phox} subunit binds to the flavocytochrome$_{b558}$ membrane component *(blue-green)* of the NADPH oxidase (gp91^{phox} plus p22^{phox}). The NADPH oxidase catalyzes the formation of superoxide by transferring an electron from NADPH to molecular oxygen (O_2), thereby forming the superoxide free radical. The unstable superoxide anion is converted to hydrogen peroxide, either spontaneously or by superoxide dismutase (SOD). H_2O_2 can follow different metabolic pathways into more potent reactive oxidants, such as OH• or HOCl) or degradation to $H_2O + O_2$. *(Adapted from Stiehm ER, Ochs HD, Winkelstein JA. Immunologic Disorders in Infants and Children, 5th ed. Philadelphia: Saunders; 2004, p. 622.)*

of H_2O_2 with ubiquitously present chloride ions to create hypochlorous acid (HOCl) in the phagosome. H_2O_2 and HOCl are potent microbicidal agents that break down and clear pathogens from sites of infection.

In addition, neutrophils secrete a wide variety of cytokines and chemokines that recruit more neutrophils to fight the infection, attract monocytes and macrophages that possess both microbicidal and scavenger functions, and promote antigen presentation to help initiate the adaptive immune response. Also, the reactive oxidants can inactivate chemotactic factors and may serve to terminate the process of neutrophil influx, thereby attenuating the inflammatory process. Finally, the release of reactive oxygen species, granule proteins, and cytokines can also damage local tissues, leading to the classic signs of inflammation or to more permanent impairment of tissue integrity and function. In addition to the role of neutrophils in tissue damage, they are now known to play a significant role in regulation of inflammation and promoting tissue repair. Turning off inflammation and removing tissue debris is an important role and, like seeking and destroying bacteria, this process is highly regulated as well.

Chapter 169

Eosinophils

Benjamin L. Wright and Brian P. Vickery

Eosinophils are nondividing, fully differentiated cells with a diameter of approximately 8 μm and a bilobed nucleus that are distinguished from other leukocytes by their morphology, constituent products, and association with specific diseases. Their characteristic membrane-bound specific granules stain bright pink with eosin and are cytotoxic for the larval stages of helminthic parasites and are also thought to contribute to much of the inflammation associated with chronic allergic diseases such as asthma (see Chapter 185). Eosinophil granule proteins including major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase are thought to inflict epithelial cell damage, although recent studies indicate their role may be more nuanced and not purely destructive. Eosinophil granule contents activate other proinflammatory cells, including mast cells, basophils, neutrophils, and platelets and have the capacity to generate large amounts of the lipid mediators, which can cause vasoconstriction, smooth muscle contraction, and mucus hypersecretion (Fig. 169.1). Eosinophils are a source of several proinflammatory cytokines and have also been shown to influence T-cell recruitment and immune polarization in inflammatory settings. Thus eosinophils have considerable potential to initiate and sustain the inflammatory response of the innate and acquired immune systems.

Eosinophil migration from the vasculature into the extracellular tissue is mediated by the binding of leukocyte adhesion receptors (e.g., VLA-4) to their ligands or counterstructures (VCAM-1) on the postcapillary endothelium. Eosinophils are recruited to tissues in inflammatory states by a group of chemokines known as **eotaxins** (eotaxin 1, 2, and 3). These unique pathways account for selective accumulation of eosinophils in allergic and inflammatory disorders. Eosinophils normally dwell primarily in tissues, especially tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal (GI), and lower genitourinary tracts. The life span of eosinophils may extend for weeks within tissues.

Interleukin (IL)-5 selectively enhances eosinophil production, adhesion to endothelial cells, and function. Considerable evidence shows that IL-5 has a pivotal role in promoting eosinophilopoiesis. It is the predominant cytokine in allergen-induced pulmonary late-phase reaction, and antibodies against IL-5 (mepolizumab, reslizumab, benralizumab) decrease sputum eosinophils and reduce exacerbations in a subset of patients with asthma. Eosinophils also bear unique receptors for several chemokines, including RANTES (regulated on activation, normal T-cell expressed and secreted), eotaxin, and monocyte chemotactic proteins 3 and 4. These chemokines appear to be key mediators in the induction of tissue eosinophilia.

DISEASES ASSOCIATED WITH EOSINOPHILIA

The **absolute eosinophil count (AEC)** is used to quantify peripheral blood eosinophilia. Calculated as the white blood cell (WBC) count/μL × percentage of eosinophils, it is usually <450 cells/μL and varies diurnally, with eosinophil numbers higher in the early morning and diminishing as endogenous glucocorticoid levels rise.

Many diseases with allergic, infectious, hematologic, autoimmune, or idiopathic origins are associated with moderate (AEC 1,500-5,000 cells/μL) or severe (AEC >5,000 cells/μL) eosinophilia in peripheral blood (Table 169.1). These disorders may range from mild and transient to chronic and life-threatening. Importantly, blood eosinophil numbers do not always reflect the extent of eosinophil involvement in tissues and degranulation products may more accurately reflect disease activity. Because prolonged eosinophilia is associated with end-organ

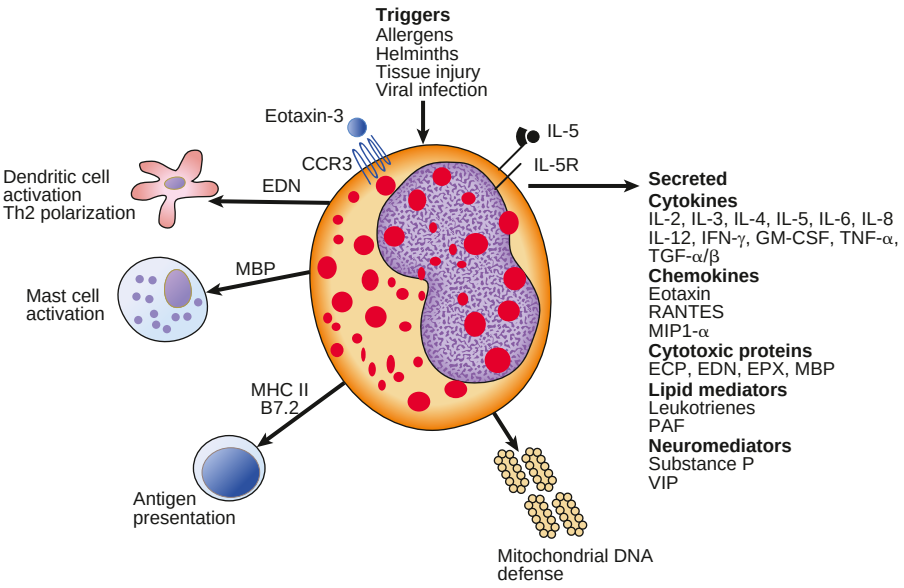

Fig. 169.1 Schematic diagram of an eosinophil and its diverse properties. Eosinophils are bilobed granulocytes that respond to diverse stimuli, including allergens, helminths, viral infections, allografts, and nonspecific tissue injury. Eosinophils express the receptor for interleukin (IL)-5, a critical eosinophil growth and differentiation factor, as well as the receptor for eotaxin and related chemokines (CCR3). The secondary granules contain four primary cationic proteins designated eosinophil peroxidase (EPX), major basic protein (MBP), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). All four proteins are cytotoxic molecules; also, ECP and EDN are ribonucleases. In addition to releasing their preformed cationic proteins, eosinophils can release a variety of cytokines, chemokines, and neuromediators and generate large amounts of leukotriene C4 (LTC4). Last, eosinophils can be induced to express major histocompatibility complex (MHC) class II and co-stimulatory molecules and may be involved in propagating immune responses by presenting antigen to T cells. PAF, platelet activating factor; VIP, vasoactive intestinal peptide. *(From Leung YM, Szefler SJ, Bomilla FA, Akdis CA, Sampson HA. Pediatric Allergy: Principles and practice. 3rd ed. Philadelphia: Elsevier; 2016. p. 42.)*

damage, especially involving the heart, patients with persistently elevated AECs should undergo a thorough evaluation to search for an underlying cause.

Allergic Diseases

Allergy is the most common cause of eosinophilia in children in the United States. Patients with allergic asthma typically have eosinophils in the blood, sputum, and/or lung tissue. **Hypersensitivity drug reactions** can elicit eosinophilia, and when associated with organ dysfunction (e.g., DRESS [drug rash with eosinophilia and systemic symptoms]), these reactions can be serious (see Chapter 193). If a drug is suspected of triggering eosinophilia, biochemical evidence of organ dysfunction should be sought, and if found, the drug should be discontinued. Various skin diseases have also been associated with eosinophilia, including atopic dermatitis/eczema, pemphigus, urticaria, and toxic epidermal necrolysis.

Eosinophilic gastrointestinal diseases (EGIDs) are important emerging allergic causes of eosinophilia in tissue and, in some cases, peripheral blood (see Chapter 383). In these conditions, eosinophils are recruited to the esophagus, stomach, and/or intestine, where they may cause tissue inflammation and clinical symptoms such as dysphagia, food aversion, abdominal pain, vomiting, or diarrhea. Eosinophilic esophagitis is the most common EGID. Treatment options include proton pump inhibitors, allergen elimination diets, topical corticosteroids, and biologics (e.g. dupilumab). Patients with nonesophageal EGIDs often require treatment with systemic steroids.

Infectious Diseases

Eosinophilia is often associated with invasive infection with multicellular helminthic parasites, which are the most common cause in developing countries. Table 169.1 includes examples of specific organisms. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion, especially by larvae such as **visceral larva migrans** (see Chapter 344). Eosinophilia often *does not* occur in established parasitic infections that are well contained within tissues or are solely intraluminal in the GI tract, such as *Giardia lamblia* and *Enterobius vermicularis* infection.

In evaluating patients with unexplained eosinophilia, the dietary history and geographic or travel history may indicate potential exposures to helminthic parasites. It is frequently necessary to examine the stool for ova and larvae at least three times. Additionally, the diagnostic parasite stages of many of the helminthic parasites that cause eosinophilia never appear in feces. Thus normal results of stool examinations do not absolutely preclude a helminthic cause of eosinophilia; diagnostic blood tests or tissue biopsy may be needed. *Toxocara* causes visceral larva migrans usually in toddlers with pica (see Chapter 344). Most young children are asymptomatic, but some develop fever, pneumonitis, hepatomegaly, and hypergammaglobulinemia accompanied by severe eosinophilia. Isohemagglutinins are frequently elevated, and serology can establish the diagnosis.

Two fungal diseases may be associated with eosinophilia: aspergillosis in the form of **allergic bronchopulmonary aspergillosis** (see Chapter 283) and **coccidioidomycosis** (see Chapter 286) following primary infection, especially in conjunction with erythema nodosum. HIV infection can also be associated with peripheral eosinophilia.

Hypereosinophilic Syndrome

The idiopathic hypereosinophilic syndrome is a heterogeneous group of disorders characterized by sustained overproduction of eosinophils. The three diagnostic criteria for this disorder are (1) AEC >1,500 cells/μL persisting for 6 months or longer or at least on two occasions or with evidence of tissue eosinophilia; (2) absence of another diagnosis to explain the eosinophilia; and (3) signs and symptoms of organ involvement. The clinical signs and symptoms of hypereosinophilic syndrome can be heterogeneous because of the diversity of potential organ (pulmonary, cutaneous, neurologic, serosal, GI) involvement. Organ-specific signs and symptoms direct the diagnostic evaluation, but common initial tests used to evaluate hypereosinophilia and potential end-organ complications include a comprehensive metabolic panel, inflammatory markers, troponin level, urinalysis, antineutrophil cytoplasmic antibodies, immunoglobulin levels, vitamin B_{12} level, tryptase level, stool examination for ova and parasites, parasite serologies, HIV testing, and a chest x-ray. Eosinophilic endomyocardial disease, one of the most serious and life-threatening complications, can cause heart failure from endomyocardial thrombosis and fibrosis. Screening for cardiac involvement should also include an electrocardiogram, an echocardiogram, and in some cases a cardiac MRI. Evaluation of the hypereosinophilic syndrome requires morphologic review of the blood and marrow, cytogenetics, fluorescence in situ hybridization, immunophenotyping by flow cytometry, and T-cell clonality assessment to detect histopathologic or clonal evidence for hematolymphoid neoplasm. Eosinophilic leukemia, a clonal myeloproliferative variant, may be distinguished from idiopathic hypereosinophilic syndrome

Table 169.1 Causes of Eosinophilia

ALLERGIC DISORDERS
- Allergic rhinitis
- Asthma
- Acute and chronic urticaria
- Atopic dermatitis
- Angioedema
- Hypersensitivity drug reactions (drug rash with eosinophilia and systemic symptoms [DRESS])
- Eosinophilic gastrointestinal disorders
- Interstitial nephritis
- Mastocytosis

INFECTIOUS DISEASES

Tissue-Invasive Helminth Infections and Other Infections
- Trichinosis
- Toxocariasis
- Strongyloidiasis
- Ascariasis
- Filariasis
- Schistosomiasis
- Echinococcosis
- Amebiasis
- Malaria
- Scabies
- Toxoplasmosis
- *Pneumocystis jirovecii*
- Scarlet fever
- Allergic bronchopulmonary aspergillosis (ABPA)
- Coccidioidomycosis
- Human immunodeficiency virus (HIV)

MALIGNANT DISORDERS
- Hodgkin disease and T-cell lymphoma
- Acute myelogenous leukemia
- Myeloproliferative disorders
- Eosinophilic leukemia
- Brain tumors

GASTROINTESTINAL DISORDERS
- Inflammatory bowel disease
- Peritoneal dialysis
- Chronic active hepatitis

Eosinophilic Gastrointestinal Disorders
- Eosinophilic esophagitis
- Eosinophilic gastritis
- Eosinophilic enteritis
- Eosinophilic colitis

RHEUMATOLOGIC DISEASE
- Rheumatoid arthritis
- Eosinophilic fasciitis
- Scleroderma
- Dermatomyositis
- Systemic lupus erythematosus
- IgG4-related disease
- Eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis)

IMMUNODEFICIENCY/IMMUNE DYSREGULATION DISEASE
- Hyperimmunoglobulin E syndromes
- Wiskott-Aldrich syndrome
- Graft-versus-host disease
- Omenn syndrome
- Severe congenital neutropenia
- Autoimmune lymphoproliferative syndromes (ALPS)
- Immune dysregulation, polyendocrinopathy, X-linked (IPEX) and IPEX-like syndrome
- Transplant rejection (solid organ)

MISCELLANEOUS
- Thrombocytopenia with absent radii
- Hypersensitivity pneumonitis
- Adrenal insufficiency
- Postirradiation of abdomen
- Histiocytosis with cutaneous involvement
- Hypereosinophilic syndromes
- Cytokine infusion
- Pemphigoid

by demonstrating a clonal interstitial deletion on chromosome 4q12 that fuses the platelet-derived growth factor receptor-α *(PDGFRA)* and FIP1-like-1 *(FIP1L1)* genes; this disorder is treated with imatinib mesylate, a tyrosine kinase inhibitor, which helps target the fusion oncoprotein (Fig. 169.2).

Therapy is aimed at suppressing eosinophilia and is initiated with corticosteroids. Patients with possible exposure to *Strongyloides* should receive concomitant empiric treatment with ivermectin to prevent corticosteroid-associated hyperinfection syndrome. Imatinib mesylate may be effective in FIP1L1-PDGFRA–negative patients. Hydroxyurea or interferon-alfa may be beneficial in patients unresponsive to corticosteroids. Specific anti–IL-5 monoclonal antibodies (mepolizumab) target this cytokine, which has a central role in eosinophil differentiation, mobilization, and activity. With therapy, the eosinophil count declines and corticosteroid doses may be reduced. For patients with prominent organ involvement who fail to respond to therapy, the mortality is about 75% after 3 years.

Miscellaneous Diseases

Eosinophilia is observed in many patients with primary immunodeficiency syndromes, especially hyper-IgE syndrome, Wiskott-Aldrich syndrome, and Omenn syndrome (see Chapter 165). Eosinophilia is also frequently present in the syndrome of thrombocytopenia with absent radii and in familial reticuloendotheliosis with eosinophilia. Eosinophilia can be found in patients with Hodgkin disease, as well as in acute lymphoid and myeloid leukemia. Other considerations include GI disorders such as ulcerative colitis, Crohn disease during symptomatic phases, chronic hepatitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis), mastocytosis, and adrenal insufficiency.

Chapter 170

Disorders of Phagocyte Function

Thomas D. Coates

Neutrophils are the first line of defense against microbial invasion. They arrive at the site of inflammation during the critical 2-4 hours after microbial invasion to contain the infection and prevent hematogenous dissemination. Much of our knowledge about neutrophil function derives from studies done in patients with genetic errors in neutrophil function. These critical functions and their associated disorders are depicted in Figure 168.2. Children with phagocytic dysfunction present at a young age with recurrent infections that often involve unusual organisms and are poorly responsive to treatment.

Primary defects of phagocytic function comprise <20% of immunodeficiencies, and there is significant overlap in the presenting signs and symptoms between phagocytic disorders and lymphocyte and humeral disorders. Children with phagocytic defects present with deep tissue infection, pneumonia, adenitis, cutaneous lesions, or osteomyelitis rather than bloodstream infections (Tables 170.1 and 170.2; Fig. 170.1). In the past, diagnosis of these disorders relied on very specialized biologic assays. Because the genes for most of these disorders have been identified, the first step in diagnosis for all of these disorders is to obtain DNA analysis through commercially available genetic panels for immunodeficiency.

Chemotaxis, the direct migration of cells into sites of infection, involves a complex series of events (see Chapter 168). Disorders of adhesion or granule abnormalities can have intermediate or profound motility defects, and the propensity to infections is related to a combination of these functional deficits. One family with recessively inherited neutrophil actin dysfunction demonstrated that a pure severe chemotactic defect can result in fatal recurrent infection. Defective in vitro chemotaxis of neutrophils can be detected in children with various clinical conditions. However, unless chemotaxis is essentially absent, it is difficult to establish whether frequent infections arise from a primary chemotactic abnormality or occur as secondary medical complications of the underlying disorder. Dental infection with *Capnocytophaga* is associated with a clear neutrophil motility defect that resolves when the infection is eliminated.

Motility defects present with significant skin and mucosal infections. Tender cutaneous nodular lesions may also be present and characteristically do not contain neutrophils. In fact, the presence of a true abscess makes the diagnosis of a significant chemotactic defect less likely.

Laboratory tests of chemotaxis are biologic assays and have high variability except in the most experienced hands. The assays must be done on freshly obtained blood and are affected by many factors related to the blood sampling. It is best to assay other features of the suspected disorder, such as surface marker expression, to establish a specific diagnosis.

Table 170.1 Infections and White Blood Cell Defects: Features That Can Be Seen in Phagocyte Disorders

SEVERE INFECTIONS		RECURRENT INFECTIONS		SPECIFIC INFECTIONS		UNUSUALLY LOCATED INFECTIONS	
TYPE OF INFECTION	**DIAGNOSIS TO CONSIDER**	**SITE OF INFECTION**	**DIAGNOSIS TO CONSIDER**	**MICRO-ORGANISM**	**DIAGNOSIS TO CONSIDER**	**SITE OF INFECTION**	**DIAGNOSIS TO CONSIDER**
Cellulitis	Neutropenia, LAD, CGD, HIES	Cutaneous	Neutropenia, CGD, LAD, HIES	*Staphylococcus epidermidis*	Neutropenia, LAD	Umbilical cord	LAD
Colitis	Neutropenia, CGD	Gums	LAD, neutrophil motility disorders	*Serratia marcescens, Nocardia, Burkholderia cepacia*	CGD	Liver abscess	CGD
Osteomyelitis	CGD, MSMD pathway defects	Upper and lower respiratory tract	Neutropenia, HIES, functional neutrophil disorders	*Aspergillus*	Neutropenia, CGD, HIES	Gums	LAD, neutrophil motility disorders
		Gastrointestinal tract	CGD, MSMD pathway defects (salmonella)	Nontuberculous mycobacteria, BCG	MSMD pathway defects, SCID, CGD		
		Lymph nodes	CGD, MSMD pathway defects (mycobacteria)	*Candida*	Neutropenia, CGD, MPO		
		Osteomyelitis	CGD, MSMD				

BCG, Bacille Calmette-Guérin; CGD, chronic granulomatous disease; HIES, hyper-IgE syndrome; LAD, leukocyte adhesion deficiency; MPO, myeloperoxidase; MSMD, mendelian susceptibility to mycobacterial disease; SCID, severe combined immunodeficiency.

Table 170.2 Clinical Disorders of Neutrophil Function

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
DEGRANULATION ABNORMALITIES			
Chédiak-Higashi syndrome (CHS)	Autosomal recessive; disordered coalescence of lysosomal granules; responsible gene is *CHSI/LYST*, which encodes a protein hypothesized to regulate granule fusion	Decreased neutrophil chemotaxis, degranulation, and bactericidal activity; platelet storage pool defect; impaired NK function, failure to disperse melanosomes	Neutropenia; recurrent pyogenic infections; propensity to develop marked hepatosplenomegaly as a manifestation of hemophagocytic syndrome
Specific granule deficiency	Autosomal recessive; functional loss of myeloid transcription factor arising from a pathogenic variant or arising from reduced expression of *Gfi-1* or *C/EBPε*, which regulates specific granule formation	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; defensins, gelatinase, collagenase, vitamin B_{12}–binding protein, and lactoferrin	Recurrent deep-seated abscesses
ADHESION ABNORMALITIES			
Leukocyte adhesion deficiency 1 (LAD-1)	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoproteins (β_2-integrins) on leukocyte membranes most commonly arising from failure to express CD18 messenger RNA	Decreased binding of iC3b to neutrophils and impaired adhesion to ICAM-1 and ICAM-2	Neutrophilia; recurrent bacterial infection associated with a lack of pus formation
Leukocyte adhesion deficiency 2 (LAD-2)	Autosomal recessive; loss of fucosylation of ligands for selectins and other glycol conjugates arising from pathogenic variants of GDP-fucose transporter	Decreased adhesion to activated endothelium expressing ELAM	Neutrophilia; recurrent bacterial infection without pus
Leukocyte adhesion deficiency 3 (LAD-1 variant syndrome)	Autosomal recessive; impaired integrin function arising from pathogenic variants of *FERMT3*, which encodes kindlin-3 in hematopoietic cells; kindlin-3 binds to β-integrin and thereby transmits integrin activation	Impaired neutrophil adhesion and platelet activation	Neutrophilia, recurrent infections, bleeding tendency

Continued

Table 170.2 Clinical Disorders of Neutrophil Function—cont'd

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
DISORDERS OF CELL MOTILITY			
Enhanced motile responses; FMF	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called pyrin; pyrin regulates caspase-1 and thereby IL-1β secretion; mutated pyrin may lead to heightened sensitivity to endotoxin, excessive IL-1β production, and impaired monocyte apoptosis	Excessive accumulation of neutrophils at inflamed sites, possibly the result of excessive IL-1β production	Recurrent fever, peritonitis, pleuritis, arthritis, amyloidosis
DEPRESSED MOTILE RESPONSES			
Defects in the generation of chemotactic signals	IgG deficiencies; C3 and properdin deficiency can arise from genetic or acquired abnormalities; mannose-binding protein deficiency predominantly in neonates	Deficiency of serum chemotaxis and opsonic activities	Recurrent pyogenic infections
Intrinsic defects of the neutrophil, e.g., LAD, CHS, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils	In the neonatal neutrophil there is diminished ability to express β_2-integrins, and there is a qualitative impairment in β_2-integrin function	Diminished chemotaxis	Propensity to develop pyogenic infections
Direct inhibition of neutrophil mobility, e.g., drugs	Ethanol, glucocorticoids, cyclic AMP	Impaired locomotion and ingestion; impaired adherence	Possible cause for frequent infections; neutrophilia seen with epinephrine arises from cyclic AMP release from endothelium
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory states	Impaired chemotaxis	Recurrent pyogenic infections
Hyper-IgE syndrome	Autosomal dominant; responsible gene is *STAT3*	Impaired chemotaxis at times; impaired regulation of cytokine production	Recurrent skin and sinopulmonary infections, eczema, mucocutaneous candidiasis, eosinophilia, retained primary teeth, minimal trauma fractures, scoliosis, and characteristic facies
Hyper-IgE syndrome–AR	Autosomal recessive; more than one gene likely contributes to its etiology	High IgE levels, impaired lymphocyte activation to staphylococcal antigens	Recurrent pneumonia without pneumatoceles sepsis, enzyme, boils, mucocutaneous candidiasis, neurologic symptoms, eosinophilia
MICROBICIDAL ACTIVITY			
Chronic granulomatous disease (CGD)	X-linked and AR; failure to express functional $gp91^{phox}$ in the phagocyte membrane in $p22^{phox}$ (AR) Other AR forms of CGD arise from failure to express protein $p47^{phox}$ or $p67^{phox}$	Failure to activate neutrophil respiratory burst, leading to failure to kill catalase-positive microbes	Recurrent pyogenic infections with catalase-positive microorganisms
G6PD deficiency	<5% of normal activity of G6PD	Failure to activate NADPH-dependent oxidase; hemolytic anemia	Infections with catalase-positive microorganisms
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense variant	H_2O_2-dependent antimicrobial activity not potentiated by myeloperoxidase	None
Rac2 deficiency	Autosomal dominant; dominant negative inhibition by variant protein of Rac2-mediated functions	Failure of membrane receptor–mediated O_2^- generation and chemotaxis	Neutrophilia, recurrent bacterial infections
Deficiencies of glutathione reductase and glutathione synthetase	AR; failure to detoxify H_2O_2	Excessive formation of H_2O_2	Minimal problems with recurrent pyogenic infections

AMP, Adenosine monophosphate; AR, autosomal recessive; C, complement; CD, cluster of differentiation; ELAM, endothelial-leukocyte adhesion molecule; FMF, familial Mediterranean fever; G6PD, glucose-6-phosphate dehydrogenase; GDP, guanosine diphosphate; ICAM, intracellular adhesion molecule; IL-1, interleukin-1; NADPH, nicotinamide adenine dinucleotide phosphate; NK, natural killer.

LEUKOCYTE ADHESION DEFICIENCY

Leukocyte adhesion deficiency types 1 (LAD-1), 2 (LAD-2), and 3 (LAD-3) are rare autosomal recessive disorders of leukocyte function. LAD-1 affects about 1 per 10 million individuals and is characterized by recurrent bacterial and fungal infections and depressed inflammatory responses despite striking blood neutrophilia (Table 170.3).

Genetics and Pathogenesis

LAD-1 results from pathogenic variants of the gene on chromosome 21q22.3 encoding CD18, the 95-kDa β_2-leukocyte transmembrane integrin subunit. Normal neutrophils express four heterodimeric adhesion molecules: LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18, also known as CR3 or iC3b receptor), p150,95 (CD11c/CD18), and $\alpha_{1\beta2}$ (CD11d/CD18). These four transmembrane adhesion molecules are composed of unique extracellular α_1 encoded on chromosome 16, and they share a common β_2 subunit (CD18) that links them to the membrane and connects them to intracellular signal transduction machinery. This group of leukocyte integrins is responsible for the tight adhesion of neutrophils to the endothelial cell surface, egress from the circulation, and adhesion to iC3b-coated microorganisms, which promotes phagocytosis and particulate activation of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Some pathogenic variants of CD11/CD18 allow a low level of assembly and activity of integrin molecules, resulting in retention of some neutrophil integrin adhesion function and a moderate phenotype.

Because of their inability to adhere firmly to intercellular adhesion molecules 1 (ICAM-1) and 2 (ICAM-2) expressed on inflamed endothelial cells (see Chapter 168), neutrophils cannot transmigrate through the vessel wall and move to the site infection. Furthermore, neutrophils that do arrive at inflammatory sites fail to recognize microorganisms opsonized with complement fragment **iC3b**, an important stable opsonin formed by the cleavage of C3b. Therefore other neutrophil functions such as degranulation and oxidative metabolism normally triggered by iC3b binding are also greatly compromised in LAD-1 neutrophils, resulting in impaired phagocytic function and high risk for serious and recurrent bacterial infections.

Monocyte function is also impaired, with poor fibrinogen-binding function, an activity that is promoted by the CD11/CD18 complex. Consequently, such cells are unable to participate effectively in wound healing.

Children with **LAD-2** share the clinical features of LAD-1 but have normal CD11/CD18 integrins. Features unique to LAD-2 include neurologic defects, cranial facial dysmorphism, and absence of the erythrocyte ABO blood group antigen (**Bombay** phenotype). LAD-2 (also known as **congenital disorder of glycosylation IIc (CDG-IIc)** derives from pathogenic variants in the gene encoding a specific guanosine diphosphate (GDP)-L-fucose transporter of the Golgi apparatus. This abnormality prevents the incorporation of fucose into various cell surface glycoproteins, including the carbohydrate structure sialyl Lewis X that is critical for low-affinity rolling adhesion of neutrophils to vascular endothelium. This is an important initial step necessary for subsequent integrin-mediated activation, spreading, and transendothelial migration. Infections in LAD-2 are milder than that in LAD-1.

LAD-3 is characterized by a **Glanzmann thrombasthenia–like** bleeding disorder, delayed separation of the umbilical cord, and serious skin and soft tissue infections similar to those seen in LAD-1, and failure of leukocytes to undergo β_2- and β_1-integrin–mediated adhesion and migration. Pathogenic variants in *KINDLIN3* affect integrin activation.

Clinical Manifestations

Patients with the severe clinical form of LAD-1 express <0.3% of the normal amount of the β_2-integrin molecules, whereas patients with the moderate phenotype may express 2–7% of the normal amount. Children with severe forms of LAD present in infancy with recurrent, indolent bacterial infections of the skin, mouth, respiratory tract, lower intestinal tract, and genital mucosa. Significant neutrophilic leukocytosis, often >25,0000/mm^3, is a prominent feature. They may have a history of delayed separation of the umbilical cord, usually with associated infection of the cord stump. The presence of significant omphalitis is an important feature that distinguishes these rare patients from the 10% of healthy infants who can have cord separation at age 3 weeks or later. Skin infection may progress to large chronic ulcers with polymicrobial infection, including anaerobic organisms (Fig. 170.2). The ulcers heal slowly, need months of antibiotic treatment, and often require plastic surgery grafting. Severe gingivitis can lead to early loss of primary and secondary teeth (Fig. 170.3). Infected areas characteristically have very little neutrophilic infiltration (absent pus).

The pathogens infecting patients with LAD-1 are similar to those affecting patients with severe neutropenia (see Chapter 171) and

Table 170.3 Leukocyte Adhesion Deficiency Syndromes

LEUKOCYTE ADHESION DEFICIENCY (LAD)	TYPE 1 (LAD-1)	TYPE 2 (LAD-2 OR CDG-IIc)	TYPE 3 (LAD-3)	E-SELECTIN DEFICIENCY	Rac2 DEFICIENCY
OMIM	116920	266265	612840	131210	602049
Inheritance pattern	Autosomal recessive	Autosomal recessive	Autosomal recessive	Unknown	Autosomal dominant
Affected protein(s)	β_2-Integrin common chain (CD18)	Fucosylated proteins (e.g., sialyl-Lewis X, CD15s)	Kindlin 3	Endothelial E-selectin expression	Rac2
Neutrophil function affected	Chemotaxis, tight adherence	Rolling, tethering	Chemotaxis, adhesion, superoxide production	Rolling, tethering	Chemotaxis, superoxide production
Delayed umbilical cord separation	Yes (severe phenotype only)	Yes	Yes	Yes	Yes
Leukocytosis/neutrophilia	Yes	Yes	Yes	No (mild neutropenia)	Yes

Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation. *Enterococcus gallinarium* was cultured from the wound. *(From Rich RR. Clinical Immunology:* Principles and Practice. *4th ed. Philadelphia: Saunders; 2013, p. 273.)*

Fig. 170.3 Oral pathology in a patient with leukocyte adhesion deficiency type 1 (LAD-1). Gingivitis and severe periodontitis are hallmarks of LAD-1. *(From Rich RR.* Clinical Immunology: Principles and Practice. *4th ed. Philadelphia: Saunders; 2013, p. 273.)*

include *Staphylococcus aureus* and enteric gram-negative organisms such as *Escherichia coli.* These patients are also susceptible to opportunistic infection by fungi such as *Candida* and *Aspergillus.* Typical signs of inflammation, such as swelling, erythema, and warmth, may be absent. Pus does not form, and few neutrophils are identified microscopically in biopsy specimens of infected tissues. Despite the paucity of neutrophils within the affected tissue, the circulating neutrophil count during infection typically exceeds 30,000/μL and can surpass 100,000/μL. During intervals between infections, the peripheral blood neutrophil count may chronically exceed 12,000/μL. LAD-1 genotypes with only moderate, rather than absent, amounts of functional integrins at the surface of the neutrophil have significantly reduced severity and frequency of infections compared with children with the severe form, although gingival disease is still a prominent feature.

Laboratory Findings

The diagnosis of LAD-1 is established most readily by flow cytometric measurements of surface CD11b/CD18 in stimulated and unstimulated neutrophils. Neutrophil and monocyte adherence, aggregation, chemotaxis, and iC3b-mediated phagocytosis demonstrate striking abnormalities. However, these assays are not clinically available. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis, although some patients have impaired T-lymphocyte–dependent antibody responses. The diagnosis of LAD-2 is established by flow cytometric measurement of sialyl Lewis X (CD15) on neutrophils. It is important to note that the flow cytometric assays are not done the same as the more common lymphocyte subset analysis and require specialized approaches to detect levels of surface expression, especially to detect milder phenotypes.

Treatment

Treatment of LAD-1 depends on the phenotype, as determined by the level of expression of functional CD11/CD18 integrins. Early allogeneic hematopoietic stem cell transplantation (HSCT) is the treatment of choice for severe LAD-1 (and LAD-3). One patient was successfully treated with ustekinumab, an inhibitor of interleukins 12 and 23. Other treatment is largely supportive. Patients can be maintained on prophylactic trimethoprim/sulfamethoxazole (TMP/SMX) and should have close surveillance for early identification of infections and initiation of empirical treatment with broad-spectrum antibiotics. Specific determination of the etiologic agent by culture or biopsy is important because of the prolonged antibiotic treatment required in the absence of neutrophil function.

Some LAD-2 patients have responded to fucose supplementation, which induced a rapid reduction in the circulating leukocyte count and appearance of the sialyl Lewis X molecules, accompanied by marked improvement in leukocyte adhesion.

Prognosis

The severity of infectious complications correlates with the degree of β_2-integrin deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe life-threatening systemic infections. Patients with moderate deficiency have infrequent life-threatening infections and relatively long survival.

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by increased susceptibility to infection caused by defective degranulation of neutrophils, a mild bleeding diathesis, partial oculocutaneous albinism, progressive peripheral neuropathy, and a tendency to develop a life-threatening form of **hemophagocytic lymphohistiocytosis** (see Chapter 556.2). CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. Pigmentary dilution involving the hair, skin, and ocular fundi results from pathologic aggregation of melanosomes. Neurologic deficits are associated with a failure of decussation of the optic and auditory nerves. Patients exhibit an increased susceptibility to infection that can be explained only in part by defects in neutrophil function. The patients have progressive neutropenia as well as abnormalities in natural killer (NK) function, again related to granule dysfunction.

Genetics and Pathogenesis

LYST (for lysosomal traffic regulator), the gene variant in CHS, is located at chromosome 1q2-q44. The LYST/CHS protein is thought to regulate vesicle transport by mediating protein-protein interaction and protein-membrane associations. Loss of function may lead to indiscriminate interactions with lysosomal surface proteins, yielding giant granules through uncontrolled fusion of lysosomes with each other.

Almost all cells of patients with CHS show some oversized and dysmorphic lysosomes, storage granules, or related vesicular structures. Melanosomes are oversized, and delivery to the keratinocytes and hair follicles is compromised, resulting in hair shafts devoid of pigment granules. This abnormality in melanosomes leads to the macroscopic impression of hair and skin that is lighter than expected from parental coloration. The same abnormality in melanocytes leads to the partial ocular albinism associated with light sensitivity.

Beginning early in neutrophil development, spontaneous fusion of giant primary granules with each other or with cytoplasmic membrane components results in huge secondary lysosomes with reduced contents of hydrolytic enzymes, including proteinases, elastase, and cathepsin G. This deficiency of proteolytic enzymes may be responsible for the impaired killing of microorganisms by CHS neutrophils.

Clinical Manifestations

Patients with CHS have light skin and silvery hair and frequently complain of solar sensitivity and photophobia that is associated with rotary nystagmus. Other signs and symptoms vary considerably, but frequent infections and neuropathy are common. The infections involve mucous membranes, skin, and respiratory tract. Affected children are susceptible to gram-positive bacteria, gram-negative bacteria, and fungi, with *S. aureus* being the most common offending organism. The **neuropathy** may be sensory or motor in type, and ataxia may be a prominent feature. Neuropathy often begins in the teenage years and becomes the most prominent problem.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting from impaired platelet aggregation associated with a deficiency of the dense granules containing adenosine diphosphate and serotonin.

The most life-threatening complication of CHS is the development of an accelerated phase characterized by pancytopenia, high fever, and lymphohistiocytic infiltration of liver, spleen, and lymph nodes. The onset of the accelerated phase, which can occur at any age, is now recognized to be a genetic form of hemophagocytic lymphohistiocytosis. This occurs in 85% of patients and usually results in death.

Laboratory Findings

The diagnosis of CHS is established by finding large inclusions in all nucleated blood cells. These can be seen on Wright-stained blood films and are accentuated by a peroxidase stain. Because of impaired egress from the bone marrow, cells containing the large inclusions may be missed on peripheral blood smear but readily identified on bone marrow examination. The patients have progressive neutropenia and abnormal platelet, neutrophil, and NK function.

Treatment

High-dose ascorbic acid (200 mg/day for infants; 2,000 mg/day for adults) may improve the clinical status of some children in the stable phase. Although controversy surrounds the efficacy of ascorbic acid, given the safety of the vitamin, it is reasonable to administer ascorbic acid to all patients.

The only curative therapy to prevent the accelerated phase is HSCT. Normal stem cells reconstitute hematopoietic and immunologic function, correct the NK cell deficiency, and prevent conversion to the accelerated phase, but cannot correct or prevent the neuropathy. If the patient is in the accelerated phase with active hemophagocytic lymphohistiocytosis, HSCT often fails to prevent death. While HSCT can cure the neutrophil defect and hemophagocytic lymphohistiocytosis, it does nothing for neurologic complications.

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase (MPO) deficiency is an autosomal recessive disorder of oxidative metabolism and is one of the most common inherited disorders of phagocytes, occurring at a frequency approaching 1 per 2,000 individuals. MPO is a green heme protein located in the azurophilic lysosomes of neutrophils and monocytes and is the basis for the greenish tinge to pus accumulated at a site of infection.

Clinical Manifestations

MPO deficiency is usually clinically silent. Rarely, patients may have disseminated candidiasis, usually in conjunction with diabetes mellitus. Acquired partial MPO deficiency can develop in acute myelogenous leukemia and in myelodysplastic syndromes.

Laboratory Findings

Deficiency of neutrophil and monocyte MPO can be identified by histochemical analysis. Severe MPO deficiency can cause the dihydrorhodamine (DHR) flow cytometric assay for chronic granulomatous disease (CGD) to be falsely positive. Unlike CGD, eosinophils in severe MPO deficiency will still reduce DHR and yield a normal reaction.

Treatment

There is no specific therapy for MPO deficiency. Aggressive treatment with antifungal agents should be provided for candidal infections. The prognosis is usually excellent.

CHRONIC GRANULOMATOUS DISEASE

CGD is characterized by neutrophils and monocytes capable of normal chemotaxis, ingestion, and degranulation, but unable to kill **catalase-positive microorganisms** because of a defect in the generation of microbicidal oxygen metabolites. CGD is a rare disease, affecting 4-5 per 1 million individuals; it is caused by four genes: one X-linked and three autosomal recessive inheritance (Table 170.4).

Genetics and Pathogenesis

Activation of the phagocyte NADPH oxidase requires stimulation of the neutrophils and involves assembly from cytoplasmic and integral membrane subunits (see Fig. 168.3). Oxidase activation initiates with phosphorylation of a cationic cytoplasmic protein, $p47^{phox}$ (47-kDa phagocyte oxidase protein). Phosphorylated $p47^{phox}$, together with two other cytoplasmic components of the oxidase, $p67^{phox}$ and the low-molecular-weight guanosine triphosphatase Rac2, translocates to the membrane, where they combine with the cytoplasmic domains of the transmembrane flavocytochrome b_{558} to form the active oxidase complex. The flavocytochrome is a heterodimer composed of $p22^{phox}$ and highly glycosylated $gp91^{phox}$. The

Table 170.4 Classification of Chronic Granulomatous Disease

COMPONENT AFFECTED	INHERITANCE	SUBTYPE*	FLAVOCYTOCHROME b SPECTRUM	NBT SCORE (% POSITIVE)	INCIDENCE (% OF CASES)
gp91^{phox}	X	X91^{0}	0	0	60
		X91^{-}	Low	80-100 (weak)	5
		X91^{-}	Low	5-10	<1
		X91^{+}	0	0	1
p22^{phox}	A	A220	0	0	4
		A22^{+}	N	0	<1
p47^{phox}	A	A470	N	0†	25
p67^{phox}	A	A670	N	0	5
		A67^{+}	N	0	<1
p40^{phox}	A	A40^{-}	N	100	<1

*In this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]), whereas the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (^{0}), diminished ($^{-}$), or normal ($^{+}$), as measured by immunoblot analysis.

†Can be weakly positive.

NBT, Nitroblue tetrazolium.

From Dinauer MC, Newburger PE, Borregaard N. Phagocyte system and disorders of granulopoiesis and granulocyte function. In: Orkin SH, Fisher DE, Ginsburg D, et al., eds. *Nathan and Oski's Hematology and Oncology of Infancy and Childhood.* 8th ed. Philadelphia: Elsevier; 2015. Table 22.12, p. 833.

gp91^{phox} glycoprotein catalyzes electron transport through its NADPH-binding, flavin-binding, and heme-binding domains. Defects in any of these NADPH oxidase components can lead to CGD.

Approximately 65% of patients with CGD are males who inherit their disorder as a result of pathogenic variants in *CYBB*, an X-chromosome gene encoding gp91^{phox}. Approximately 35% of patients inherit CGD in an autosomal recessive fashion resulting from pathogenic variants in the *NCF1* gene on chromosome 7, encoding p47^{phox}. Defects in the genes encoding p67^{phox} (*NCF2* on chromosome 1) and p22^{phox} (*CYBA* on chromosome 16) are inherited in an autosomal recessive manner and account for approximately 5% of cases of CGD.

The CGD phagocytic vacuoles lack microbicidal reactive oxygen species and remain acidic, so bacteria are not killed or digested properly (Fig. 170.4). Hematoxylin-eosin–stained sections from patients' tissues show multiple granulomas that give CGD its descriptive name.

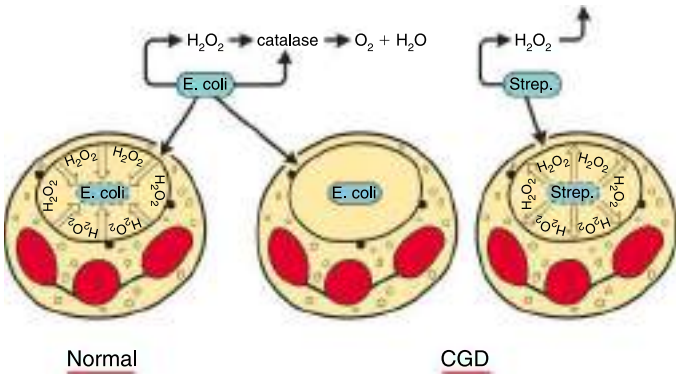

Fig. 170.4 Pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils stimulate hydrogen peroxide (H_2O_2) in the phagosome containing ingested *Escherichia coli*. Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the *closed circles*. In this setting, H_2O_2 acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines that kill the microbes. The quantity of H_2O_2 produced by the normal neutrophil is sufficient to exceed the capacity of catalase, an H_2O_2-catabolizing enzyme of many aerobic microorganisms, including *Staphylococcus aureus,* most gram-negative enteric bacteria, *Candida albicans,* and *Aspergillus.* When organisms such as *E. coli* gain entry into CGD neutrophils, they are not exposed to H_2O_2 because the neutrophils do not produce it, and the H_2O_2 generated by microorganisms themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci, which lack catalase, the organisms generate enough H_2O_2 to result in a microbicidal effect. As indicated *(middle),* catalase-positive microbes such as *E. coli* can survive within the phagosome of the CGD neutrophil. *(Adapted from Boxer LA. Quantitative abnormalities of granulocytes. In: Beutler E, Lichtman MA, Coller BS, et al., eds.* Williams Hematology. *6th ed. New York: McGraw-Hill; 2001. p. 845.)*

Clinical Manifestations

Although the clinical presentation is variable, several features suggest the diagnosis of CGD. These include any patient with *recurrent* pneumonia, lymphadenitis, hepatic, subcutaneous, or other abscesses, osteomyelitis at multiple sites, family history of recurrent infections, or any infection with an unusual catalase-positive organism requires evaluation (Fig. 170.5). Other clinical features include chronic colitis or enteritis, gastric outlet or ureteral obstruction from granulomas, or bloodstream infection caused by *Salmonella*, *Burkholderia cepacia,* or *Candida*.

The onset of clinical signs and symptoms usually occurs in early infancy, although a few patients with very rare CGD subtypes have presented later in life. The attack rate and severity of infections are exceedingly variable; however, the infection incidence decreases in the second decade, coincident with maturation of the lymphocyte and humoral immunity. The most common pathogen is *S. aureus,* but any catalase-positive microorganism may be involved. Other organisms frequently causing infections include *Serratia marcescens, B. cepacia, Aspergillus, Candida albicans, Nocardia,* and *Salmonella.* There may also be increased susceptibility to mycobacteria, including the bacille Calmette-Guérin vaccine. Pneumonia, lymphadenitis, osteomyelitis, and skin infections are the most common illnesses encountered. Bacteremia or fungemia occurs but is much less common than focal infections and usually only occurs when local infections have been inappropriately treated for long periods. Patients may have sequelae of chronic infection, including anemia of chronic disease, poor growth, lymphadenopathy, hepatosplenomegaly, chronic purulent dermatitis, restrictive lung disease, gingivitis, hydronephrosis, esophageal dysmotility, and pyloric outlet narrowing. Perirectal abscesses and recurrent skin infections, including folliculitis, cutaneous granulomas, and discoid lupus erythematosus, also suggest CGD.

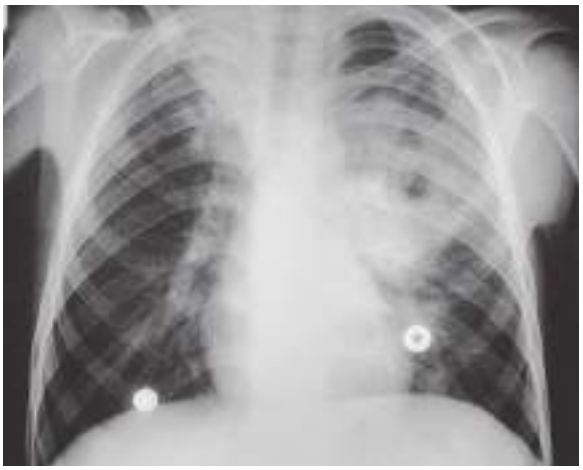

Fig. 170.5 Chest radiograph of a 10-year-old boy with chronic granulomatous disease shows a left-sided pulmonary infiltrate and cavitary lung lesion. Biopsy revealed an *Aspergillus fumigatus* infection. *(From Chinn IK, Chinen J, Shearer WT. Primary immunodeficiency diseases. In Cherry JD, Harrison GJ, Kaplan SL, et al., eds.* Feigin and Cherry's Textbook of Pediatric Infectious Diseases. *8th ed. Philadelphia: Elsevier; 2019. Fig. 67.6, p. 652.)*

Granuloma formation and inflammatory processes are a hallmark of CGD and may be the presenting symptoms that prompt testing for CGD if they cause pyloric outlet obstruction, bladder outlet or ureter obstruction, or rectal fistulas and granulomatous colitis simulating Crohn disease. More than 80% of CGD patients have positive serology for Crohn disease. Persistent fever, especially with splenomegaly and cytopenia, warrants an evaluation for secondary macrophage activation syndrome. This has been seen in CGD and may require treatment with corticosteroids and discontinuation of interferon-γ treatment.

Laboratory Findings

The diagnosis is most often made by performing flow cytometry using DHR to measure oxidant production through its increased fluorescence when oxidized by hydrogen peroxide (H_2O_2). The nitroblue tetrazolium dye test is frequently cited in the literature but is only rarely used clinically. The X-linked carrier state is usually easily diagnosed in the mother by DHR fluorescence through a bimodal response to stimulation. It is important to test the mother as some extremely lyonized carriers with <5% positive cells may have chronic clinical problems as well. Ideally, at least the first patient in a kindred should have DNA analysis to facilitate prenatal diagnosis and for genetic counseling purposes.

A few individuals have been described with apparent CGD caused by severe glucose-6-phosphate dehydrogenase deficiency, leading to insufficient NADPH substrate for the phagocyte oxidase. The erythrocytes of these patients also lack the enzyme, leading to chronic hemolysis.

Treatment

HSCT is the only known cure for CGD, although gene therapy has been transiently successful in a few patients and is the topic of active research. HSCT transplant for all patients with CGD is strongly recommended if a suitable sibling or unrelated donor can be identified. The long-term outcome for survival late into adulthood is not good, even in the hands of experienced CGD physicians. Curative therapy at an early age is strongly recommended by many experts.

Patients with CGD should be given daily oral TMP/SMX because it reduces the number of bacterial infections. A placebo-controlled study found that interferon-γ 50 μg/m^2 three times per week significantly reduces the number of hospitalizations and serious infections, although the mechanism of action is unclear. Itraconazole (200 mg/day for patients weighing >50 kg and 100 mg/day for patients <50 kg and ≤5 years old) administered prophylactically reduces the frequency of fungal infections.

Management of infection is dramatically different than in normal children. CGD patients are always at risk for deep-seated, indolent bacterial infections that can become widespread if not treated properly. They also develop the same kinds of infections that occur in normal children, so determination of the appropriate treatment can be difficult. The ESR can be quite helpful. If the child does not have a deep-seated infection, the ESR will be normal or will normalize within several days with standard management. If it does not, however, a search for deep tissues is warranted, as is consideration of empirical antibiotics. Cultures should be obtained, but are usually negative. Because all neutrophil functions in CGD except killing are normal, there is often an exuberant inflammatory reaction to a very small number of organisms. Thus blood cultures and direct cultures of biopsy samples are usually negative unless there are many organisms. Most abscesses require surgical drainage for therapeutic and diagnostic purposes. Prolonged use of antibiotics is required even for common bacterial infections. A simple pneumonia may require 6-8 weeks or more of parenteral antibiotics. Infections should be treated for at least 1 week past normalization of ESR to prevent recurrence. Severe pneumonias can be cleared completely but may require many months of parenteral antibiotics. Especially because cultures are often not helpful, many support an "antibiotic sensitivity by sedimentation rate response" approach to treatment. The ESRs are often 40-80 mm/hr or more with severe infection and will decrease monotonically over a week or so after starting antibacterial drugs. It is important to check the ESR daily or every other day because of moderate variability in this test, and changes in treatment need to be based on trends rather than individual values. If there is a clear downward trend over 3-10 days, continue with antibacterials alone. If this is not the case, parenteral voriconazole should be added to cover *Aspergillus*. Failure of the ESR to decrease suggests another antimicrobial approach needs to be tried. This sequential addition of antimicrobials offers some insight into the nature of the infection. If both antibacterials and antifungal are started at the same time, one cannot know what caused a response.

Because of the rarity of this disorder, it is critical to seek counsel from someone with significant direct experience with management of several CGD patients. Granulocyte transfusions have been used, but their benefit is unclear. The ESR should be regularly monitored in well patients and whenever they appear ill. A high ESR itself is usually not enough to trigger treatment. However, in the presence of symptoms, one should search for sources at least by contrast CT of the sinus, chest, and abdomen. If the patient is unstable or has very high fevers, *B. cepacia* should be considered and empirically covered. This organism can cause septic shock quickly, unlike the usual smoldering infections seen in CGD. The patient can be treated with antibiotics until the ESR is normal and radiographic evidence of infection has been cleared, if possible. The overall incidence of infection decreases in the second decade of life as nonneutrophil immunity matures, but increased risk of infection is lifelong.

Corticosteroids may be useful for the treatment of children with antral and urethral obstruction or severe granulomatous colitis. Corticosteroids can also be helpful in pneumonia to shrink granulomas in the lung and promote drainage. Short (4-6 days) pulses of 1-2 mg/kg of prednisone are recommended, with rapid taper to avoid long-term side effects and risk of fungus. Pulses can be repeated if clinical effect has not been achieved.

Genetic Counseling

Identifying a patient's specific genetic subgroup by DNA analysis is useful primarily for genetic counseling and prenatal diagnosis. In X-linked CGD, all possibly affected females should be tested by DHR to exclude carrier state. Diagnosis by DNA is strongly recommended in suspected carriers with normal DHR who are related to a known proband, because rarely DHR testing is normal in obligate carriers and may indicate that the patient has a spontaneous mutation and the mother may not be a carrier at all. Counseling is best done by a physician who has direct knowledge of the clinical manifestations of CGD.

Prognosis

The overall mortality rate for CGD is about two patient deaths per year per 100 cases, with the highest mortality among young children. The development of effective infection prophylaxis regimens, close surveillance for signs of infections, and aggressive surgical and medical interventions have improved the prognosis.

Chapter 171

Leukopenia

Thomas F. Michniacki and Kelly J. Walkovich

Leukopenia refers to an abnormally low number of white blood cells (WBCs) in the circulating blood secondary to a paucity of lymphocytes, granulocytes, or both. Because there are marked developmental changes in normal values for WBC counts during childhood, normal ranges must be considered in the context of age. For newborns, the mean WBC count at birth is high, followed by a rapid fall beginning at 12 hours through the first week of life. Thereafter, values are stable until 1 year of age, after which a slow, steady decline in the WBC count continues throughout childhood until adult values are reached during adolescence. Evaluation of patients with leukopenia begins with a thorough history, physical examination, and at least one confirmatory complete blood count with differential. Further evaluation then depends on whether the leukopenia represents a decreased number of neutrophils, lymphocytes, or both cell populations (Table 171.1). Treatment depends on the etiology and clinical manifestations of the leukopenia.

NEUTROPENIA

Neutropenia is defined as a decrease in the absolute number of circulating segmented neutrophils and bands in the peripheral blood. The **absolute neutrophil count (ANC)** is determined by multiplying the total WBC count by the percentage of segmented neutrophils plus bands. Normal neutrophil counts must be stratified for age and race. Neutrophils predominate at birth but rapidly decrease in the first few days of life. During infancy, neutrophils constitute 20–30% of circulating leukocyte populations. Near-equal numbers of neutrophils and lymphocytes are found in the peripheral circulation at 5 years of age, and the characteristic 70% predominance of neutrophils that occurs in adulthood is usually attained during puberty. For White children >12 months old, the lower limit of normal for the ANC is 1,500/μL; for Black children >12 months old, the lower limit of normal is 1,200/μL. The relatively lower limit of normal in Black individuals likely reflects the prevalence of the **Duffy negative** (Fy−/−) blood group, which is enriched in populations in the malarial belt of Africa and is associated with ANCs 200-600/μL less than those who are Duffy positive.

Neutropenia may be characterized as **mild** (ANC 1,000-1,500/μL), **moderate** (ANC 500-1,000/μL), or **severe** (ANC <500/μL). ANC <200 is also termed **agranulocytosis**. This stratification aids in predicting the risk of pyogenic infection in patients who have neutropenia resulting from disorders of bone marrow production, because only patients with severe neutropenia have a significantly increased susceptibility to life-threatening infections. Neutropenia associated with monocytopenia, lymphocytopenia, or hypogammaglobulinemia increases the risk for infection compared with isolated neutropenia. *Patients with neutropenia caused by increased destruction (e.g., autoimmune) may tolerate very low ANCs without increased frequency of infection,* because of their often robust ability to generate additional neutrophils from their functioning marrow when needed.

Acute neutropenia evolves over a few days and is often a result of rapid neutrophil use and compromised neutrophil production. **Chronic neutropenia** by definition lasts longer than 3 months and arises from reduced production, increased destruction, or excessive splenic sequestration of neutrophils. The etiology of neutropenia can be classified as either an acquired disorder or extrinsic insult (Table 171.2) or more rarely an inherited, intrinsic defect (Table 171.3).

Clinical Manifestations of Neutropenia

Individuals with neutrophil counts <500/μL are at substantial risk for developing infections, primarily from their endogenous flora as well as from nosocomial organisms. However, some patients with isolated chronic neutropenia may not experience many serious infections, probably because the remainder of the immune system remains intact or because neutrophil delivery to tissues is preserved, as in autoimmune neutropenias (AINs). In contrast, children whose neutropenia is secondary to acquired disorders of production, as occurs with cytotoxic therapy, immunosuppressive drugs, or radiation therapy, are likely to develop serious bacterial infections because many arms of the immune system are markedly compromised and the ability of the marrow to robustly generate new phagocytes is impaired. Neutropenia associated with additional monocytopenia or lymphocytopenia is more highly associated with serious infection than neutropenia alone. The integrity of skin and mucous membranes, the vascular supply to tissues, and nutritional status also influence the risk of infection.

The most common clinical presentation of profound neutropenia includes fever, frequent infections, aphthous stomatitis, and gingivitis. Infections frequently associated with neutropenia include cellulitis, furunculosis, perirectal inflammation, colitis, sinusitis, warts, and otitis media, as well as more serious infections such as pneumonia, deep tissue abscess, and sepsis. The most common pathogens causing infections in neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria. Isolated neutropenia does not heighten a patient's susceptibility to parasitic or viral infections or to bacterial meningitis but does increase the risk of fungal pathogens causing disease. The usual signs and symptoms of local infection and inflammation (e.g., exudate, fluctuance, regional lymphadenopathy) may be diminished in the absence of neutrophils because of the inability to form pus, but patients with agranulocytosis still experience fever and feel pain at sites of inflammation.

Laboratory Findings

Isolated absolute neutropenia has a limited number of causes (see Tables 171.2 to 171.6). The duration and severity of the neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fevers and chronic gingivitis should have WBC counts and differential counts determined 3 times a week for 6-8 weeks to evaluate for periodicity suggestive of **cyclic neutropenia**. Bone marrow aspiration and biopsy should be performed on select patients to assess cellularity and myeloid maturation. Additional marrow studies, such as cytogenetic analysis and flow cytometry for detecting leukemia and other malignant disorders, should be obtained for patients with suspected intrinsic defects in the myeloid progenitors and for patients with suspected malignancy. Children of African or Arabic descent with mild to moderate neutropenia should have Duffy null, Fy(a-b-) variant, screening completed. Selection of further laboratory tests is determined by the duration and severity of the neutropenia and the associated findings on physical examination (see Table 171.1).

Acquired Neutropenia

Infection-Related Neutropenia

Transient neutropenia often accompanies or follows **viral infections** and is the most frequent cause of neutropenia in childhood (Table 171.4). Viruses causing acute neutropenia include influenzas A and B, SARS-CoV-2, adenovirus, respiratory syncytial virus, enteroviruses, human herpesvirus 6, measles, rubella, and varicella. Parvovirus B19 and hepatitis A or B may also cause neutropenia,

Table 171.1 Diagnostic Approach for Patients with Leukopenia

EVALUATION	ASSOCIATED CLINICAL DIAGNOSES
INITIAL EVALUATION	
History of acute or chronic leukopenia	
General medical history including prior serious, recurrent or unusual infections and malignancy Physical examination: stomatitis, gingivitis, dental defects, warts, lymphedema, congenital anomalies	Congenital syndromes (severe congenital neutropenia, cyclic neutropenia, Shwachman-Diamond, Wiskott-Aldrich, Fanconi anemia, dyskeratosis congenita, glycogen storage disease type Ib, disorders of vesicular transport, GATA2 haploinsufficiency, and primary immunodeficiencies)
Spleen size	Hypersplenism
History of drug exposure	Drug-associated neutropenia
Complete blood count with differential and reticulocyte counts	Neutropenia, aplastic anemia, autoimmune cytopenias
IF ANC <1,000/μL	
Evaluation of Acute-Onset Neutropenia	
Repeat blood counts in 3-4 wk	Transient myelosuppression (e.g., viral)
Serology and cultures for infectious agents	Active or chronic infection with viruses (e.g., EBV, CMV), bacteria, mycobacteria, rickettsia
Discontinue drug(s) associated with neutropenia	Drug-associated neutropenia
Test for antineutrophil antibodies	Autoimmune neutropenia
Measure quantitative immunoglobulins (IgG, IgA, IgM, IgE), lymphocyte subsets	Neutropenia associated with disorders of immune function
IF ANC <500/μL ON THREE SEPARATE TESTS	
Bone marrow aspiration and biopsy, with cytogenetics	Severe congenital neutropenia, cyclic neutropenia, Shwachman-Diamond syndrome, myelokathexis; chronic benign or idiopathic neutropenia; reticular dysgenesis
Glucocorticoid stimulation test	Chronic benign or idiopathic neutropenia, some autoimmune neutropenias
Serial CBCs (3/wk for 6 wk)	Cyclic neutropenia
Exocrine pancreatic function	Shwachman-Diamond syndrome
Skeletal radiographs	Shwachman-Diamond syndrome, cartilage-hair hypoplasia, Fanconi anemia
IF ALC <1,000/μL	
Repeat blood counts in 3-4 wk	Transient leukopenia (e.g., viral)
IF ALC <1,000/μL THREE SEPARATE TESTS	
HIV antibody or RNA test	HIV infection, AIDS
Quantitative immunoglobulins (IgG, IgA, IgM, IgE), vaccine titers, lymphocyte subsets; qualitative lymphocyte proliferation to mitogens/antigens	Congenital or acquired disorders of immune function
IF THERE IS PANCYTOPENIA	
Bone marrow aspiration and biopsy	Bone marrow replacement by malignancy, fibrosis, granulomata, storage cells; aplastic anemia
Bone marrow cytogenetics and flow cytometry	Myelodysplasia, leukemia
Copper, vitamin B12 and folate levels	Vitamin deficiencies

ALC, Absolute lymphocyte count; ANC, absolute neutrophil count; CBC, complete blood count; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

but are more often associated with pure red cell aplasia or multiple cytopenias, respectively. Viral-associated acute neutropenia often occurs during the first 24-48 hours of illness and usually persists for 3-8 days, which generally corresponds to the period of viremia. The neutropenia is related to virus-induced redistribution of neutrophils from the circulating to the marginating pool. In addition, neutrophil sequestration may occur after virus-induced tissue damage or splenomegaly.

Significant neutropenia also may be associated with severe bacterial, protozoal, rickettsial, or fungal infections (see Table 171.4). **Bacterial sepsis** is a particularly serious cause of neutropenia, especially among younger infants and children. Premature neonates are especially prone to exhausting their marrow reserve and rapidly succumbing to bacterial sepsis.

Chronic neutropenia often accompanies infection with Epstein-Barr virus, cytomegalovirus, or HIV and certain immunodeficiencies

Table 171.2 Causes of Neutropenia Extrinsic to Marrow Myeloid Cells

CAUSE	ETIOLOGIC FACTORS/AGENTS	ASSOCIATED FINDINGS
Infection	Viruses, bacteria, protozoa, rickettsia, fungi	Clinical features and laboratory findings of the infectious agent
Drug induced	Phenothiazines, sulfonamides, anticonvulsants, penicillins, aminopyrine	Usually none; occasional hypersensitivity reaction (fever, lymphadenopathy, rash, hepatitis, nephritis, pneumonitis, aplastic anemia) or antineutrophil antibody
Immune neutropenia	Alloimmune, autoimmune	Myeloid hyperplasia with left shift in bone marrow (may appear to be "arrested" at metamyelocyte or band stage)
Reticuloendothelial sequestration	Hypersplenism	Anemia, thrombocytopenia
Bone marrow replacement	Myelofibrosis, malignancy (leukemia, lymphoma, metastatic solid tumor, etc.)	Anemia, thrombocytopenia, marrow fibrosis, malignant cells in bone marrow sites of extramedullary hematopoiesis
Cancer chemotherapy or radiation therapy	Suppression of myeloid cell production	Anemia, thrombocytopenia, bone marrow hypoplasia

Table 171.3 Acquired Disorders of Myeloid Cells

CAUSE	ETIOLOGIC FACTORS/AGENTS	ASSOCIATED FINDINGS
Aplastic anemia	Stem cell destruction and depletion	Pancytopenia
Vitamin B_{12}, copper, or folate deficiency	Malnutrition; congenital deficiency of B_{12} absorption, transport, and storage; vitamin avoidance	Megaloblastic anemia, hyper-segmented neutrophils
Acute leukemia, chronic myelogenous leukemia	Bone marrow replacement with malignant cells	Pancytopenia, leukocytosis
Myelodysplasia	Dysplastic maturation of stem cells	Bone marrow hypoplasia with megaloblastoid red cell precursors, thrombocytopenia
Prematurity with birthweight <2 kg	Impaired regulation of myeloid proliferation and reduced size of postmitotic pool	Maternal preeclampsia
Chronic idiopathic neutropenia	Impaired myeloid proliferation and/or maturation	None
Paroxysmal nocturnal hemoglobinuria	Acquired stem cell defect secondary to *PIGA* gene variant	Pancytopenia, thrombosis (hepatic vein thrombosis)

Table 171.4 Infections Associated with Neutropenia

Viral	Cytomegalovirus, dengue, Epstein-Barr virus, hepatitis viruses, HIV, influenza, measles, parvovirus B19, rubella, varicella, HHV-6, SARS-CoV-2
Bacterial	*Brucella,* paratyphoid, pertussis, tuberculosis (disseminated), tularemia, *Shigella*, typhoid; any form of sepsis
Fungal	Histoplasmosis (disseminated)
Protozoan	Malaria, leishmaniasis (kala-azar)
Rickettsial	*Anaplasma* (formerly *Ehrlichia*) *phagocytophilum,* psittacosis, Rocky Mountain spotted fever, typhus, rickettsialpox

HHV-6, Human herpesvirus-6.

such as X-linked agammaglobulinemia (XLA), hyper-IgM syndrome and AIDS. The neutropenia associated with AIDS likely arises from a combination of viral bone marrow suppression, antibody-mediated destruction of neutrophils, and effects of antiretroviral or other drugs.

Drug-Induced Neutropenia

Drugs constitute a common cause of neutropenia (Table 171.5). The incidence of drug-induced neutropenia increases dramatically with age; only 10% of cases occur among children and young adults. The majority of cases occur among adults >65 years, likely reflecting the more frequent use of multiple medications in that age-group. Almost any drug can cause neutropenia. The most common offending drug classes are antimicrobial agents, antithyroid drugs, antipsychotics, antiepileptics, antipyretics, and antirheumatics. **Drug-induced neutropenia** has several underlying mechanisms (immune-mediated, toxic, idiosyncratic, hypersensitivity, idiopathic) that are distinct from the severe neutropenia that predictably occurs after administration of antineoplastic drugs or radiotherapy.

Drug-induced neutropenia from immune mechanisms usually develops abruptly, is accompanied by fever, and lasts for about 1 week after the discontinuation of the drug. The process likely arises from effects of drugs such as propylthiouracil or penicillin that act as haptens to stimulate antibody formation, or drugs such as quinine that induce immune complex formation. Other drugs, including the antipsychotic drugs such as the phenothiazines, can cause neutropenia when given in toxic amounts, but some individuals, such as those with preexisting neutropenia, may be susceptible to levels at the high end of the usual therapeutic range. Late-onset neutropenia can occur after rituximab therapy. Idiosyncratic reactions,

Table 171.5 Forms of Drug-Induced Neutropenia

	IMMUNOLOGIC	TOXIC	HYPERSENSITIVITY
Paradigm drugs	Aminopyrine, propylthiouracil, penicillins	Phenothiazines, clozapine	Phenytoin, phenobarbital
Time to onset	Days to weeks	Weeks to months	Weeks to months
Clinical appearance	Acute, often explosive symptoms	Often asymptomatic or insidious onset	May be associated with fever, rash, nephritis, pneumonitis, or aplastic anemia
Rechallenge	Prompt recurrence with small test dose	Latent period; high doses required	Latent period; high doses required
Laboratory findings	Antineutrophil antibody may be positive; bone marrow myeloid hyperplasia	Bone marrow myeloid hypoplasia	Bone marrow myeloid hypoplasia

for example to chloramphenicol, are unpredictable with regard to dose or duration of use. Hypersensitivity reactions are rare and may involve arene oxide metabolites of aromatic anticonvulsants. Fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, and aplastic anemia are often associated with hypersensitivity-induced neutropenia. Acute hypersensitivity reactions such as those caused by phenytoin or phenobarbital may last for only a few days if the offending drug is discontinued. Chronic hypersensitivity may last for months to years.

Once neutropenia occurs, the most effective therapeutic measure is withdrawal of nonessential drugs, particularly drugs most commonly associated with neutropenia. Usually, the neutropenia will resolve soon after withdrawal of the offending drug. If the neutropenia fails to improve with drug withdrawal and the patient is symptomatic with infection or stomatitis, subcutaneous administration of recombinant human granulocyte colony-stimulating factor (G-CSF; filgrastim, 5 μg/kg/day) should be considered. Drug-induced neutropenia may be asymptomatic and noted only as an incidental finding or because of regular monitoring of WBC counts during drug therapy. For patients who are asymptomatic, continuation of the suspected offending drug depends on the relative risks of neutropenia vs discontinuation of a possibly essential drug. If the drug is continued, blood counts should be monitored for possible progression to agranulocytosis.

Neutropenia usually and predictably follows the use of anticancer drugs or radiation therapy, especially radiation directed at the pelvis or vertebrae, secondary to cytotoxic effects on rapidly replicating myeloid precursors. A decline in the WBC count typically occurs 7-10 days after administration of the anticancer drug and may persist for 1-2 weeks. The neutropenia accompanying malignancy or following cancer chemotherapy is frequently associated with compromised cellular immunity and barrier compromise secondary to central venous lines and mucositis, thereby predisposing patients to a much greater risk of infection than found in disorders associated with isolated neutropenia. Patients with chemotherapy/radiation-related neutropenia and fever must be treated aggressively with broad-spectrum antibiotics.

Nutrition-Related Neutropenia

Poor nutrition can contribute to neutropenia. Ineffective myelopoiesis may result in neutropenia caused by acquired dietary **copper, vitamin B_{12}, or folic acid deficiency**. In addition, megaloblastic pancytopenia also can result from extended use of antibiotics such as trimethoprim/sulfamethoxazole that inhibit folic acid metabolism and from the use of phenytoin, which may impair folate absorption in the small intestine, or from surgical resection of the small intestine. Neutropenia also occurs with starvation and marasmus in infants, with anorexia nervosa, and occasionally among patients receiving prolonged parenteral nutrition without vitamin supplementation. Patients receiving prolonged parenteral nutrition and supplemental lipids are additionally at risk for neutropenia given hepatosplenomegaly-related sequestration and marrow infiltration by abnormal macrophages filled with blue-staining pigment granules and atypical lipid vacuoles; these cells are termed **sea-blue histiocytes**.

Immune-Mediated Neutropenia

Immune-mediated neutropenia is usually associated with the presence of circulating antineutrophil antibodies, which may mediate neutrophil destruction by complement-mediated lysis or splenic phagocytosis of opsonized neutrophils, or by accelerated apoptosis of mature neutrophils or myeloid precursors.

Alloimmune neonatal neutropenia occurs after transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils, analogous to Rh-hemolytic disease. Prenatal sensitization induces maternal IgG antibodies to neutrophil antigens on fetal cells. The neutropenia is often severe and infants may present within the first 2 weeks of life with skin or umbilical infections, fever, and pneumonia caused by the usual microbes that cause neonatal disease. By 7 weeks of age, the neutrophil count usually returns to normal, reflecting the decay of maternal antibodies in the infant's circulation. Treatment consists of supportive care and appropriate antibiotics for clinical infections, plus G-CSF for severe infections without neutrophil recovery.

Mothers with autoimmune disease may give birth to infants who develop transient neutropenia, known as **neonatal passive AIN**. The duration of the neutropenia depends on the time required for the infant to clear the maternally transferred circulating IgG antibody. It persists in most cases for a few weeks to a few months. Neonates almost always remain asymptomatic.

AIN of infancy is a benign condition with an annual incidence of approximately 1 per 100,000 among children between infancy and 10 years of age. Antineutrophil antibodies are inappropriately created by the child during an inflammatory episode, most commonly a mild viral infection. Patients usually have severe neutropenia on presentation, with ANC <500/μL, but the total WBC count is generally within normal limits. Monocytosis or eosinophilia may occur but does not impact the low rate of infection. The median age of presentation is 8-11 months, with a range of 2-54 months. The diagnosis is often evident when a blood count incidentally reveals neutropenia in a child with a minor infection or when a routine complete blood count is obtained at the 12-month well-child visit. Occasionally, children may present with more severe infections, including abscesses, pneumonia, or sepsis. The diagnosis may be supported by the presence of antineutrophil antibodies in serum; however, the test has frequent false-negative and false-positive results, so the absence of detectable antineutrophil antibodies does not exclude the diagnosis, and a positive result does not exclude other conditions. Therefore the diagnosis is best made clinically based on a benign course and, if obtained, a normal or hyperplastic myeloid maturation in the bone marrow. There is considerable overlap between AIN of infancy and "**chronic benign neutropenia**."

Treatment is not generally necessary because the disease is only rarely associated with severe infection and usually remits spontaneously. Low-dose G-CSF may be useful for severe infections, to promote wound healing following surgery, or to avert emergency room visits or hospitalizations for febrile illnesses. Longitudinal studies of infants with AIN demonstrate median duration of disease ranging from 7-30 months. Affected children generally have no evidence or risk of other autoimmune diseases.

AIN in older children can occur as an isolated process, as a manifestation of other autoimmune diseases, or as a secondary complication of infection, drugs, or malignancy. In primary AIN, low circulating neutrophil counts are the only hematologic finding, and associated diseases or other factors that cause neutropenia are absent. Secondary AIN associated with immune dysregulation or other factors is more often identified in older children and is less likely to remit spontaneously. AIN is distinguished from other forms of neutropenia by the demonstration of antineutrophil antibodies (with caveats previously discussed) and myeloid hyperplasia on bone marrow examination. The most common antineutrophil antibody targets are human neutrophil antigens 1a, 1b, and 2.

Treatment of AIN relies on management of any underlying disorders. In addition, judicious use of appropriate antibiotics for bacterial infections is generally beneficial, as is family and primary care provider education. Regular dental hygiene, always strongly recommended, is even more important. Infections tend to be less frequent in AIN than with the corresponding degree of neutropenia from other causes, probably because tissue delivery of neutrophils is greater than that in conditions resulting from impaired production. Prophylactic antibiotics may be helpful for the management of recurrent minor infections. For patients with serious or recurrent infections, G-CSF is generally effective at raising the ANC and preventing infection. Very low doses (<1-2 μg/kg/day) are usually effective, and administration of standard doses can lead to severe bone pain from marrow expansion.

Neutropenia Secondary to Bone Marrow Replacement

Various acquired bone marrow disorders lead to neutropenia, usually accompanied by anemia and thrombocytopenia. Hematologic malignancies, including leukemia, lymphoma, and metastatic solid tumors, suppress myelopoiesis by infiltrating the bone marrow with tumor cells. Neutropenia may also accompany aplastic anemia, myelodysplastic disorders, or preleukemic syndromes, which are characterized by multiple cytopenias and often macrocytosis. Treatment requires management of the underlying disease.

Neutropenia Secondary to Reticuloendothelial Sequestration

Splenic enlargement resulting from intrinsic splenic disease (storage disease), portal hypertension, or systemic causes of splenic hyperplasia (inflammation or neoplasia) can lead to neutropenia. Most often the neutropenia is mild to moderate and is accompanied by corresponding degrees of thrombocytopenia and anemia. The reduced neutrophil survival corresponds to the size of the spleen, and the extent of the neutropenia is inversely proportional to bone marrow compensatory mechanisms. Usually, the neutropenia can be corrected by successfully treating the underlying disease. In select cases, splenectomy may be necessary to restore the neutrophil count to normal, but results in increased risk of infections by encapsulated bacterial organisms. Patients undergoing splenectomy should receive appropriate preoperative immunizations and may benefit from antibiotic prophylaxis after splenectomy to help mitigate the risk of sepsis. Splenectomy should be avoided in patients with common variable immunodeficiency (CVID), autoimmune lymphoproliferative disease, and other immunodeficiency syndromes because of the higher risk of sepsis.

Inherited Neutropenia

Intrinsic disorders of proliferation or maturation of myeloid precursor cells are rare. Table 171.6 presents a classification based on genetics (Fig. 171.1) and molecular mechanisms; other organ involvement or physical features may suggest an etiology (Table 171.7).

Primary Disorders of Granulopoiesis

Cyclic neutropenia is an autosomal dominant congenital granulopoietic disorder occurring with an estimated incidence of 0.5-1 cases per 1 million population. The disorder is characterized by regular, periodic oscillations, with the ANC ranging from normal to <200/μL, mirrored by reciprocal cycling of monocytes. Cyclic neutropenia is sometimes termed *cyclic hematopoiesis* because of the secondary cycling of other blood cells, such as platelets and reticulocytes. The mean oscillatory period of the cycle is 21 days (±4 days). During the neutropenic nadir, many patients develop malaise, fever, oral and genital ulcers, gingivitis, periodontitis, or pharyngitis, and occasionally lymph node enlargement. More serious infections occasionally occur, including pneumonia, mastoiditis, and intestinal perforation with peritonitis leading to life-threatening clostridial sepsis. Before the availability of G-CSF, approximately 10% of patients developed fatal clostridial or gram-negative infections. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells and is almost invariably associated with pathologic variants in the neutrophil elastase gene, *ELANE*, that lead to accelerated apoptosis as a result of abnormal protein folding. Many patients experience abatement of symptoms with age. The cycles tend to become less noticeable in older patients, and the hematologic picture often begins to resemble that of chronic idiopathic neutropenia.

Cyclic neutropenia is diagnosed by obtaining blood counts 3 times a week for 6-8 weeks. The requirement for repeated blood counts is necessary because some of the elastase variants overlap with those in patients who have **severe congenital neutropenia (SCN)**. Demonstrating oscillation or a lack thereof in the blood counts helps to identify patients' risks for progression to **myelodysplastic syndrome (MDS)/acute myelogenous leukemia (AML)**, a risk that is only associated with SCN. The diagnosis can be confirmed with genetic studies demonstrating a pathologic variant in *ELANE*. Affected patients with neutrophil nadirs <200/μL are treated with G-CSF, and their cycle of profound neutropenia changes from a 21-day period with at least 3-5 days of profound neutropenia to 9-11 days with 1 day of less profound neutropenia. The dose needed to maintain nadirs >500/μL is usually 2-4 μg/kg/day administered daily or every other day.

SCN is a rare, genetically heterogeneous, congenital granulopoietic disorder with an estimated incidence of 1-2 cases per 1 million population. The disorder is characterized by an arrest in myeloid maturation at the promyelocyte stage in the bone marrow, resulting in ANCs consistently <200/μL and may occur sporadically, with autosomal dominant or recessive inheritance. The **dominant** form is caused most often by pathologic variants in ***ELANE***, which accounts for 60–80% of SCN cases, whereas **recessive** forms arise from variants in ***HAX1*** (the form also known as **Kostmann disease**) or *G6PC3* (encoding a myeloid-specific isoform of glucose-6-phosphatase). Pathologic alterations in *GFI1, CSF3R,* and *JAGN1* additionally may lead to the condition. *HAX1* variants may be associated with neurologic deficits, and *G6PC3* with heart defects, urogenital abnormalities, and venous angiectasia. In addition to severe neutropenia, peripheral blood counts generally show monocytosis and many also exhibit eosinophilia; chronic inflammation may lead to secondary anemia and thrombocytosis. Patients who have SCN experience frequent episodes of fever, skin infections (including omphalitis), oral ulcers, gingivitis, pneumonia, and perirectal abscesses, typically appearing in the first few months of life. Infections often disseminate to the blood, meninges, and peritoneum and are usually caused by *S. aureus*, *Escherichia coli,* and *Pseudomonas* species. Without filgrastim therapy, most patients die of infectious complications within the first 1-2 years of life despite prophylactic antibiotics.

Table 171.6 Intrinsic Disorders of Myeloid Precursor Cells

SYNDROME	INHERITANCE *(GENE)*	CLINICAL FEATURES (INCLUDING STATIC NEUTROPENIA UNLESS OTHERWISE NOTED)
PRIMARY DISORDERS OF MYELOPOIESIS		
Cyclic neutropenia	AD *(ELANE)*	Periodic oscillation (21-day cycles) in ANC
Severe congenital neutropenia	AD (primarily *ELANE*, also *GFI1* and others)	Risk of MDS/AML
	AR *(G6PC3, HAX1, JAGN1, CSF3R)* (*HAX1* = Kostmann syndrome)	*G6PC3:* cardiac and urogenital anomalies, venous angioectasias; *HAX1:* neurologic abnormalities, risk of MDS/AML
	XL *(WAS)*	Neutropenic variant of Wiskott-Aldrich syndrome
DISORDERS OF MOLECULAR PROCESSING		
Shwachman-Diamond syndrome	Ribosomal defect: AR *(SBDS, DNAJC21, EFL1, SRP54)*	Pancreatic insufficiency, metaphyseal dysostosis, bone marrow failure, MDS/AML
Telomere biology disorders/ dyskeratosis congenita	Telomere length abnormality: XL *(DKC1)*, AD or AR *(ACD, RTEL1, TERC, TERT)*, AD *(NAF1, TINF2)*, AR *(CTC1, NHP2, NOP10, PARN, STN1, WRAP53)*	Nail dystrophy, leukoplakia, abnormal and carious teeth, lacey reticulated hyperpigmentation of the skin, bone marrow failure, various malignancies, Coats plus syndrome (*CTC1* and *STN1*)
DISORDERS OF VESICULAR TRAFFICKING		
Chédiak-Higashi syndrome	AR *(LYST)*	Partial albinism, giant granules in myeloid cells, platelet storage pool defect, impaired NK cell function, HLH
Griscelli syndrome, type II	AR *(RAB27a)*	Partial albinism, impaired NK cell function, neurologic impairment, HLH
Cohen syndrome	AR *(COH1)*	Partial albinism, pigmentary retinopathy, developmental delay, facial dysmorphism
Hermansky-Pudlak syndrome, type II	AR *(AP3B1)*	Cyclic neutropenia, partial albinism, HLH
p14 deficiency	AR *(MAPBPIP)*	Partial albinism, coarse facial features, decreased B and T cells
VPS45 defects	AR *(VPS45)*	Neutrophil dysfunction, bone marrow fibrosis, nephromegaly
DISORDERS OF METABOLISM		
Glycogen storage disease, type 1b	AR *(G6PT1)*	Hepatic enlargement, growth retardation, impaired neutrophil motility
Methylmalonic/propionic acidemia/ aciduria	AR (*CLPB*) Mutase or cobalamin transporters/ propionyl coenzyme A carboxylase	Ketoacidosis, metabolic stroke, depressed consciousness, megaloblastic anemia
3-Methylglutaconic aciduria	AR (*CLPB*)	Nonspecific finding indicative of mitochondrial dysfunction or associated with known syndromes
Barth syndrome	XL *(TAZ)*	Episodic neutropenia, dilated cardiomyopathy, methylglutaconic aciduria
Pearson syndrome	Mitochondrial (DNA deletions)	Episodic neutropenia, pancytopenia; defects in exocrine pancreas, liver, and kidneys
NEUTROPENIA IN DISORDERS OF IMMUNE FUNCTION		
Common variable immunodeficiency	Familial, sporadic *(TNFRSF13B)*	Hypogammaglobulinemia, other immune system defects
IgA deficiency	Unknown (Unknown or *TNFRSF13B*)	Decreased IgA
Severe combined immunodeficiency	AR, XL (multiple loci)	Absent humoral and cellular immune function
Hyper-IgM syndrome	XL *(HIGM1)*	Absent IgG, elevated IgM, autoimmune cytopenias
WHIM syndrome	AD *(CXCR4)*	Warts, hypogammaglobulinemia, infections, myelokathexis
Cartilage-hair hypoplasia	AR *(RMRP)*	Lymphopenia, short-limbed dwarfism, metaphyseal chondrodysplasia, fine sparse hair
Schimke immunoosseous dysplasia	AR *(SMARCAL1)*	Lymphopenia, pancytopenia, spondyloepiphyseal dysplasia, growth retardation, renal failure
X-linked agammaglobulinemia	XL (Bruton tyrosine kinase (*BTK*))	Agammaglobulinemia, neutropenia in ~25%
GATA2 haploinsufficiency	AD (*GATA2*)	Pulmonary alveolar proteinosis, lymphedema, monocytopenia, decreased B and NK cells, risk for severe fungal/mycobacterial/viral infections, susceptibility to leukemia/MDS, MonoMAC syndrome

AD, Autosomal dominant; AML, acute myelogenous leukemia; ANC, absolute neutrophil count; AR, autosomal recessive; HLH, hemophagocytic lymphohistiocytosis; MDS, myelodysplastic syndrome; NK, natural killer; XL, X-linked.

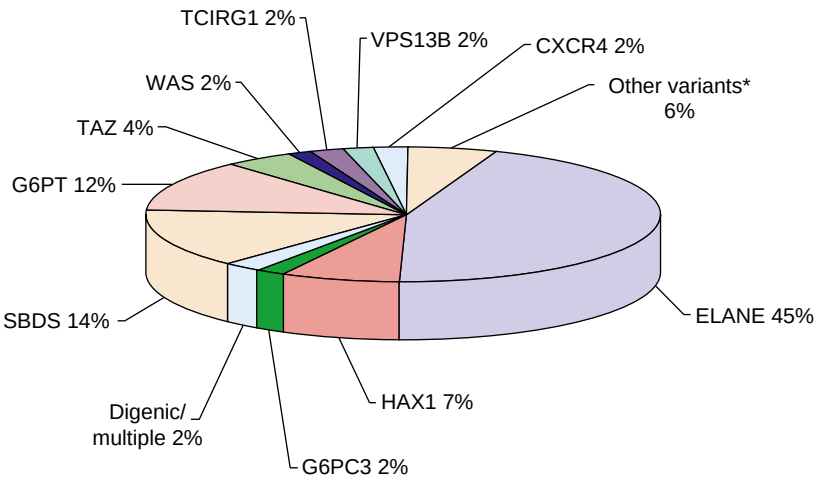

Fig. 171.1 Genes with germline variants associated with severe congenital neutropenia. Data based on 650 patients with severe congenital neutropenia registered in the European and North American Branches of the Severe Chronic Neutropenia International Registry. *Pathogenic variants in *JAGN1, LAMTOR2, GFI1, LYST, USB1,* or mitochondrial DNA. *(From Skokowa J, Dale DC, Touw IP, Zeidler C, Welte K. Severe congenital neutropenias. Nat Rev Dis Primers. 2017;3:17032. Fig. 3.)*

More than 95% of SCN patients respond to filgrastim (G-CSF) treatment with an increase in the ANC and a decrease in infections. Doses required to achieve an ANC >1,000/μL vary greatly. A starting dose of filgrastim at 5 μg/kg/day is recommended; the dose should be gradually increased, if necessary, to as high as 100 μg/kg/day to attain an ANC of 1,000-2,000/μL. The 5% of patients who do not respond to filgrastim or who require high doses (>8 μg/kg/day) should be considered for hematopoietic stem cell transplantation (HSCT). Along with infections, patients with SCN are at risk for developing MDS associated with monosomy 7 and AML. For this reason, regular monitoring with blood counts and yearly bone marrow surveillance, including karyotyping and fluorescence in situ hybridization, should be performed on all SCN patients. Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for HSCT, which is much more likely to be successful before progression to MDS/AML.

Disorders of Molecular Processing

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder classically characterized by neutropenia, pancreatic insufficiency, and short stature with skeletal abnormalities. SDS is most commonly caused by pro-apoptotic pathologic variants of the *SBDS* gene, which encodes a protein that plays a role in ribosome biogenesis and RNA processing. The initial symptoms are usually steatorrhea and failure to thrive because of malabsorption secondary to pancreatic insufficiency, which usually develops by 4 months of age, although the gastrointestinal symptoms may be subtle in some patients and go unrecognized. Patients have also been reported to have respiratory problems with frequent otitis media, pneumonia, and eczema. Virtually all patients with SDS have neutropenia, with the ANC periodically <1,000/μL. Some children have hypogammaglobulinemia, defects in chemotaxis, or a reduction in the number or function of B, T, and natural killer (NK) cells that may contribute to the increased susceptibility to pyogenic infection. The diagnosis of SDS is based on clinical phenotype; approximately 90% of patients have pathologic variants identified in *SBDS* with additional disease-causing variants now recently discovered in *DNAJC21, EFL1,* and *SRP54*. SDS may progress to bone marrow hypoplasia or MDS/AML; identification of increasing *TP53* variants or cytogenetic abnormalities, particularly isochromosome i(7q) and del(20q), often precede conversion to MDS, so routine bone marrow monitoring is warranted. Treatment includes pancreatic enzyme replacement, plus G-CSF in patients with severe neutropenia.

Telomere biology disorders (TBDs), including **dyskeratosis congenita**, are disorders of telomere length that most often present as bone marrow failure rather than isolated neutropenia. Various pathologic variants have now been identified to cause such conditions (see Table 171.6), including alterations in *ACD, PARN, DKC1, RTEL1, TERC,* and *TERT*. Moreover, the classic phenotype includes nail dystrophy, leukoplakia, malformed teeth, and reticulated hyperpigmentation of the skin, although many patients, particularly young ones, do not exhibit these clinical features. Pulmonary and hepatic fibrosis is also a concern in individuals with TBDs. Patients are at risk for not only hematologic dysplasia/malignancy but additionally neoplasms involving the gastrointestinal tract, skin, and head and neck. Early and routine screening for these malignancies can be lifesaving.

Vesicular Trafficking Disorders

This group of rare **primary immunodeficiency syndromes** (see Table 171.6) derives from autosomal recessive defects in the biogenesis or trafficking of lysosomes and related endosomal organelles. The syndromes share phenotypic characteristics, including defects in melanosomes contributing to partial albinism, abnormal platelet function, and immunologic defects involving not only neutrophil number, but also the function of neutrophils, B lymphocytes, NK cells, and cytotoxic T lymphocytes. The syndromes share a high risk of hemophagocytic lymphohistiocytosis (HLH) as a result of defects in T and NK cells.

Chédiak-Higashi syndrome has characteristic giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes, and is a disorder of subcellular vesicular dysfunction caused by pathologic variants in the *LYST* gene, with resultant giant granules in all granule-bearing cells. Patients have increased susceptibility to infections, mild bleeding diathesis, progressive peripheral neuropathy, and predisposition to life-threatening HLH. The only curative treatment is HSCT, but transplant does not treat all aspects of the disorder.

Griscelli syndrome type II also features neutropenia, partial albinism, and a high risk of HLH, but peripheral blood granulocytes do not show giant granules. Patients often have hypogammaglobulinemia. The disorder is caused by alterations in *RAB27a*, which encodes a small guanosine triphosphatase that regulates granule secretory pathways. The only curative treatment is HSCT.

Disorders of Metabolism

Recurrent infections with neutropenia are a distinctive feature of **glycogen storage disease (GSD) type Ib**. As in classic von Gierke disease (GSDIa), glycogen storage in GSDIb causes massive hepatomegaly and severe growth retardation. Pathologic variants in glucose-6-phosphate transporter 1, *G6PT1*, inhibit glucose transport in GSDIb, resulting in both defective neutrophil motility and increased apoptosis associated with neutropenia and recurrent bacterial infections. Treatment with

G-CSF, Granulocyte colony-stimulating factor; SCN, severe congenital neutropenia; WHIM, warts, hypogammaglobulinemia, infections, myelokathexis.
From Donadieu J, Fenneteau O, Beaupain B, Mahlaoui N, Chantelot CB. Congenital neutropenia: diagnosis, molecular bases and patient management. *Orphanet J Rare Dis.* 2011;6:26. Table 2.

G-CSF can correct the neutropenia but does not correct the underlying functional neutrophil defects.

Neutropenia in Disorders of Immune Dysfunction

Congenital immunologic disorders that have severe neutropenia as a clinical feature include XLA, CVID, the severe combined immunodeficiencies (SCIDs), autoimmune lymphoproliferative syndrome, hyperimmunoglobulin M syndrome, WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome, GATA2 haploinsufficiency, and a number of even rarer immunodeficiency disorders (see Table 171.6).

Unclassified Neutropenic Disorders

Chronic benign neutropenia of childhood represents a common group of disorders characterized by mild to moderate neutropenia that does not lead to an increased risk of pyogenic infections. Spontaneous remissions are often reported, although these may represent misdiagnosis of AIN of infancy, in which remissions often occur during

Table 171.8 Causes of Lymphocytopenia

ACQUIRED	
Infectious diseases	AIDS, hepatitis, influenza, sepsis, tuberculosis, typhoid, COVID-19

PUVA, Psoralen and ultraviolet A irradiation; SCID, severe combined immunodeficiency.

childhood. Chronic benign neutropenia may be sporadic or inherited in either dominant or recessive form. Because of the relatively low risk of serious infection, patients usually do not require any therapy.

Idiopathic chronic neutropenia is characterized by the onset of neutropenia after 2 years of age, with no identifiable etiology. Patients with an ANC persistently <500/μL may have recurrent pyogenic infections involving the skin, mucous membranes, lungs, and lymph nodes. Bone marrow examination reveals variable patterns of myeloid formation with arrest generally occurring between the myelocyte and band forms. The diagnosis overlaps with chronic benign and AINs.

Treatment

The management of acquired transient neutropenia associated with malignancies, myelosuppressive chemotherapy, or immunosuppressive chemotherapy differs from that of congenital or chronic forms of neutropenia. In the former situation, infections sometimes are heralded only by fever, and sepsis is a major cause of death. Early recognition and treatment of infections may be lifesaving. Therapy of severe chronic neutropenia is dictated by the clinical manifestations. Patients with benign neutropenia and no evidence of repeated bacterial infections or chronic gingivitis require no specific therapy. Superficial infections in children with mild to moderate neutropenia may be treated with appropriate oral antibiotics. In patients who have invasive or life-threatening infections, broad-spectrum intravenous antibiotics should be started promptly.

Subcutaneously administered G-CSF can provide effective treatment of severe chronic neutropenia, including SCN, cyclic neutropenia, and chronic symptomatic idiopathic neutropenias. Treatment leads to dramatic increases in neutrophil counts, resulting in marked attenuation of infection and inflammation. Doses range from 2-5 μg/kg/day for cyclic, idiopathic, and AINs, to 5-100 μg/kg/day for SCN. The long-term effects of G-CSF therapy include a propensity for the development of moderate splenomegaly, reduced bone density, thrombocytopenia, and rarely vasculitis; only patients with SCN are at risk for MDS/AML.

Patients with SCN or SDS who develop MDS or AML respond only to HSCT; chemotherapy is ineffective. HSCT is also the treatment of choice for aplastic anemia or familial HLH.

LYMPHOPENIA

The definition of lymphopenia, as with neutropenia, is age dependent and can have acquired or inherited causes. **The absolute lymphocyte count (ALC)** is determined by multiplying the total WBC count by the percentage of total lymphocytes. For children <12 months old, lymphopenia is defined as an ALC <3,000 cells/μL. For older children and adults, an ALC <1,000 cells/μL is considered lymphopenia. In isolation, mild to moderate lymphopenia is generally a benign condition often detected only in the evaluation of other illnesses. However, severe lymphopenia can result in serious, life-threatening illness. Lymphocyte subpopulations can be measured by flow cytometry, which uses the pattern of lymphocyte antigen expression to quantitate and classify T, B, and NK cells.

Acquired Lymphopenia

Acute lymphopenia is most often a result of infection and/or is iatrogenic from lymphocyte-toxic medications and treatments (Table 171.8). Microbial causes include viruses (e.g., respiratory syncytial virus, cytomegalovirus, influenza, measles, hepatitis, COVID-19), bacterial infections (e.g., tuberculosis, typhoid fever, histoplasmosis, brucellosis), and malaria. The mechanisms behind infection-associated lymphopenia are not fully elucidated but probably include lymphocyte redistribution and accelerated apoptosis. Corticosteroids are a common cause of medication-induced lymphopenia, as are lymphocyte-specific immunosuppressive agents (e.g., antilymphocyte globulin, alemtuzumab, rituximab), chemotherapy drugs, and radiation. In most cases, infectious and iatrogenic causes of acute lymphopenia are reversible, although full lymphocyte recovery from chemotherapy and lymphocyte-specific immunosuppressive agents may take several months to years. Prolonged lymphopenia (see Table 171.8) may be caused by recurrent infection, persistent infections (mostly notably HIV), malnutrition, mechanical loss of lymphocytes through protein-losing enteropathy or thoracic duct leaks, or systemic diseases such as lupus erythematosus, rheumatoid arthritis, sarcoidosis, renal failure, lymphoma, and aplastic anemia.

Inherited Lymphopenia

Primary immunodeficiencies and bone marrow failure syndromes are the main cause of inherited lymphopenia in children (see Table 171.8). Primary immunodeficiency may result in a severe quantitative defect, as in XLA and SCID, or a qualitative or progressive defect, as in Wiskott-Aldrich syndrome and CVID. XLA is characterized by a near-absence of mature B cells because of a pathologic alteration in *BTK* that results in a dysfunctional tyrosine kinase. SCIDs are a genetically heterogeneous group of disorders characterized by abnormalities of thymopoiesis and T-cell maturation. Newborn screening for severe T-cell deficiency, by analysis of T-cell receptor excision circles (TRECs) from dried blood spot Guthrie cards, aids in the rapid identification and treatment of infants with SCID and other T-cell disorders. Quantitative defects in lymphocytes can also be appreciated in select forms of inherited bone marrow failure such as reticular dysgenesis, SCN secondary to *GFI1* variants, and dyskeratosis congenita.

Chapter 172

Leukocytosis

Thomas F. Michniacki and Kelly J. Walkovich

Leukocytosis is an elevation in the total leukocyte or white blood cell (WBC) count that is 2 standard deviations (SDs) above the mean for age. It is most often caused by elevated numbers of neutrophils (i.e., neutrophilia), although marked increases in monocytes, eosinophils, basophils, and lymphocytes can be seen. Before extensive evaluation, it is important to assess for spurious elevations in the WBC count caused by platelet clumping (secondary to insufficient sample anticoagulation or the presence of EDTA-dependent agglutinins), high numbers of circulating nucleated red blood cells (RBCs), and the presence of cryoglobulins by review of the peripheral smear.

Malignancy, namely leukemia and lymphoma, is a primary concern for patients with leukocytosis. For discussion of WBC elevation caused by immature leukocytes in acute and chronic leukemias, see Chapter 544. Nonmalignant WBC counts exceeding 50,000/μL have historically been termed a **leukemoid reaction.** Unlike leukemia, leukemoid reactions show relatively small proportions of immature myeloid cells, consisting largely of band forms, occasional metamyelocytes, and progressively rarer myelocytes, promyelocytes, and blasts. Leukemoid reactions are most often neutrophilic and are frequently associated with severe bacterial infections, including shigellosis, salmonellosis, and meningococcemia; physiologic stressors; and certain medications.

The presence of a **left shift**, defined as having >5% immature neutrophils in the peripheral blood, is consistent with marrow stress. Higher degrees of left shift with more immature neutrophil precursors are indicative of serious bacterial infections and may be a dire sign of depletion of the bone marrow reserve pool of neutrophils. Marked left shift may occasionally be encountered with trauma, burns, surgery, acute hemolysis, or hemorrhage.

NEUTROPHILIA

Neutrophilia is an increase in the total number of blood neutrophils that is 2 SD above the mean count for age. Elevated absolute neutrophil counts represent disturbances of the normal equilibrium involving bone marrow neutrophil production, migration out of the marrow compartments into the circulation, and neutrophil destruction. Neutrophilia may arise either alone or in combination with enhanced mobilization into the **circulating pool** from either the bone marrow storage compartment or the peripheral blood **marginating pool**, by impaired neutrophil egress into tissues, or by expansion of the circulating neutrophil pool secondary to increased granulopoiesis. Myelocytes are not released to the blood except under extreme circumstances.

Acute Acquired Neutrophilia

Neutrophilia is usually an acquired, secondary finding associated with inflammation, infection, injury, or an acute physical or emotional stressor (Table 172.1). Bacterial infections, trauma (especially with hemorrhage), and surgery are among the most common causes encountered in clinical practice. Neutrophilia may also be associated with heat stroke, burns, diabetic ketoacidosis, vaccines, pregnancy, or cigarette use.

Drugs commonly associated with neutrophilia include epinephrine, corticosteroids, and recombinant growth factors such as recombinant human granulocyte colony-stimulating factor (G-CSF) and recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF). Epinephrine causes release into the circulation of a sequestered pool of neutrophils that normally marginate along the vascular endothelium. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow and impair the migration of neutrophils from the circulation into tissues. G-CSF and GM-CSF cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and stimulating neutrophil production.

Acute neutrophilia in response to inflammation and infections occurs because of release of neutrophils from the marrow storage pool. The postmitotic marrow neutrophil pools are approximately 10 times the size of the blood neutrophil pool, and about half of these cells are bands and segmented neutrophils. Exposure of blood to foreign substances such as hemodialysis membrane activates the complement system and causes transient neutropenia, followed by neutrophilia secondary to release of bone marrow neutrophils. Reactive neutrophils often have toxic granulation and Döhle bodies present.

Chronic Acquired Neutrophilia

Chronic acquired neutrophilia is usually associated with continued stimulation of neutrophil production resulting from persistent inflammatory reactions or chronic infections (e.g., tuberculosis), vasculitis, postsplenectomy states, Hodgkin disease, chronic myelogenous leukemia, chronic blood loss, sickle cell disease, some chronic hemolytic anemias, and prolonged administration of corticosteroids (see Table 172.1). Chronic neutrophilia can arise after expansion of cell production secondary to stimulation of cell divisions within the mitotic precursor pool, which consists of promyelocytes and myelocytes. Subsequently, the size of the postmitotic pool increases. These changes lead to an increase in the marrow reserve pool, which can be readily mobilized for release of neutrophils into the circulation. The neutrophil production rate can increase greatly in response to exogenously administered hematopoietic growth factors, such as G-CSF, with a maximum response taking at least 1 week to develop.

Lifelong Neutrophilia

Congenital or acquired asplenia is associated with lifelong neutrophilia. Some patients with trisomy 21 also have neutrophilia. Uncommon genetic disorders that present with neutrophilia include leukocyte function disorders such as leukocyte adhesion deficiency and Rac2 deficiency (see Chapter 170) and systemic disorders such as familial cold urticaria, periodic fever syndromes, and familial myeloproliferative disease (see Table 172.1). Rare patients with an autosomal dominant hereditary neutrophilia have been reported.

Evaluation of persistent neutrophilia requires a careful history, physical examination, and laboratory studies to search for infectious, inflammatory, and neoplastic conditions. The leukocyte alkaline phosphatase score of circulating neutrophils can differentiate chronic myelogenous leukemia, in which the level is uniformly almost zero, from reactive or secondary neutrophilia, which features normal to elevated levels.

ADDITIONAL FORMS OF LEUKOCYTOSIS

Monocytosis

The average absolute blood monocyte count varies with age, which must be considered in the assessment of monocytosis. Given the role of monocytes in antigen presentation and cytokine secretion and as effectors of ingestion of invading organisms, it is not surprising that many clinical disorders give rise to monocytosis (Table 172.2). Typically, monocytosis occurs in patients recovering from myelosuppressive chemotherapy and is a harbinger of the return of the neutrophil count to normal. Monocytosis is occasionally a sign of an acute bacterial, viral, protozoal, or rickettsial infection and may also occur in some forms of chronic neutropenia and postsplenectomy states. Chronic inflammatory conditions can stimulate sustained monocytosis, as can preleukemia, chronic myelogenous leukemia, and lymphomas.

Eosinophilia

Eosinophilia is defined as an absolute eosinophil count >1500 cells/μL. The majority of eosinophilic conditions are reactive, including infections (especially parasitic diseases), connective tissue disorders, allergic and hyperinflammatory diseases, pulmonary disorders, and dermatologic conditions (see Chapter 169). Drug reaction with eosinophilia and systemic symptoms (DRESS) is a particularly important condition

Table 172.1 Causes of Neutrophilia

TYPE	CAUSE	EXAMPLE
Acute acquired	Bacterial infections	
	Neutrophil disorder	Leukocyte adhesion defects
	Surgery	
	Acute stress	Burns, diabetic ketoacidosis, heat stroke, postneutropenia rebound, exercise
	Drugs	Corticosteroids, epinephrine, hematopoietic growth factors, lithium
Chronic acquired	Chronic inflammation	Inflammatory bowel disease, rheumatoid arthritis, vasculitis, cigarette exposure
	Persistent infection	Tuberculosis
	Persistent stress	Chronic blood loss, hypoxia, sickle cell and other chronic hemolytic anemias
	Drugs	Corticosteroids, lithium; rarely ranitidine, quinidine
	Other	Postsplenectomy, tumors, Hodgkin disease, pregnancy, Sweet syndrome
Lifelong	Congenital asplenia	
	Hereditary disorders	Familial cold urticaria, hereditary neutrophilia, leukocyte adhesion deficiencies, periodic fever syndromes

Table 172.2 Causes of Monocytosis

CAUSE	EXAMPLE
Infections	
Bacterial	Brucellosis, subacute bacterial endocarditis, syphilis, tuberculosis, typhoid
Nonbacterial	Fungal infections, kala-azar, malaria, Rocky Mountain spotted fever, typhus
Hematologic disorders	Congenital and acquired neutropenias, hemolytic anemias
Malignant disorders	Acute myelogenous leukemia, chronic myelogenous leukemia, juvenile myelomonocytic leukemia, Hodgkin disease, non-Hodgkin lymphomas, preleukemia
Chronic inflammatory diseases	Inflammatory bowel disease, polyarteritis nodosa, rheumatoid arthritis, sarcoidosis, systemic lupus erythematosus
Miscellaneous	Cirrhosis, drug reaction, postsplenectomy, recovery from bone marrow suppression

to consider in those with prominent eosinophilia as severe cases are associated with significant morbidity and mortality (see Chapter 686.2). Hypereosinophilic syndrome and systemic mastocytosis are additional important causes of an elevated eosinophil count. However, persistent eosinophilia can also herald a malignancy such as leukemia, lymphoma, or carcinoma.

Basophilia

Basophilia is defined as an absolute basophil count >120 cells/μL. Basophilia is a nonspecific sign of a wide variety of disorders and is usually of limited diagnostic importance. Basophilia is most often present in hypersensitivity reactions and frequently accompanies the leukocytosis of chronic myeloid leukemia.

Lymphocytosis

The most common cause of lymphocytosis is an acute viral illness, as part of the normal T-cell response to the infection. In infectious mononucleosis, the B cells are infected with the Epstein-Barr virus, and the T cells react to the viral antigens present in the B cells, resulting in **atypical lymphocytes** with characteristic large, vacuolated morphology. Other viral infections classically associated with lymphocytosis are cytomegalovirus and viral hepatitis. Chronic bacterial infections such as tuberculosis and brucellosis may lead to a sustained lymphocytosis. Pertussis is accompanied by marked lymphocytosis in approximately 25% of infants infected before 6 months of age. Thyrotoxicosis and Addison disease are endocrine disorders associated with lymphocytosis. Persistent or pronounced lymphocytosis suggests acute lymphocytic leukemia.

Section 4

Complement System

Chapter 173

Complement System

Anete Sevciovic Grumach

173.1 Complement Components, Pathways, and Evaluation

Anete Sevciovic Grumach

The complement system (CS) forms a network of soluble and cell surface–bound components, pattern-recognition proteins (PRPs), proteases, receptors, effectors, and regulators to perform multiple sensor and effector functions as part of the *innate* immune system (Tables 173.1 and 173.2). It represents an essential part of immunity, having a major role in host defense against pathogens, homeostasis, and inflammation, such as promoting phagocytic removal of senescent cells, molecular debris, and weak or superfluous synapses during brain formation. Complement acts not only in the extracellular space but also within cells and subcellular compartments, where it is involved in the regulation of basic processes of the cell, suggesting that complement directs both innate and adaptive immune responses. Cells are generally protected from amplification and effector insult by a group of complement regulators, which are expressed on their surface or mobilized from the circulation. However, if the equilibrium between complement activation and regulation is disturbed, complement can harm the host and precipitate or worsen adverse processes that result in diseases.

Circulating complement proteases are zymogens and, once activated, they initiate an amplification cascade through cleavage of specific targets and/or interaction with other proteins. Depending on the activating surface, the CS can be triggered by the **classical** (CP), **lectin** (LP), and **alternative** (AP) **pathways**. Each pathway is triggered by different interactions. The CP is initiated by immune complexes through binding of complement protein C1q to immune complexes containing IgM or IgG, in solution or bound to antigens on the cell surface. Certain bacteria, RNA viruses, and the lipid A component of bacterial endotoxin as **pathogen-associated molecular patterns (PAMPs)** on microbial surfaces can activate C1q directly and trigger the full complement cascade. The LP is activated when **mannose-binding lectin (MBL),** or ficolins, recognize unique carbohydrate structures present on the surface of pathogens or altered glycosylation patterns (DAMPs, danger-associated molecular patterns) on abnormal host cells. **The mannose-binding lectin-associated serine proteases (MASPs)** cleave C2 and C4, following the same sequence as CP.

The **AP** is rapidly activated after contact with pathogens, independent of antibody; however, antibody will accelerate the rate of activation. The fluid phase C3 convertase complex C3(H2O)Bb is generated with the spontaneous hydrolysis of C3, referred to as "tick over." An amplification loop leads to rapid opsonization stabilized by properdin. Therefore each of these pathways converge toward the cleavage of the abundant plasma protein C3 by a C3 convertase, followed by the formation of a C5 convertase, which cleaves C5 into C5a and C5b, and induces the activation of the common lytic effector **terminal pathway (TP).** The interaction among C5b, C6, C7, C8, and C9 is nonenzymatic and depends on changes in molecular configuration. The subsequent insertion of TP components into the cell wall leads to lysis via the **membrane attack complex (MAC),** which is composed of complement proteins C5b to C9.

Cell membrane receptors bind complement components or fragments to mediate complement activity, and a large array of serum and membrane regulatory proteins control the activation of CS (Fig. 173.1). The circulating components and regulators together comprise approximately 15% of the globulin fraction and 4% of the total serum proteins. The normal concentrations of serum complement components vary by age; newborn infants have mild to moderate deficiencies of all components.

CLASSICAL AND LECTIN PATHWAYS

The CP sequence begins with fixation of C1, by way of C1q, to the Fc non–antigen-binding part of the antibody molecule after antigen-antibody interaction. On binding, the C1 complex changes conformation, activating the C1r and C1s protease subunits; the C1s subcomponent becomes an active enzyme, **C1 esterase**. The activation leads to cleavage of C2 and C4 and the formation of the CP C3 convertase (C4bC2a).

As part of the **innate immune response**, broadly reactive "natural" antibodies and C-reactive protein (CRP), which react with carbohydrates from microorganisms and with dying cells, can substitute for specific antibodies in the fixation of C1q and initiate reaction of the entire sequence. Endogenous substances, including uric acid crystals, amyloid deposits, DNA, and components of damaged cells, such as apoptotic blebs and mitochondrial membranes, can activate C1q directly. In this case, however, the ligand-C1q complex interacts strongly with the inhibitor's C4-binding protein and factor H, allowing some C3-mediated **opsonization** and **phagocytosis** but limiting the full inflammatory response typically triggered by microbes.

Table 173.1 Nomenclature for Complement Components

	EXAMPLES
Classical pathway components are labeled with a C and a number	C1, C2, C4
Alternative pathway components are lettered	B, P, D
Some components are called factors	Factor B, factor D
Activated components or complexes have a bar over to indicate activation	$\overline{\text{C4bC2a}}$
Cleavage fragments are designated with a small letter	C3a, C3b
Cell membrane receptor	CR1, CR2, CR3, CR4

Table 173.2 Components of Complement System

SERUM COMPONENTS THAT ARE THE CORE OF THE COMPLEMENT SYSTEM
Classical pathway: C1q, C1r, C1s, C4, C2, C3
Alternative pathway: factor B, factor D
Lectin pathway: Mannose-binding lectin (MBL), ficolins 1/2/3, MBL-associated serine proteases (MASPs) 1/2/3
Membrane attack complex: C5, C6, C7, C8, C9
Regulatory protein, enhancing: properdin
Regulatory proteins, downregulating: C1 inhibitor (C1-INH), C4-binding protein (C4-bp), factor H, factor I, vitronectin, clusterin, carboxypeptidase N (anaphylatoxin inactivator)
MEMBRANE REGULATORY PROTEINS
CR1 (CD35), membrane cofactor protein (MCP; CD46), decay-accelerating factor (DAF, CD55), CD59 (membrane inhibitor of reactive lysis)
MEMBRANE RECEPTORS
CR1 (CD35), CR2 (CD21), CR3 (CD11b/CD18), CR4 (CD11c/CD18)
C3a receptor, C5a receptor, C1q receptors, complement receptor of the immunoglobulin superfamily (CRIg)

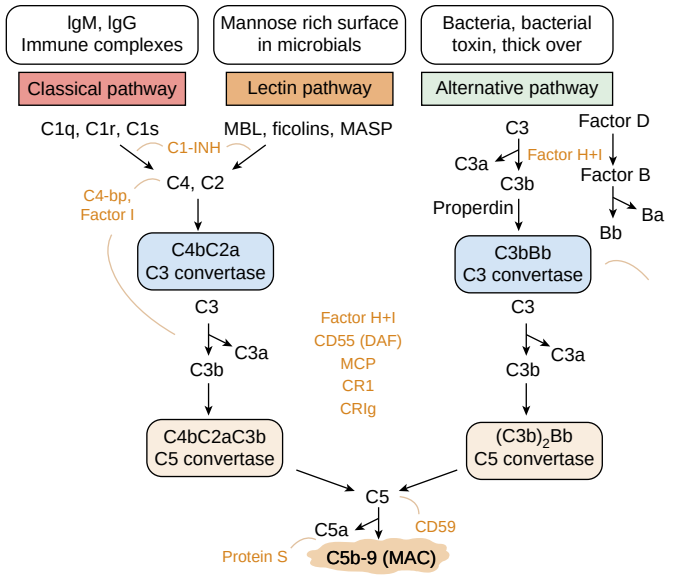

Fig. 173.1 Activation and control of the complement system. C1-INH, C1 inhibitor; C4-bp, C4-binding protein; CD59, cell membrane–associated protein; CR1 (CD35), complement receptor 1; CRIg, complement receptor of the immunoglobulin superfamily; DAF, CD55, decay-accelerating factor; MASP, mannose-binding lectin–associated serine protease; MAC, membrane attack complex; MCP, membrane cofactor protein.

C1q synthesized in the brain and retina fixes to superfluous synapses, which then can be cleared through C1q receptors on microglia, clearing the way for fresh synapses to populate the developing nervous system.

Recognition molecules in the **LP** are **MBL**, **ficolins, or collectins** (**CL-11** or kidney collectin or CL-K1; **CL-10**, collectin liver 1). MBL is the prototype of the collectin family of carbohydrate-binding proteins (**lectins**) that play an important part in innate, nonspecific immunity; its structure is homologous to that of C1q. Three ficolins have been identified in humans: **L-ficolin (ficolin-2), H-ficolin (ficolin-3),** and **M-ficolin (ficolin-1).** Ficolins show specificity for *N*-acetylglucosamine residues in complex oligosaccharides, but not for mannose or high-mannose-type oligosaccharides. Individual members display additional specificities, e.g., H-ficolin binds to *N*-acetyl-D-galactosamine and D-fucose, M-ficolin binds to sialic acid, and L-ficolin recognizes lipoteichoic acid and 1,3-β-D-glucan, the major component of yeast and fungal cell walls. These lectins, in association with **MASP-1, -2, and -3,** can bind to mannose, lipoteichoic acid, and other carbohydrates on the surface of bacteria, fungi, parasites, and viruses. There, MASPs then function like C1s to cleave C4 and C2 and activate the complement cascade. The peptide C4a has weak **anaphylatoxin** activity and reacts with mast cells to release the chemical mediators of immediate hypersensitivity, including histamine. The activation of C3 and C5 also liberates potent chemotactic fragments (i.e., the anaphylatoxins C3a and C5a) that recruit immune cells to the site of activation and prime them. Fixation of C4b to the complex permits it to adhere to neutrophils, macrophages, B cells, dendritic cells, and erythrocytes. MASP-2 can activate clotting by generating thrombin from prothrombin, which could prevent microbial spread.

Cleavage of C3 and generation of **C3b** is the next step in the sequence. The serum concentration of C3 is the highest of any component, and its activation is the most crucial step in terms of biologic activity. Cleavage of C3 can be achieved through the **C3 convertase** of the CP, C142, or of the AP, $\overline{C3bBb}$. Once C3b is fixed to a complex or dead or dying host cell, it can bind to cells with receptors for C3b (complement receptor 1, **CR1**), including B lymphocytes, erythrocytes, and phagocytic cells (neutrophils, monocytes, and macrophages). Efficient **phagocytosis** of most microorganisms, especially by neutrophils, requires binding of C3 to the microbe. The severe pyogenic infections that frequently occur in C3-deficient patients illustrate this point. The biologic activity of C3b is controlled by cleavage by **factor I** to iC3b, which promotes phagocytosis on binding to the **iC3b receptor (CR3)** on phagocytes. Further degradation of iC3b by factor I and proteases yields C3dg, then C3d; C3d binds to CR2 on B lymphocytes, thereby serving as a co-stimulator of antigen-induced B-cell activation.

ALTERNATIVE PATHWAY

The AP can be activated by C3b generated through CP activity or proteases from neutrophils or the clotting system. It can also be activated by a form of C3 created by a low-grade, spontaneous reaction of native C3 with a molecule of water, or a tick over that occurs constantly in plasma. Once formed, C3b or the hydrolyzed C3 can bind to any nearby cell or to factor B. **Factor B** attached to C3b in the plasma or on a surface can be cleaved to Bb by the circulating protease **factor D**. The complex C3bBb becomes an efficient C3 convertase, which generates more C3b through an amplification loop. **Properdin** can bind to C3bBb, increasing stability of the enzyme and protecting it from inactivation by **factors I and H**, which modulate the loop and the pathway.

Certain activating surfaces promote AP activation if C3b is fixed to them, including bacterial teichoic acid and endotoxin, virally infected cells, antigen–immunoglobulin A complexes, and cardiopulmonary bypass and renal dialysis membranes. These surfaces act by protecting the C3bBb enzyme from the control otherwise exercised by factors I and H. Rabbit red blood cell (RBC) membrane is such a surface, which serves as the basis for an assay of serum AP activity. Conversely, sialic acid on the surface of microorganisms or cells prevents the formation of an effective AP C3 convertase by promoting the activity of factors I and H. Significant activation of C3 can occur through the AP, and the resultant biologic activities are qualitatively the same as those achieved through activation by C142.

MEMBRANE ATTACK COMPLEX

The sequence leading to cytolysis begins with the attachment of C5b to the C5-activating enzyme from the CP, $\overline{C4b2a3b}$, or from the AP, $\overline{C3bBb3b}$. C6 is bound to C5b without being cleaved, stabilizing the activated C5b fragment. The C5b6 complex then dissociates from C423 and reacts with C7. C5b67 complexes must attach promptly to the membrane of the parent or a bystander cell, or they lose their activity. Next, C8 binds, and the C5b678 complex then promotes the addition of multiple C9 molecules. The C9 polymer of at least 3-6 molecules forms a transmembrane channel, and lysis ensues.

CONTROL MECHANISMS

Without control mechanisms acting at multiple points, there would be unbridled consumption of components, which would generate severe, potentially lethal host damage. Cells are generally protected from amplification and effector insult by a panel of complement regulators, which are expressed on their surface or recruited from circulation At the first step, **C1 inhibitor (C1-INH)** inhibits C1r and C1s enzymatic activity and thus the cleavage of C4 and C2. C1-INH also inhibits MASP-2, factors XIa and XIIa of the clotting system, and kallikrein of the contact system. Activated C2 has a short half-life, and this relative instability limits the effective life of C42 and C423. The AP enzyme that activates C3, $\overline{C3bBb}$, also has a short half-life, although it can be prolonged by the binding of **properdin** to the enzyme complex. Properdin can also bind directly to microbes and promote assembly of the AP C3 convertase.

The serum contains the enzyme carboxypeptidase N, which cleaves the N-terminus arginine from C4a, C3a, and C5a, thereby limiting their biologic activity. Factor I inactivates C4b and C3b; factor H accelerates inactivation of C3b by factor I; and an analogous factor, **C4-binding protein (C4-bp)**, accelerates C4b cleavage by factor I, thus limiting assembly of the C3 convertase. Three protein constituents of cell membranes (**CR1**, **membrane cofactor protein** [**MCP**], and **decay-accelerating factor** [**DAF**]) promote the disruption of C3 and C5 convertases assembled on those membranes. Another **cell membrane–associated protein**, **CD59**, can bind C8 or both C8 and C9, thereby interfering with the insertion of the MAC (C5b6789). The serum proteins **vitronectin** and **clusterin** can inhibit attachment of the C5b67 complex to cell membranes, bind C8 or C9 in a full MAC, or

interfere with the formation or insertion of this complex. Vitronectin also promotes macrophage uptake of dying neutrophils. The genes for the regulatory proteins factor H, C4-bp, MCP, DAF, CR1, and CR2 are clustered on chromosome 1.

PARTICIPATION IN HOST DEFENSE

Neutralization of virus by antibody can be enhanced with C1 and C4 and further enhanced by the additional fixation of C3b through the classical or alternative pathway. Complement may therefore be particularly important in the early phases of a viral infection when the antibody titer is limited. Antibody and the full complement sequence can also eliminate infectivity of at least some viruses by the production of typical complement "holes," as seen by electron microscopy. Fixation of C1q can opsonize (promote phagocytosis) through binding to the phagocyte C1q receptor.

C4a, **C3a**, and **C5a** can bind to mast cells and thereby trigger the release of histamine and other mediators, leading to vasodilation and the swelling and redness of inflammation. C5a can enhance macrophage phagocytosis of C3b-opsonized particles and induce macrophages to release the cytokines tumor necrosis factor and interleukin-1. C5a is a major **chemotactic factor** for neutrophils, monocytes, and eosinophils, which can efficiently phagocytize microorganisms opsonized with C3b or cleaved C3b (iC3b). Further inactivation of cell-bound C3b by cleavage to C3d and C3dg removes its opsonizing activity, but it can still bind to B cells. Fixation of C3b to a target cell can enhance its lysis by natural killer cells or macrophages (Fig. 173.2).

Insoluble immune complexes can be solubilized if they bind C3b, apparently because C3b disrupts the orderly antigen-antibody lattice. Binding C3b to a complex also allows it to adhere to **C3 receptors (CR1)** on RBCs, which then transport the complexes to hepatic and splenic macrophages for removal. This phenomenon may at least partially explain the immune complex disease found in patients who lack C1, C4, C2, or C3.

The CS serves to link the innate and adaptive immune systems. C4b or C3b coupled to immune complexes promotes their binding to antigen-presenting macrophages, dendritic cells, and B cells. The coupling of antigens to C3d allows binding to CR2 on B cells, which greatly reduces the amount of antigen needed to trigger an antibody response.

Neutralization of endotoxin in vitro and protection from its lethal effects in experimental animals require C1-INH and later-acting components of complement, at least through C6. Activation of the entire complement sequence can result in lysis of virus-infected cells, tumor cells, and most types of microorganisms. **Bactericidal activity** of complement has not appeared to be important to host defense, except for the occurrence of *Neisseria* infections in patients lacking later-acting components of complement.

Complement Evaluation

Good quality blood sampling requires that after clotting (about 20-120 minutes), the serum must be separated by centrifugation as soon as possible, and stored under controlled conditions. In case complement testing cannot be performed on the day of blood sampling, the serum and plasma samples must be stored in a deep freezer (−20°C) for up to 3 months or in an ultra-deep freezer (−70°C) for a longer storage until analysis. If the analysis will be done by a specialized laboratory, the samples must be shipped on dry ice by courier. Repeated freezing and thawing should be avoided because of the risk of in vitro activation. The serum is sufficient for the analysis of the total function of complement proteins and regulators as well as of autoantibodies. A quantitation of activation products requires the use of EDTA plasma because it blocks the in vitro activation of the CS by way of its Mg^{2+} and Ca^{2+} complexing properties. Heparin and citrate are less useful. The utilization of the less invasive dried blood spot (DBS)-based assays can also be used for diagnosis; enzyme activities could be retained, facilitating the samples' transportation.

The indication for using assays for complement evaluation is to detect genetic, acquired, or the effect of complement inhibitory therapy. Functional assays can screen and direct the following steps for the evaluation of specific protein deficiencies (Fig. 173.3). Assays including hemolysis of RBCs **(CH50, AP50)** check the activation of classical and alternative pathways. In both cases, CH50 and AP50, the functional result is the lytic destruction of erythrocytes on membrane insertion of C5b-9 (MAC). Low but not absent CH50 results could reflect complement consumption due to active immune complex disease, diminished hepatic production due to liver disease, and immaturity of hepatic production seen in young infants. *Screening with hemolytic assays is not adequate for C9, properdin, MBL, MASP-2, or ficolin deficiencies.* In patients with these defects, the hemolytic assay value may be minimally decreased or normal. An alternative assay, popular in Europe, is a plate-based activation assay, which more specifically detects complement

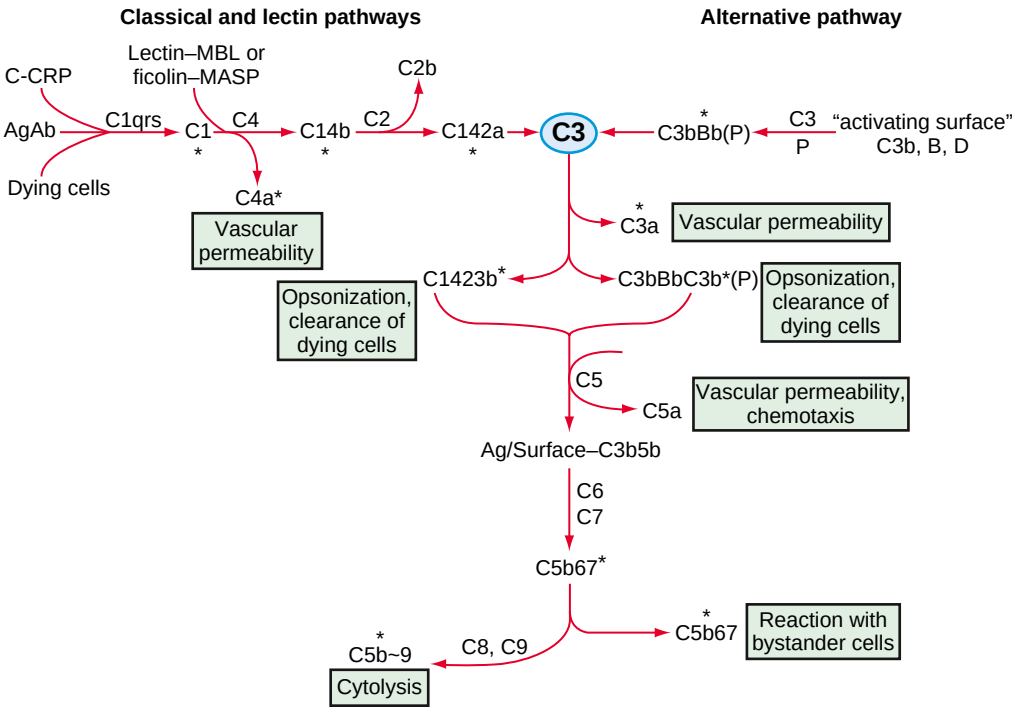

Fig. 173.2 Sequence of activation of the components of the classical and lectin pathways of complement and interaction with the alternative pathway. Functional activities generated during activation are enclosed in boxes. The multiple sites at which inhibitory regulator proteins (not shown) act are indicated by asterisks. Ab, Antibody (immunoglobulin G or M class); Ag, antigen (bacterium, virus, tumor, or tissue cell); B, D, P, factors B, D, and properdin; C-CRP, carbohydrate–carbohydrate-reactive protein; MBL, mannose-binding lectin; MASP, MBL-associated serine protease.

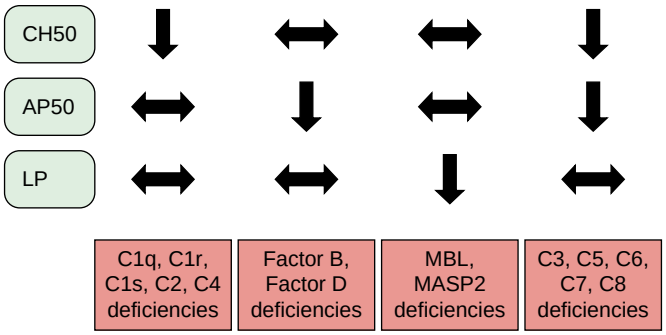

Fig. 173.3 Laboratory screening of complement system. LP, Lectin pathway; MBL, mannose-binding lectin; MASP, MBL-associated serine protease.

activation through CP, LP, and AP ("CS screen" test). Although the result target of these enzyme-linked immunosorbent assays (ELISAs) is principally the same as for the lytic assays, it is based on detecting full assembly of C5b-9 by using an antibody to a C9 neoantigen when serum is added to microtiter wells coated with the activation agent for the different pathways (e.g., IgM for CP, mannan for LP, and lipopolysaccharides for AP).

Once an abnormal CH50 or AP50 has been confirmed, immunochemical tests can be used to define the serum levels of specific components, the second step for defining complement deficiencies. Normal concentrations of single components do not exclude functional defects. The functional activity of a single component can be tested. Sera depleted of the actual component and patient's fresh serum are mixed to see whether the activity can be restored by using hemolysis as a result. Reduced functional activity of individual complement components either reflects a deficiency state, or indicates consuming complement activation. To distinguish primary or acquired defects, activation products generated by CS activation could be measured. Different approaches can be applied for this aim: detection of split fragments, generated after enzymatic cleavage of certain components, e.g., C4 (C4a, C4b/c, C4d), C3 (C3a, C3b/c, iC3b, C3d), factor B (Ba, Bb), and C5 (C5a), or the identification of protein complexes where activated components are bound to their respective regulators, like C1rs-C1-inhibitor, the properdin-containing AP convertase, C3bBbP, and sC5b-9 (soluble terminal complement complex). Detection of complement activation products like C3d and C4d on red cells using *flow cytometry* has been used to evaluate in vivo complement activation in autoimmune diseases and trauma. The terminal **C5b-9 complement complex** exists in two forms, the MAC and the soluble form (sC5b-9). The in vitro–generated surface-bound C5b-9 must not be confused with sC5b-9, which is found in plasma and if increased is a useful marker of complement activation in vivo reflecting diseases with disturbed complement function. sC5b-9 can be quantified by ELISA and is based on the same C9 neoepitope principle. In the case of efficient C5 blockade, there should ideally be no sC5b-9 present.

C4 levels have been used as a screening test for **C1-INH deficiency** in **hereditary angioedema (HAE)**; this test does not substitute quantitative and/or functional evaluation of C1-INH. C4 concentrations can be within normal range between episodes in approximately 5–10% of the patients. Also, a defective C1-INH protein can reflect only a functional assay with normal quantitative values. **Deficiency of factor I or H** permits persistence of the classical and alternative pathway convertase and thus consumption of C3, with reduction in the CH50 value. If multiple components are decreased, it is possible that sample handling was improper, a regulatory protein was deficient, or autoantibodies were present. Flow cytometry is the standard technique for the diagnosis of **paroxysmal nocturnal hemoglobinuria (PNH)** by detecting reduced levels of CD55 and CD59 on blood cells.

Autoantibodies to complement components could simulate deficiencies and assays for their detection would be relevant according to clinical information. They are often associated with specific diseases, e.g., anti-C1q antibody is associated with hypocomplementemic urticarial vasculitis and/or proliferative systemic lupus erythematosus (SLE) nephritis.

Assessment of cell surface expression of receptors and tissue deposition of complement proteins or fragments are further steps for complement evaluation. Specific gene panels are another accessible tool that could supply additional information (Table 173.3).

Table 173.3 The Steps for Complement System Evaluation

COMPLEMENT EVALUATION	EXAMPLES
Total complement activity	CH50, AP50, lectin pathway
Quantification of single components	C3, C4, MBL, properdin
Functional activity of single components	Functional C1 inhibitor
Products of complement activation	C3d; C3dg
Autoantibodies to complement components	Anti-C1q; nephritic factor
Cell surface expression	CD55; CD59; CR3/4
Tissue deposition of complement proteins or fragments	Deposition of C3 or factor H in injury burns
Genetic evaluation	Next generation sequencing or specific gene panels

173.2 Complement Pathway Deficiencies

Anete Sevciovic Grumach

Most genetically determined complement deficiencies are inherited in an autosomal recessive fashion. Exceptions are properdin deficiency, which is X-linked, and C1-INH deficiency, which is autosomal dominant. In most cases, it is possible to predict the effects of a particular deficiency based on understanding the normal physiologic function of that protein. Increased susceptibility to **infections** caused by encapsulated bacteria and **autoimmunity** are the most common presentations of complement deficiencies. Deficiency of components of TP and properdin deficiency are associated with neisserial infections. When there is an imbalance between complement activation and regulation, complement can quickly attack the host and trigger and/or exacerbate adverse processes that result in diseases and clinical complications. Genetic variants in the **complement factor H (CFH)** and **complement factor I (CFI)** genes have been associated with **atypical hemolytic uremic syndrome (aHUS)** and **aging macular degeneration (AMD).** A distinct clinical manifestation is described for deficiency of C1-INH causing recurrent **angioedema.**

CLASSICAL PATHWAY DEFICIENCIES

Patients deficient in the initial components of the CP are prone to autoimmune connective tissue diseases (Table 173.4). Most patients with primary **C1q deficiency** have SLE; some have SLE-like syndrome without typical SLE serology, a chronic rash with underlying vasculitis, or membranoproliferative glomerulonephritis (MPGN). The association with SLE is due to compromised clearance of apoptotic debris and impaired B-cell tolerance. Some C1q-deficient children have serious infections, including septicemia and meningitis. Only a few patients with **inherited deficiencies of C1r and C1s** have been described. It is thought that neither component is stable without the other so that a pathogenic variant in one often leads to diminished levels of both. Glomerulonephritis and lupus have been reported in C1r/C1s-deficient patients.

Table 173.4 Pathway Deficiencies of Complement System

DEFICIENCY	INHERITANCE	ASSOCIATED SYMPTOMS/DISORDERS
C1q, C1r/s (often combined), C2, C4 (total C4 deficiency)	AR	SLE, systemic infections with encapsulated organisms; heterozygous C2 deficiency may have a reduced CH50 but remain asymptomatic
C4A or C4B	Complex	Susceptibility to infections and/or autoimmunity (SLE); mostly asymptomatic
C3 GOF	AD	aHUS (2–10% of the cases)
C3	AR	Pyogenic infections, neisserial infections, glomerulonephritis, AMD
C5, C6, C7, C8α–γ/C8β	AR	Neisserial infections; recurrent meningitis
C9	AR	Neisserial infections (mostly asymptomatic)
Factor B	AR*	Neisserial and pneumococcal infections, aHUS (1–4% of the cases)
Factor D	AR	Bacterial infections
MBL	Polymorphism	Bacterial infections (mostly asymptomatic) and susceptibility to autoimmunity in some cases
Ficolin-3 (H-ficolin)	Polymorphism	Various clinical phenotypes
MASP-1	AR	3MC syndrome
MASP-2	AR	Respiratory infections, mostly asymptomatic

*AR, Autosomal recessive non-codominant.
AR, Autosomal recessive; AD, Autosomal dominant; C4A and C4B, isotypes encoded by C4A and C4B genes, respectively; GOF, gain of function; SLE, systemic lupus erythematosus; aHUS, atypical hemolytic uremic syndrome; AMD, aging macular degeneration; 3MC, Mingarelli, Malpuech, Michels and Carnevale.

Complement component **C4** is a central protein in the classical and lectin pathways within the CS. **C4A** and **C4B genes** encode the two isoforms of the component C4, an essential element for the effector arm of the humoral immune response. The two isotypes of C4, which differ by only four amino acids, demonstrate differential chemical reactivities: C4A displays a higher affinity for amino group–containing antigens or immune complexes, and C4B for hydroxyl group-containing antigens. The presence of one C4A or C4B gene is called *heterozygous* C4A or C4B deficiency, whereas the presence of no functional C4A or C4B genes causes *complete* C4A or C4B deficiency and is called **homozygous C4 deficiency**. Homozygous deficiencies of complement C4A or C4B are detected in 1–10% of populations. Homozygous deficiency of C4A is associated with an increased frequency of SLE; whereas homozygous C4B deficiency has been associated with increased susceptibility to bacterial and enveloped viral infections. Within each C4 gene, there can be deletions or duplications or simple inactivating variants; therefore interpretation of a serum level is difficult.

C2 deficiency is found with a frequency of 1/10,000 in the White population. The lowest frequency of autoimmunity (10–42%), among the proteins of the CP, is observed in C2-deficient patients. Individuals with C2 deficiency also carry the risk of life-threatening septicemic illnesses, usually caused by pneumococci; however, most have not had problems, presumably because of protective effects of other complement pathways. The genes for C2, factor B (AP), and C4 are situated close to each other on chromosome 6, and a partial depression of factor B levels can occur in conjunction with C2 deficiency.

Patients with C1, C2, or C4 deficiency have an increased occurrence of **autoantibodies**; antinuclear antibodies are present in 75% of patients with C1 or C4 deficiency and 25–55% of patients with C2 deficiency. Anti-dsDNA antibodies are present in 20% of patients with C1q/C4 deficiency and 33% of patients with C2 deficiency. Individuals with heterozygous C2 or C4 deficiency often remain asymptomatic. Also, there is an increased incidence of **bacterial infections** associated with deficiency of components in CP, including meningitis, pneumonia, arthritis, or septicemia. Other infections such as epiglottitis, and peritonitis have been described. The most common organisms identified in C2-deficient patients have been *Streptococcus pneumoniae* and *Haemophilus influenzae* type b.

C3 Deficiency

C3 deficiency is rare and the disease manifests early in life. Severe infections (pneumonia, meningitis, osteomyelitis, or bacteremia) caused by encapsulated bacteria *(H. influenzae*, *Neisseria meningitidis)* occur. The infections reflect the impairment in the C3b opsonization, generation of chemotactic factor, influence in B-cell stimulation, and failure of complete complement activation. **MPGN** is noted in approximately 30% of the cases of C3 deficiency. Slightly more common is a partial deficiency of C3, termed *hypomorphic* C3. This partial deficiency has been seen in some autoimmune disorders. Rare C3 gain-of-function (GOF) variants may lead to **aHUS** and endothelial damage in the glomerulus. One common and several rare variants in C3 have been associated with increased risk of AMD. A unique feature of C3 deficiency is a vasculitic rash that may appear during infections; symptoms of serum sickness may occasionally be seen. These unusual findings are due to the lack of immune complex solubilization by C3. They typically are transient in nature but can cause confusion with lupus, particularly in the presence of glomerulonephritis.

DEFICIENCY OF TERMINAL COMPONENTS (C5, C6, C7, C8, C9)

Terminal components are shared by the classical, lectin, and alternative pathways, and are ultimately responsible for the formation of the **MAC**. The risk of developing **meningococcal sepsis or meningitis** is markedly increased in people who have a deficiency of one terminal component. In contrast to the immunocompetent population (median age for meningococcal infection: 3 years), the onset of symptoms in patients with terminal deficiencies is 17 years. However, infections generally lead to lower mortality, may be recurrent, and have a milder course than in an immunocompetent person. Rarely, SLE or other autoimmune disorders has been identified in these defects. Disseminated ***Neisseria gonorrhoeae*** infections have also been described; an increased frequency of other bacterial infections is not observed. A terminal component deficiency should be suspected if there is a family history of meningococcal infections, repeated neisserial infections, or if the causative meningococcal serotype is W-135, X, Y, or Z, which less frequently cause infections in healthy individuals. Early vaccination of children could change the profile of serotypes causing infection in those patients.

C6 deficiency occurs more frequently in African Americans and in people from South Africa. Two variations of C6 deficiency have been described. In one case, a splice defect leads to a smaller than usual protein, C6SD. This protein functions less efficiently than wild-type C6; however, it is not clear whether bearing C6SD leads to compromised host defense. The other variation is combined C6 and C7 deficiency. **C7 deficiency** is rare and in the few reported cases, the clinical presentations have varied.

C8 is composed of three chains: α, β, and γ. **C8β deficiency** is more common in White people, whereas **C8α-γ deficiency** is more common among African Americans. Approximately 1 patient in 1000 carries a homozygous common nonsense variant causing **C9 deficiency** as described in Japan and Korea. It is more difficult to diagnose than most of the other complement deficiencies because the CH50 is diminished but not absent. Lytic activity can be generated in the absence of C9. The neisserial disease can occur, although the penetrance appears to be less than that with other terminal component deficiencies.

ALTERNATIVE PATHWAY DEFICIENCIES

The AP is a highly conserved surveillance system that is continuously turning over (tick over) due to a labile thioester bond in C3 and thus does not require antibodies or lectins for activation. **Properdin** is a positive regulator of AP activity and works by stabilizing AP convertases. **Properdin deficiency** is rare, hereditary, and is the only X-linked complement deficiency. A small number of patients have been identified with properdin deficiency; these patients are unusually susceptible to ***Neisseria* infections.** There is a particularly high fatality rate for meningococcal disease in properdin-deficient patients, in contrast with the protection from early death seen in patients with terminal complement component deficiencies. It manifests with either complete absence of the molecule (type I), partial deficiency (type II), or a normal level of dysfunctional protein (type III). Properdin-deficient individuals are susceptible to **meningococcal disease**, which is frequently complicated by sepsis and most commonly occurs in adolescence. **Factor D** and **Factor B deficiencies** were described in few cases and the association with *Neisseria* infections was also identified. Systemic streptococcal infections have also been involved in factor D deficiency. GOF pathogenic variants in factor B are associated with the aHUS.

LECTIN PATHWAY DEFICIENCIES

The **LP** is focused on the recognition of repetitive carbohydrate patterns found on the surface of microbial pathogens. Lectin **pattern recognition molecules (PRMs)**, which include MBL, ficolin-1, ficolin-2, ficolin-3, collectin-10, and collectin-11, activate the pathway in an analogous manner to antibodies in the CP. **MASPs**, which act in a similar fashion to C1r and C1s, associate with MBL and activate C4 and C2 by proteolytic cleavage (see Fig.173.1). Among White populations, approximately 5–7% of people have inherited MBL deficiency. LP impairment due to insufficient production of any of these components is common and may be associated with no clear clinical phenotype. However, MBL insufficiency is, in combination with other factors, associated with more severe forms of sepsis and fatal outcomes. The deficiency appears to represent a modest risk factor for infection, typically revealed in a high-risk setting. Similarly, it may subtly alter the course or contribute to the overall risk of developing several autoimmune diseases. MBL deficiency has been associated as an additional severity influence for common variable immunodeficiency, cystic fibrosis, and hepatitis. In contrast, low MBL levels have been described as protective for mycobacterial infection. MBL deficiency is not typically associated with absent levels, and it has been difficult to define the normal range in healthy people.

MASP-1, the most abundant protease of the LP, has a central role in pathway activation via MASP-2. MASP-1 may be involved in coagulation, renal, gastrointestinal, and myocardial ischemia/reperfusion-related pathology; there is no firm evidence for this type of pathology in humans.

The **Malpuech, Michels, Mingarelli, Carnevale (3MC) syndrome** is a rare, autosomal recessive genetic disorder associated with pathogenic variants in the **MASP1/3; COLEC11; or COLEC10** genes. The number of 3MC patients with known pathogenic variants in these three genes reported so far remains very small. The clinical manifestations of the 3MC syndrome consist of developmental delay, facial dysmorphia, and various skeletal anomalies. Developmental defects include cleft lip and palate, postnatal growth deficiency, cognitive impairment, and hearing loss. Excess or unusual infections and autoimmunity have not yet been described in this syndrome. The proposed mechanism was revealed by an unexpected role for these proteins in cuing neural crest cell migration.

MASP-2 deficiency was initially described in a patient with serious infections and autoimmune disease. MASP-2 deficiency has been included in the classification of primary immunodeficiencies. Asymptomatic individuals have been described; the frequency is 6/10,000, suggesting that the phenotype is mild. Healthy individuals homozygous for p.D120G have also been found by chance in genetic association studies. These findings suggest that MASP-2 deficiency could no longer be associated to a specific clinical phenotype. In contrast, increased levels of MBL or MASP-2 may contribute to poor disease outcome associated with mycobacterial infections or pneumococcal meningitis.

Complete **ficolin-3 (or H-ficolin) deficiency** was initially associated with increased susceptibility to infections and necrotizing enterocolitis. A heterogeneous range of clinical manifestations have been described in patients with complete ficolin-3 deficiency, and the first case described was later diagnosed with Wiskott-Aldrich syndrome. Respiratory and nervous system involvement in the few reported cases of FCN3 deficiency raises awareness regarding the significance of ficolin-3 in respiratory and nervous immunity.

DEFICIENCIES OF COMPLEMENT REGULATION

The CS has several levels of **regulation** at the initiation, amplification (formation of convertases), and membrane attack phases, thereby preventing inadvertent tissue damage. Deficiency of complement inhibitors leads to dysregulation either in the fluid phase or on cell surfaces and consequent recurrent infections (mostly bacterial), inflammatory disorders, and presentations with a broader clinical phenotype. These include angioedema (**C1-INH deficiency**), kidney and eye diseases (**factor H, factor I, or CD46/MCP deficiency**), **protein-losing enteropathy (CD55/DAF deficiency)**, and **PNH (CD55 + CD59 deficiency**). In addition, there are seven complement receptors (C1qR, C3aR, C5aR, CR1, CR2, CR3, and CR4). The same disease spectrum may be caused and shaped by a broad variety of different alterations in complement activators and/or regulators. The individual complement profile of a patient (sometimes referred to as **complotype**) often determines the course and severity of the disease. Disorders such as AMD, aHUS, or C3 glomerulopathy (C3G) are among the most well-described examples in this context.

Approximately 50% of patients with aHUS have genetic pathogenic variants of factors H and I, C3, factor B, and/or MCP, and deletion of complement factor H–related proteins 1 and 3 (CFHR1/CFHR3). Approximately 20% of patients with aHUS have pathologic variants in more than one gene and patients with autoantibodies to regulatory proteins also comprise a significant subset. The majority of aHUS cases are sporadic and occur in the absence of prior family history. Furthermore, even in familial forms of aHUS, penetrance is incomplete.

Thrombomodulin (CD141) also has a regulatory role and binds to factor H and C3b, thereby inhibiting complement activation. Interestingly, pathologic variants in factor H, MCP, and factor I have also been reported in **C3** MPGN, as well as preeclampsia and hemolysis, elevated liver enzyme levels, and low platelet levels (HELLP) syndrome.

Several complement proteins, their activation products, and regulators have also been related to **AMD**, particularly, C3 and factors H and I.

Hereditary Angioedema

HAE comprises a group of diseases characterized by recurrent angioedema without wheals, showing an autosomal dominant inheritance pattern. It was first recognized in patients with heterozygous **deficiencies of C1-INH** and the estimated prevalence is 1:50,000 (Chapter 189.1). Patients with angioedema without wheals have also been described with normal C1-INH levels. Several pathogenic variants

were associated with this group of patients with **primary angioedema**: factor XII (FXII-HAE), plasminogen (PLG-HAE), angiopoietin-1 (ANGPT1-HAE), kininogen-1 (KNG1-HAE), myoferlin (MYOF-HAE), and heparan sulfate-glucosamine 3-*O*-sulfotransferase 6 (HS-HAE). However, a significant proportion do not have a defined molecular explanation.

The angioedema is self-limited and recurrent, affecting the deep layers of skin and mucosa, commonly causing swelling of extremities (hands, feet, limbs), face, lips, tongue, genitalia, bowels, and the upper airway. The involvement of the gastrointestinal tract causes severe abdominal pain, distension, vomiting, and, less frequently, diarrhea. The symptoms can be misdiagnosed, and unnecessary surgery may be performed. The obstruction of upper airways due to edema of the glottis is associated with asphyxia if the attacks are not prevented. Swelling attacks are transitory and usually last from 2-5 days, but their severity and frequency vary widely from patient to patient. Approximately 5% of people who carry a C1-INH pathologic variant are asymptomatic.

In the most frequent subtype, HAE with C1-INH deficiency (HAE-C1INH, OMIM #106100), the first HAE episodes occur at a mean age of 10 years; however, the onset of symptoms may occur at an early age (Chapter 189.1). This type of HAE is classified as **type I** when there is low quantitative and functional C1-INH levels (85% of the cases) and **type II** for decreased functional C1-INH values. A typical functional level is approximately 25–40% of normal in both types. Attacks, when identified, are triggered by stress, trauma, hormones (estrogen), infections, extreme temperatures, and alcohol. Although many patients can identify triggers, many episodes have no identifiable trigger, which increases anxiety and contributes to feelings of loss of control. The symptoms are preceded by prodromes, such as erythema marginatum, irritability, nausea, and flulike symptoms. Consumption of C2 and C4 increases the risk for the development of SLE. Positive family history occurs in 75% of the cases and de novo pathogenic variants are described in 25% of the cases.

The **third type** of HAE referred to as **HAE with normal C1-INH** (previously called type III), is not a complement deficiency. It is characterized by normal serum levels and functional activity of C1-INH. It has been described primarily in females; however, both sexes are affected.

Acquired C1-INH deficiency is rarer than HAE-C1-INH (1:9) and is clinically indistinguishable from inherited C1-INH deficiency except that onset is later in life (>40 years old). Patients with acquired C1-INH deficiency require careful surveillance for malignancy; B-cell malignancies, autoimmunity, and monoclonal gammopathies are the most common. The laboratory features are similar to those of hereditary C1-INH deficiency, except that C1q levels are diminished in these patients. Anti–C1-INH can be detected in approximately 70% of the cases.

C4 Binding Protein Deficiency

C4 binding protein deficiency has been described in one family. The proband presented with angioedema, vasculitis, and arthritis. The manifestations were thought to relate to uncontrolled activation of the CP and the release of anaphylatoxins.

Factor H Deficiency

Factor H (CFH), which is present at high concentrations (500 μg/mL) in plasma, works in both the liquid and solid phases and attenuates the activity of C3 convertase in the AP and acts as a cofactor for factor I in the cleavage of C3b and C4b. It is a multifunctional molecule that has the function of decay acceleration and plays a very important role in regulating complement activation. Infections, aHUS, glomerulonephritis, and macular degeneration are the main disease phenotypes seen in patients with factor H deficiency. Infections occur due to secondary consumption of C3 with consequent partial deficiency. Diagnosis is suggestive when C3 has diminished levels and low but not absent CH50 and AP50 is found. The antigenic levels of factor H are typically low.

Several people with **MPGN** were identified with factor H deficiency. CFH deficiency was found to be the underlying basis for the pathophysiologic changes in 15–30% of patients with **aHUS**. aHUS is a thrombotic microangiopathy characterized by hemolytic anemia, thrombocytopenia, and renal failure, which occurs in the absence of its usual cause (infection with a Shiga toxin–producing organism). It is called "atypical" because it lacks the common trigger of infectious diarrhea. CFH deficiency probably affects the ability to protect the fenestrated endothelium in the glomerulus from complement-mediated damage. Recurrent aHUS also has been seen in patients with antibodies to factor H, defining an acquired form as well. This form may be slightly more amenable to therapy. Both autosomal recessive and heterozygous pathogenic variants have been seen. The age at onset is quite young in most cases, and the disease is recurrent. Mortality is not uncommon. These patients have a diminished C3 level, although the antigenic level of factor H typically is normal or elevated. Normal C3 levels are sometimes seen, and the only way in which this disorder can be identified is with direct genetic analysis.

A common tyrosine-histidine polymorphism of factor H was identified as a significant risk factor for **macular degeneration** with a higher risk of the development of macular degeneration and blindness subsequently. In macular degeneration, the central region of the retina is gradually destroyed by a process that leaves deposits of protein that contain factor H and terminal complement components. It has been hypothesized that the abnormal factor H provides less protection to the choroidal vessels, allowing smoldering complement activation with gradual damage to the endothelium.

FACTOR I DEFICIENCY

Not only factor H but also factor I is a key regulator of the AP. Deficiency of factor I results in uncontrolled activation of the AP with subsequent secondary C3 deficiency and a reduction in circulating factor H levels. Distinct clinical manifestations have been associated with **factor I deficiency.** Marked susceptibility to infections relates to the role of factor I as a cofactor for C3bBb dissociation. When factor I is lacking, C3bBb continues to cleave C3 resulting in secondary C3 deficit. Both the CH50 and the AP50 are depressed but not absent, and C3 antigen levels are low. In factor I deficiency, infections are similar to those seen in true C3 deficiency. Neisserial disease has been reported, as well as infections with encapsulated organisms such as *S. pneumoniae* and *H. influenzae.* Partial factor I deficiency has been described. aHUS, or MPGN II, has also been associated with factor I deficiency, probably related to the capacity of complement regulatory proteins to protect vascular endothelium from activating complement after microtrauma. These cases of factor I deficiency are difficult to identify because complement studies often give normal results. C3 may be depressed but is not necessarily affected. The pathogenic variants inactivate certain binding sites like surface-bound C3b and polyanion surfaces such as the fenestrated endothelium of the glomerulus, which exposes the basement membrane. A third phenotype resembles an autoinflammatory process and has been described in a small number of patients. Central nervous system inflammation has been the hallmark. Partial factor I deficiency has also been previously associated with clinical manifestations including recurrent tonsillitis, urinary infections, otitis, pyelonephritis, severe meningitis, and sepsis.

Membrane Cofactor Protein (CD46) Deficiency

MCP is a membrane protein, and its defect is intrinsic to the kidney. Deficiencies of MCP are associated with a later onset of atypical HUS compared with factor H and factor I deficiencies and it accounts for approximately 10% of all cases. There is no other known phenotype for MCP deficiency. Findings on traditional complement analysis are normal, although the mechanism is thought to be the same as for factor H and factor I deficiencies. Considering the local defect, renal transplantation can be successful.

CD59 Deficiency

CD59 is the key membrane regulator of the TP that prevents insertion of the MAC into host tissue. It is expressed on most hematopoietic cells and endothelial cells, where it confers protection from intravascular complement-mediated lysis. Isolated CD59 deficiency manifests by chronic hemolytic anemia, recurrent stroke, and severe Guillain-Barré–like neurologic symptoms with hemolysis. This defect

Table 173.5 Protein Regulators and Receptor Deficiencies of Complement System

DEFICIENCY	INHERITANCE	ASSOCIATED SYMPTOMS/DISORDERS
C1 inhibitor	AD	HAE with C1-INH deficiency
C4-binding protein	Unknown	Atypical Morbus Behçet, angioedema, protein S deficit
Properdin	X-linked recessive	Meningitis (*Neisseria*)
Factor H	AR	Membranoproliferative glomerulonephritis, AMD, aHUS (20–30% of the cases)
Factor I	AR	Pyogenic infections, neisserial infections, glomerulonephritis, aHUS (5–10% of the cases), central nervous system inflammation
CFHR1 (FHR3)	Complex	aHUS, C3G, AMD, RA, SLE
Thrombomodulin (CD141)	AD	aHUS (3–5% of the cases)
CD46/MCP	Most often heterozygous or compound heterozygous pathogenic variants	aHUS (10–15% of the cases)
CD55/DAF	AR	Protein losing enteropathy
CD55 (DAF) or CD59	AR	PNH
CD59	AR	Chronic hemolysis and relapsing peripheral demyelinating disease, cerebral infarction
CR2 (CD21)	AR	Infections, associated with CVID
CR3 (CD18/CD11b); CR4 (CD18/CD11c, LFA-1)	AR	LAD

CFHR1, Complement factor H related 1; MCP, membrane cofactor protein; DAF, decay-accelerating factor; LFA-1, integrin called lymphocyte function-associated antigen 1; AR, autosomal recessive; AD, autosomal dominant; aHUS, atypical hemolytic uremic syndrome; C3G, C3 glomerulopathy; SLE, systemic lupus erythematosus; AMD, aging macular degeneration; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; PNH, paroxysmal nocturnal hemoglobinuria; CVID, common variable immunodeficiency; LAD, leukocyte adhesion deficiency.

in CD59 was suspected in cases of chronic hemolysis because of the phenotypic resemblance to **PNH**. PNH is caused by acquired somatic variants of phosphatidylinositol glycan class A (PIG-A) or phosphatidylinositol glycan class M (PIG-M) in a clone of bone marrow progenitor cells. The protein product of PIG-A is an anchoring structure for C8 binding protein, DAF (CD55), and CD59. Glycosylphosphatidylinositol (GPI)-anchored proteins protect hematopoietic cells from complement-mediated lysis. PNH is characterized by recurrent episodes of hemoglobinuria secondary to intravascular hemolysis and can be associated with thrombosis and aplastic anemia. The red cells are the most vulnerable because they have no ability to repair membrane damage. When the cells develop from the variant-bearing progenitor, they lack all GPI-anchored membrane proteins, although the major features relate to loss of CD59. The diagnosis of PNH is made by flow cytometry for CD59 or CD55 (DAF).

Decay-Accelerating Factor (CD55) Deficiency

DAF (CD55) is a membrane-bound regulator that dissociates both classical and alternative C3 convertases. In certain kindreds, DAF deficiency has been associated with protein-losing enteropathy, whereas in others, all of the members have been completely healthy, with the deficiency being identified at the time of blood donation or cross matching for a transfusion. The *Cromer blood group* antigens reside on DAF. The RBCs of people with the Cromer-null phenotype, Inab, lack DAF but do not appear to show increased susceptibility to hemolysis. This finding suggests that CD59 is substantially more important in regulating red cell lysis by complement.

DEFICIENCIES OF COMPLEMENT RECEPTORS

CR1 Deficiency

CR1 (CD35) is a multiple modular protein that binds C3b/C4b-opsonized foreign antigens, mediating the immune adherence phenomenon. No cases of complete inherited CR1 deficiency have been reported; however, acquired mild C1R deficiency is quite common in patients with immune complex diseases and serum sickness. Similarly, a polymorphic variant of CR1 with diminished levels and function has been described, although it does not appear to be a risk factor for autoimmune disease.

CR3/CR4 Deficiency

CR3/CR4 deficiency (LFA-1) is a defect in the 3 β_2-integrin adhesion molecules. Pathogenic variants in the common β chain (CD18) lead to failure to express adequate α chains: CD11a, CD11b, and CD11c. **Leukocyte adhesion deficiency (LAD)** is an autosomal recessive disorder of neutrophil function resulting from a deficiency of β_2-integrin subunit of the leukocyte cell adhesion molecule (Table 173.5; see Chapter 170). The leukocyte cell adhesion molecule is present on the surface of peripheral blood mononuclear leukocytes and granulocytes and mediates cell-cell and cell-extracellular matrix adhesion. LAD is characterized by a delayed separation of the umbilical cord, recurrent bacterial and fungal infections, and impaired pus formation and wound healing associated with heavy mortality; bone marrow transplantation often is recommended. The infections are characteristic in that necrosis predominates, with little neutrophilic infiltrate. With some residual β_2-integrin expression, the patient may be able to survive without a bone marrow transplant and infections are common.

The manifestations of the disorder are due to the combined effects of ineffective opsonization and an inability to traverse the vascular endothelium to phagocytose bacteria. β_2-Integrins are essential for the firm adhesion step and diapedesis. Lacking β_2-integrins, the neutrophils remain in the vascular space, where they are unable to participate in the defense against bacteria. This explains the lack of pus at sites of active infection.

Two other forms of LAD are recognized: **LAD type II** is due to a defect in fucosylation of selectin ligands and **LAD type III** is due to an activation defect of integrins. The major manifestations are the infection pattern just described and a moderate to severe bleeding tendency secondary to impaired activation of platelet adhesion molecules. LAD-III results from pathogenic variants in FERMT3, or KINDLIN3, which encodes an intracellular protein that interacts with β-integrins in hematopoietic cells. In LAD-III, the adhesive functions of integrins on both leukocytes and platelets are disrupted, most likely due

to defects in activation-dependent alterations of surface integrins that enable high-avidity binding to ligands on target cells, a process termed inside-out signaling.

MANAGEMENT OF COMPLEMENT DEFICIENCIES

Prophylactic antibiotics may offer additional protection from serious infection. With the onset of unexplained fever, cultures should be obtained and antibiotic therapy instituted rapidly and with less stringent indications than in an unaffected child. The parent or patient should be given a written action plan describing any predisposition to systemic bacterial infection or autoimmune disease associated with the patient's deficiency, along with the recommended initial approach to management, for possible use by school, camp, or emergency department physicians. Therapy for infection is not standardized, but it is usually directed to prevent infections caused by encapsulated bacteria. Early complement component deficiencies have major risks to acquire infections caused by *S. pneumoniae* and *H. influenzae.*
