relationship of the hemoglobin-CO_2 dissociation allows for averaging of capillary P_{CO_2} (P_{cCO_2}) from hyperventilated and hypoventilated areas. Because the association between oxygen tension and hemoglobin saturation plateaus with increasing Pa_{O_2} (i.e., "S-shaped" curve), the decreased hemoglobin-O_2 saturation in poorly ventilated areas cannot be compensated for by well-ventilated areas where hemoglobin-O_2 saturation has already reached near-maximum. This results in decreased arterial oxyhemoglobin saturation (Sa_{O_2}) and Pa_{O_2}. Elevation of Pa_{CO_2} in such situations is indicative of coincident alveolar hypoventilation. Examples of diseases leading to venous admixture include asthma and aspiration pneumonia and pulmonary embolism, and those of intrapulmonary shunt include lobar pneumonia and ARDS.

Diffusion

Even if ventilation and perfusion are matched, gas exchange requires diffusion across the interstitial space between the alveoli and pulmonary capillaries. Under normal conditions, there is sufficient time for the pulmonary capillary blood to equilibrate with alveolar gas across the interstitial space. When the interstitial space is thickened by extravasated fluid or inflammatory cells, diffusion is impaired. Because the diffusion capacity of CO_2 is 20 times greater than that of O_2, diffusion defects manifest as hypoxemia rather than hypercarbia. Even with the administration of 100% oxygen, P_{AO_2} increases to approximately 660 mm Hg from 100 mm Hg at sea level, and the concentration gradient for diffusion of O_2 is increased by only 6.6 times. Therefore, with diffusion defects, lethal hypoxemia will set in before clinically significant CO_2 retention results. In fact, in such situations, Pa_{CO_2} is often decreased because of the hyperventilation that accompanies hypoxemia. The presence of hypercarbia in diseases that impair diffusion is indicative of alveolar hypoventilation from coexisting airway obstruction, CNS depression, or exhaustion. Examples of disease that impair diffusion are interstitial pneumonia, scleroderma, pulmonary lymphangiectasia, and ARDS.

Acute Respiratory Distress Syndrome

Some patients with respiratory failure meet criteria for ARDS, a pulmonary condition of myriad etiologies characterized by hypoxemia of acute onset and chest radiograph findings consistent with acute pulmonary parenchymal disease (Fig. 86.1). ARDS affects both children and adults and can be the result of pulmonary (direct) or extrapulmonary (indirect) insults. Causes of direct ARDS include pneumonia, aspiration of gastric contents or toxic chemicals, lung contusion, and smoke inhalation. Causes of indirect ARDS include sepsis, transfusion-related lung injury, and pancreatitis, to name a few. The diagnostic criteria for pediatric acute respiratory distress syndrome (PARDS) are outlined in Table 86.7.

Table 86.7 Pediatric Acute Respiratory Distress Syndrome (PARDS 2.0) Definition

Age	Excludes patients with perinatal-related lung disease		
Timing	Within 7 days of a known clinical insult		
Origin of edema	Not fully explained by cardiac failure or fluid overload		
Chest imaging	New opacities (unilateral or bilateral) consistent with acute pulmonary parenchymal disease and which are not due primarily to atelectasis or pleural effusion[a]		
Oxygenation[b]	IMV: OI ≥ 4 or OSI ≥ 5 NIV[c]: Pa_{O_2}/ F_{IO_2} ≤ 300 or SP_{O_2}/ F_{IO_2} ≤ 250		
	Stratification of PARDS severity: Apply ≥ 4 after initial diagnosis of PARDS		
	IMV PARDS	Mild/moderate: OI <16 or OSI <12	Severe: OI ≥16 or OSI ≥12
	NIV PARDS[c]	Mild/moderate: Pa_{O_2}/ F_{IO_2}>100 or SP_{O_2}/ F_{IO_2} >150	Severe: Pa_{O_2}/ F_{IO_2} ≤ 100 or SP_{O_2}/ F_{IO_2} ≤ 150
Special Populations[d]			
Cyanotic heart disease	Above criteria, with acute deterioration in oxygenation not explained by cardiac disease		
Chronic lung disease	Above criteria, with acute deterioration in oxygenation from baseline		

[a]Children in resource-limited settings where imaging is not available who otherwise meet PARDS criteria are considered to have possible PARDS.
[b]Oxygenation should be measured at steady state and not during transient desaturation episodes. When S_{PO_2} is used, ensure that S_{PO_2} is ≤ 97%.
[c]Diagnosis of PARDS on NIV (NIV PARDS) requires full facemask interface with continuous airway positive pressure/positive end-expiratory pressure ≥ 5cm H_2O.
[d]Stratification of PARDS severity does not apply to these populations.
IMV, invasive mechanical ventilation; NIV noninvasive ventilation; OI, oxygenation index; OSI, oxygen saturation index; PARDS, pediatric acute respiratory distress syndrome; S_{PO_2}, pulse oximeter oxygen saturation; Pa_{O_2}, partial pressure of arterial oxygen; F_{IO_2}, fraction of inspired oxygen.
OI = mean airway pressure (MAP) (cm H2O) × F_{IO_2} /Pa_{O_2} (mm Hg).
OSI = MAP (cm H2O) × F_{IO_2} /S_{PO_2}.

MONITORING A CHILD IN RESPIRATORY DISTRESS AND RESPIRATORY FAILURE

Clinical Examination

Clinical observation is the most important component of monitoring. The presence and magnitude of abnormal clinical findings, their progression with time, and their temporal relation to therapeutic interventions serve as guides to diagnosis and management (see Chapter 421). As much as possible, the child with respiratory distress or failure should be observed in the position of greatest comfort and in the least threatening environment.

Pulse oximetry is the most commonly used technique to monitor oxygenation. Noninvasive and safe, it is the standard of care in bedside monitoring of children during transport, procedural sedation, surgery, and critical illness. It indirectly measures arterial hemoglobin-O_2 saturation by differentiating oxyhemoglobin from deoxygenated hemoglobin through their respective light absorption at wavelengths of 660 nm (red) and 940 nm (infrared). A pulsatile circulation is required to enable detection of arterialized blood entering the capillary bed. Percentage of arterial oxyhemoglobin is reported as Sa_{O_2}; however, the correct description is *oxyhemoglobin saturation as measured by pulse oximetry* (Sp_{O_2}). Such precision is needed because Sp_{O_2} may not always reflect Sa_{O_2}. It is important to be familiar with the hemoglobin-O_2 dissociation curve (see Chapter 421) to estimate Pa_{O_2} at a given oxyhemoglobin saturation. Because of the shape of the hemoglobin-O_2 dissociation curve, changes in Pa_{O_2} above 70 mm Hg are not readily identified by pulse oximetry. Also, at the same Pa_{O_2}, there may be significant change in Sp_{O_2} at a different blood pH value. In most situations, Sp_{O_2} >95% is a reasonable goal, especially in emergency care. In patients receiving supplemental oxygen, a target saturation range of 94–96% should be considered in order to decrease unnecessary exposure that could result in oxygen toxicity. There are exceptions, such as in patients with large left-to-right shunts (e.g., ventricular septal defect, patent ductus arteriosus) or with single-ventricle cardiac lesions in whom the pulmonary and systemic circulations are receiving blood flow from the same ventricle (e.g., after stage I palliation for hypoplastic left heart syndrome). In the latter, a lower Sp_{O_2} (75–85%) is desired to avoid excessive blood flow to the lungs and reduced blood flow to the systemic circulation that can lead to morbidity and death. Because most commercially available pulse oximeters recognize all types of hemoglobin as either oxyhemoglobin or deoxygenated hemoglobin, they provide inaccurate information in the presence of carboxyhemoglobin and methemoglobin. In carbon monoxide poisoning, **carboxyhemoglobin** absorbs light in the same (red) wavelength as oxyhemoglobin, leading to overestimation of oxygen saturation. **Methemoglobin** absorbs light in both the oxygenated and deoxygenated wavelengths, which can cause either an overestimation or underestimation of oxygen saturation. Data suggest that increasing methemoglobin concentrations tend to drive Sp_{O_2} toward 85%, no matter the actual percent of oxyhemoglobin. At lower methemoglobin levels, the pulse oximetry reading is falsely low, whereas high levels lead to a falsely high pulse oximetry reading. Newer specialized pulse oximeters can distinguish dyshemoglobinemias and prevent false readings, but their use is not widespread. It should be recognized that dangerous levels of hypercarbia may exist in patients with ventilatory failure, who have satisfactory Sp_{O_2} if they are receiving supplemental oxygen. Pulse oximetry should not be the only monitoring method in patients with primary ventilatory failure, such as neuromuscular weakness and CNS depression. It is also unreliable in patients with poor perfusion and poor pulsatile flow to the extremities. Pulse oximetry may underestimate the degree of hypoxia in Black patients. Despite these limitations, pulse oximetry is a noninvasive, easily applicable, and effective means of assessing oxygenation in most patients.

Volumetric capnography (end-tidal CO_2 [Pet_{CO_2}] measurement) is helpful to noninvasively assess the effectiveness of ventilation and pulmonary circulation. The Pet_{CO_2} can be used to determine the alveolar dead space fraction (V_D/V_T) and is calculated as follows:

$$V_D/V_T = (Pa_{CO_2} - Pet_{CO_2}) \div Pa_{CO_2}$$

Changes in the alveolar dead space fraction usually correlate well with changes in the gradient of Pa_{CO_2} and Pet_{CO_2} ($Pa_{CO_2} - Pet_{CO_2}$). Thus a change in $Pa_{CO_2} - Pet_{CO_2}$ can be used as an index of changes in alveolar dead space. Diseases resulting in increased alveolar dead space (e.g., asthma with dynamic hyperinflation) or decreased pulmonary blood flow (e.g., pulmonary embolism, low cardiac output) lead to decreases in Pet_{CO_2} and an increase in $Pa_{CO_2} - Pet_{CO_2}$. Pet_{CO_2} alone may overestimate adequacy of ventilation.

Blood Gas Abnormalities

Arterial blood gas analysis offers valuable assistance in diagnosis, monitoring, and management of a child in respiratory distress and failure. Because arterial blood sampling in children can be impractical without an indwelling catheter, a *capillary blood gas* (CBG) sample often is obtained, especially in emergency situations. A properly arterialized CBG sample obtained by warming the digit or heel that yields free-flowing blood is an acceptable surrogate. The blood sample needs to be processed without delay. CBG provides a good estimate of $Paco_2$ and arterial pH, but less so for Pao_2. In patients who mainly require monitoring of ventilation (especially those whose oxygenation is being monitored with pulse oximetry), a *venous blood gas* sample provides a reasonable estimate of arterial pH and $Paco_2$ values, provided tissue perfusion is adequate. Venous Pco_2 ($Pvco_2$) is approximately 6 mm Hg higher and pH approximately 0.03 lower than the arterial values. Pvo_2 has a poor correlation with Pao_2. Mixed venous O_2 saturation obtained from a central venous catheter in the right atrium is a useful marker of the balance between oxygen delivery and oxygen consumption. In patients with a constant arterial O_2 content and O_2 consumption, mixed venous O_2 saturation offers valuable information about cardiac output.

Blood gas analysis is important not only for determining the adequacy of oxygenation and ventilation but also for determining the site of respiratory pathology and planning treatment (see Chapter 421). Briefly, in the presence of pure alveolar hypoventilation (e.g., airway obstruction above carina, decreased CO_2 responsiveness, neuromuscular weakness), the blood gas will show respiratory acidosis with an elevated $Paco_2$ but a relative sparing of oxygenation. $\dot{V}/\dot{Q}$ mismatch (peripheral airway obstruction, bronchopneumonia) will be reflected in increasing hypoxemia and variable levels of $Paco_2$ (low, normal, high) depending on severity of disease. Intrapulmonary right-to-left shunting and diffusion defects (alveolar-interstitial diseases such as pulmonary edema, ARDS) will be associated with a large A-ao_2 gradient and hypoxemia with relative sparing of CO_2 elimination, unless there is coincident fatigue or CNS depression.

Acid-Base Abnormalities

It is crucial to analyze the magnitude and appropriateness of changes in pH, $Paco_2$, and bicarbonate concentration ($[HCO_3^-]$) because they provide useful clues to the underlying pathophysiology and presence of more than one disorder. To do so, it is useful to assume baseline values of pH 7.40, $Paco_2$ 40 mm Hg, and $[HCO_3^-]$ 24 mEq/L. Newborns have a lower renal threshold for bicarbonate and therefore have slightly different baseline values of pH 7.38, $Paco_2$ 35 mm Hg, and $[HCO_3^-]$ 20 mEq/L.

Metabolic Acidosis with Respiratory Compensation

Patients with metabolic acidosis have decreased pH resulting from decreased serum $[HCO_3^-]$. Chemoreceptor stimulation results in hyperventilation and respiratory compensation that may clinically manifest as respiratory distress. Normal compensation does not completely correct the pH, but rather minimizes a change in pH that would otherwise occur without compensation. The adequacy of respiratory compensation is judged by the extent of the decline in $Paco_2$ in response to the decline in $[HCO_3^-]$ or pH. A normal compensation for metabolic acidosis results in a fall in $Paco_2$ by 1.2 mm Hg for every 1 mEq/L fall in $[HCO_3^-]$. The most commonly used method to analyze the adequacy of respiratory compensation is Winter's formula:

$$Paco_2 \text{ mm Hg} = (HCO_3^- \times 1.5) + 8 \pm 2$$

A quick method is to look at the last two digits of pH (provided it is not <7.10), which should be within 2 mm Hg of $Paco_2$. For example, pH 7.27, $Paco_2$ 26 mm Hg, and $[HCO_3^-]$ 12 mEq/L represent metabolic acidosis with a normal respiratory compensation response. On the other hand, pH 7.15, $Paco_2$ 30 mm Hg, and $[HCO_3^-]$ 10 mEq/L constitutes metabolic acidosis with inadequate respiratory compensation. The reasons for inadequate compensation include decreased CO_2 responsiveness (e.g., narcotic poisoning, cerebral edema), abnormalities of lungs and airways, or neuromuscular weakness. A decrease in $Paco_2$ that is greater than what could be expected as a normal compensatory response to metabolic acidosis is indicative of a mixed disorder. A pH 7.20, $Paco_2$ 15 mm Hg, and $[HCO_3^-]$ 7.5 mEq/L represent metabolic acidosis with a concomitant respiratory alkalosis because the decline in $Paco_2$ is greater than what can be expected as normal compensation. A combination of metabolic acidosis and respiratory alkalosis is often encountered in serious conditions such as cardiogenic shock (e.g., stimulation of baroreceptors), sepsis, or toxic-metabolic states (e.g., salicylates, organic acidemia).

Respiratory Acidosis with Metabolic Compensation

Patients with respiratory acidosis have decreased pH as a result of elevated $Paco_2$. An acute increase in $Paco_2$ of 10 mm Hg results in a decrease in pH by 0.08. Thus a child with severe critical asthma and a $Paco_2$ of 60 mm Hg will have a blood pH of approximately 7.24. Chronically elevated (>3-5 days) $Paco_2$ is accompanied by renal compensation and increase in serum $[HCO_3^-]$, limiting the fall in pH to 0.03 for every 10 mm Hg rise in $Paco_2$. Thus an infant with bronchopulmonary dysplasia who has a basal $Paco_2$ of 60 mm Hg will have a blood pH of approximately 7.34. These findings are helpful in distinguishing acute from chronic changes in $Paco_2$. Also, for a given level of CO_2 accumulation, a decrease in pH that is greater than expected is indicative of concomitant metabolic acidosis, and a decline in pH that is less than expected is caused by accompanying metabolic alkalosis.

Assessment of Oxygenation and Ventilation Deficits

For standardizing management, following clinical progress, and determining prognosis for patients with defects in oxygenation or ventilation, the following indicators have been proposed, each with its strengths and limitations:

- **A-ao_2 gradient** is calculated by the subtraction, $Pao_2 - Pao_2$. For the comparison to be valid, both values must be taken at the same time and with the same fraction of oxygen in the inspired gas (Fio_2).
- **Pao_2/Fio_2 ratio** (P/F ratio) is calculated by dividing Pao_2 by Fio_2. The P/F ratio is the measure of oxygenation adequacy employed in the Berlin definition of ARDS in adults (Table 86.8). According to the Berlin definition, a P/F ≤300 mm Hg is consistent with mild ARDS, a P/F ratio between 100 and 200 mm Hg is consistent with moderate ARDS, and a P/F ratio ≤100 mm Hg is consistent with severe ARDS. Although the intent is to gauge the degree of $\dot{V}/\dot{Q}$ mismatch, intrapulmonary shunt, and diffusion defect, the status of alveolar hypoventilation could have a significant impact on P/F ratio.
- **Spo_2/Fio_2 ratio** may be used as a surrogate measure of oxygenation adequacy when Pao_2 is not available. It is calculated by dividing the pulse oximeter saturation by the Fio_2. P/F ratios of 200 mm

Table 86.8 The Berlin Definition of ARDS

- Acute onset (within 7 days of new or worsening respiratory symptoms)
- Bilateral radiographic opacities that are not fully explained by effusion, atelectasis, or masses
- Arterial hypoxemia defined by thresholds:
  - *Mild:* 200 <Pao_2/Fio_2 ratio ≤300 mm Hg, on CPAP* or PEEP† ≥5 cm H_2O (observed mortality 27%)
  - *Moderate:* 100 <Pao_2/Fio_2 ratio ≤200 mm Hg, on PEEP ≥5 cm H_2O (observed mortality 32%)
  - *Severe:* Pao_2/Fio_2 ratio ≤100 mm Hg, on PEEP ≥5 cm H_2O (observed mortality 45%)
- Identified risk factor for ARDS (if no clear risk factor, exclude heart failure as a cause)
- Not exclusively the result of cardiac causes

ARDS, acute respiratory distress syndrome; CPAP, continuous positive airway pressure; Fio_2, fraction of inspired oxygen; Pao_2, partial pressure of oxygen; PEEP, positive end-expiratory pressure.

*Delivered by noninvasive or invasive ventilation.

†Delivered by invasive mechanical ventilation.

From Meyer NJ, Gattinoni L, Calfee CS. Acute respiratory distress syndrome. *Lancet.* 2021;398:622-637, Panel 1, p. 622.

Hg and 300 mm Hg correlate approximately with S/F ratios of 235 and 315, respectively. This relationship is most valid for Spo_2 values between 80% and 97%.

Pao_2/PAo_2 ratio is determined by dividing Pao_2 by PAo_2. The level of alveolar ventilation is accounted for in the calculation of Pao_2. Therefore Pao_2/PAo_2 is more indicative of $\dot{V}/\dot{Q}$ mismatch and alveolar capillary integrity.

Oxygenation index (OI) is aimed at standardizing oxygenation to the level of concomitant therapeutic interventions (e.g., mean airway pressure [MAP] and FIo_2) that influence oxygenation. None of the indicators of oxygenation mentioned earlier take into account the degree of positive pressure respiratory support. The OI is calculated as follows:

$$OI = (MAP \times FIo_2 \times 100) / Pao_2$$

Oxygenation saturation index (OSI) is analogous to OI and useful when Pao_2 measurements are not available. It substitutes Spo_2 for Pao_2 in the formula as follows:

$$OSI = (MAP \times FIo_2 \times 100) / Spo_2$$

Both the OI and OSI are used in the Pediatric Acute Lung Injury Consensus Conference (PALICC) definition of PARDS. The main limitation of OI and OSI is that level of ventilation is not accounted for in the assessment.

MANAGEMENT

The goal of management for respiratory distress and respiratory failure is to ensure a patent airway and provide necessary support for adequate oxygenation of the blood and removal of CO_2. Compared with hypercapnia, **hypoxemia** is a life-threatening condition; therefore initial therapy for respiratory failure should be aimed at ensuring adequate oxygenation.

Oxygen Administration

Supplemental oxygen administration is the least invasive and most easily tolerated therapy for hypoxemic respiratory failure. **Nasal cannula** oxygen provides low levels of oxygen supplementation and is easy to administer. Oxygen is humidified in a bubble humidifier and delivered via nasal prongs inserted into the nares. In children, a flow rate <5 L/min is most often used because of increasing nasal irritation with higher flow rates. A common formula for an estimation of the FIo_2 during use of a nasal cannula in older children and adults follows:

$$FIo_2 \text{ (as a percentage)} = 21\% + (\text{Nasal cannula flow [L/min]} \times 3)$$

The typical FIo_2 value (expressed as a percentage rather than a fraction of 1) using this method is between 23% and 40%, although the FIo_2 varies according to the size of the child, the respiratory rate, and the volume of air moved with each breath. In a young child, because typical nasal cannula flow rates are a greater percentage of total minute ventilation, significantly higher FIo_2 may be provided. Alternatively, a **simple mask** may be used, which consists of a mask with open side ports and a valveless oxygen source. Variable amounts of room air are entrained through the ports and around the side of the mask, depending on the fit, size, and minute volume of the child. Oxygen flow rates administered through a simple mask generally vary from 5 to 10 L/min, yielding typical FIo_2 values (expressed as a percentage rather than a fraction of 1) between 30% and 65%. If more precise delivery of oxygen is desired, other mask devices should be used.

A **Venturi mask** provides preset FIo_2 through a mask and reservoir system by entraining precise flow rates of room air into the reservoir along with high-flow oxygen. The adapter at the end of each mask reservoir determines the flow rate of entrained room air and the subsequent Fio_2 adapters provide Fio_2 of 0.30-0.50. Oxygen flow rates of 5-10 L/min are recommended to achieve the desired FIo_2 and to prevent rebreathing. Partial rebreather and non-rebreather masks use a reservoir bag attached to a mask to provide higher FIo_2. **Partial rebreather masks** have two open exhalation ports and contain a valveless oxygen reservoir bag. Some exhaled gas can mix with reservoir gas, although most exhaled gas exits the mask via the exhalation ports. Through these same ports, room air is entrained, and the partial rebreather mask can provide FIo_2 up to 0.60 for as long as oxygen flow is adequate to keep the bag from collapsing (typically 10-15 L/min). As with nasal cannulas, smaller children with smaller tidal volumes entrain less room air, and their delivered FIo_2 will be higher. **Non-rebreather masks** include two one-way valves, one between the oxygen reservoir bag and the mask and the other on one of the two exhalation ports. This arrangement minimizes mixing of exhaled and fresh gas and entrainment of room air during inspiration. The second exhalation port has no valve, a safeguard to allow some room air to enter the mask in the event of disconnection from the oxygen source. A non-rebreather mask can provide FIo_2 up to 0.95. The use of a non-rebreather mask in conjunction with an oxygen blender allows delivery of FIo_2 between 0.50 and 0.95 (Table 86.9). When supplemental oxygen alone is inadequate to improve oxygenation, or when ventilation impairments coexist, additional therapies may be necessary.

Airway Adjuncts

Maintenance of a patent airway is a critical step in establishing adequate oxygenation and ventilation. Artificial pharyngeal airways may be useful in patients with oropharyngeal or nasopharyngeal airway obstruction and in those with neuromuscular weakness in whom inherent extrathoracic airway resistance contributes to respiratory compromise. An **oropharyngeal airway** is a stiff plastic spacer with grooves along each side that is placed in the mouth to run from the teeth along the tongue to its base just above the vallecula. The spacer prevents the tongue from opposing the posterior pharynx and occluding the airway. Because the tip sits at the base of the tongue, it is usually not tolerated by patients who are awake or whose gag reflex is strong. The **nasopharyngeal airway**, or *nasal trumpet,* is a flexible tube that can be inserted into the nose to run from the nostril along the top of the hard and soft palate with the tip ending in the hypopharynx. It is useful in bypassing obstruction from enlarged adenoids or from contact of the soft palate with the posterior pharynx. Because it is inserted past the adenoids, a nasopharyngeal airway should be used with caution in patients with bleeding tendencies.

Inhaled Gases

Helium-oxygen mixture (heliox) is useful in overcoming airway obstruction and improving ventilation. Helium is much less dense and slightly more viscous than nitrogen. When substituted for nitrogen in the inspired gas, helium helps maintain laminar flow across an obstructed airway, decreases airway resistance, and improves ventilation. It is especially helpful in diseases of large airways obstruction in which turbulent airflow is more common, such as acute laryngotracheobronchitis, subglottic stenosis, and vascular ring. To be effective, helium should be administered in concentrations of at least 60%, so associated hypoxemia may limit its use in patients requiring >40% oxygen.

Table 86.9 Approximate Oxygen Delivery According to Device and Flow Rates in Infants and Older Children*

DEVICE	FLOW (L/min)	FIo_2 DELIVERED
Nasal cannula	0.1-6	0.21-0.4
Simple face mask	5-10	0.4-0.6
Partial rebreather	6-15	0.55-0.7
Non-rebreather	6-15	0.7-0.95
Venturi mask	5-10	0.25-0.5
Hood/tent	7-12	0.21-1.0
High-flow systems	1-60	0.21-1.0

*Individual delivery varies and depends on the patient's size, respiratory rate, and gas volume moved with every breath.

Inhaled nitric oxide (iNO) is a powerful pulmonary vasodilator. Its use may improve pulmonary blood flow and $\dot{V}/\dot{Q}$ matching in patients with diseases that elevate pulmonary vascular resistance, such as persistent pulmonary hypertension of the newborn, primary pulmonary hypertension, and secondary pulmonary hypertension from chronic excess pulmonary blood flow (e.g., ventriculoseptal defect) or collagen vascular diseases. iNO is administered in doses ranging generally from 5 to 20 parts per million of inspired gas. Although administration of iNO to unintubated patients is possible, it is most commonly used in patients undergoing mechanical ventilation via an endotracheal tube.

Positive Pressure Respiratory Support

Noninvasive positive pressure respiratory support is useful in treating both hypoxemic and hypoventilatory respiratory failure. Positive airway pressure helps with aeration of partially atelectatic or fluid-filled alveoli, prevention of alveolar collapse at end exhalation, and increase in functional residual capacity (FRC). These actions improve pulmonary compliance and hypoxemia, and decrease intrapulmonary shunt. In addition, positive pressure ventilation is useful in preventing collapse of extrathoracic airways by maintaining positive airway pressure during inspiration. Improving compliance and overcoming airway resistance also improves tidal volume and, therefore, ventilation.

A **high-flow nasal cannula (HFNC)** delivers conditioned (heated and humidified) gas at flows generally ranging from 0.5 to 2 L/kg/min up to a maximum of 60 L/min. The F_{IO_2} can be adjusted by provision of gas flow through an oxygen blender, or directly, when a dedicated commercial high-flow system is employed. A properly sized cannula for HFNC support should have prongs that occupy no more than 50% of the cross-sectional area of the nostrils, thus allowing for ample leakage of gas (open system). Therefore although elevated pressures may be generated in areas of the nasopharynx, very low levels of positive expiratory pressure (<1 cm H_2O) thought to be clinically insignificant are transmitted to the intrathoracic airway. The principal mechanisms of action of HFNC are washout of CO_2 from the pharyngeal anatomic dead space and facilitation of gas movement across the nasopharyngeal airway resistor. This is in contrast to **continuous positive airway pressure (CPAP)**, a clinically equivalent support modality predicated on the use of a tight-fitting interface (closed system) in the form of nasal prongs, masks, or helmet. CPAP creates a stable level of operator-selected airway pressure that is transmitted to the intrathoracic airway. CPAP levels of 6-7 cm H_2O have been shown to unload the diaphragm and decrease work of breathing in infants with bronchiolitis. CPAP is most useful in diseases of mildly decreased lung compliance and low FRC, such as bronchiolitis with atelectasis and pneumonia. Patients with diseases of extrathoracic airway obstruction, in which extrathoracic negative airway pressures during inspiration result in airway narrowing (e.g., laryngotracheitis, laryngomalacia, obstructive sleep apnea, postextubation airway edema), may also benefit from CPAP. Potential risks include nasal irritation, pressure injury, hyperinflation from excessive CPAP in smaller patients, and abdominal distention from swallowed air.

Noninvasive positive airway pressure ventilation (NIPPV) provides positive airway pressure during exhalation and a higher pressure that supports inspiration, also termed *bilevel noninvasive ventilation* (see Chapter 86.1).

Endotracheal Intubation and Mechanical Ventilation

When hypoxemia or significant hypoventilation persists despite the interventions already described, endotracheal intubation and mechanical ventilation are indicated. Additional indications for intubation include maintaining airway patency in patients who have the potential for airway compromise, such as those with actual or potential neurologic deterioration, and in patients with hemodynamic instability.

Proper monitoring is essential to ensuring a safe and successful endotracheal intubation. Pulse oximetry, heart rate, and blood pressure monitoring are mandatory and should be forgone only in situations calling for emergency intubation. All necessary equipment, including bag-mask ventilation device, laryngoscope, endotracheal tube (ETT) with stylet, and suction equipment, must be available and working properly before intubation. The proper internal diameter (ID) for the ETT can be estimated using the following formula:

$$ID = (Age\ [yr]/4)+4$$

Table 86.10 provides average values for age, size, and depth of insertion for tracheal tubes. Preoxygenation of the patient with high F_{IO_2} is essential and will allow maximum procedure time before the onset of hypoxemia. Although intubation can be accomplished without sedation and pharmacologic paralysis in selected patients, the physiologic benefits of these measures to the patient and to the facilitation of the intubation usually far outweigh the risks. Administration of a sedative and analgesic followed by a neuromuscular-blocking agent is a common pharmacologic regimen for facilitating intubation. In fact, sedation and paralysis with neuromuscular blocking agents should be considered standard unless contraindicated. The particular type and dose of each agent often depends on the underlying disease and clinician preference. Table 86.11 lists commonly used agents. *Dexmedetomidine* has been a standard sedating agent for maintenance during mechanical ventilation. An alternative to this pharmacologic approach is **rapid sequence intubation**, used when endotracheal intubation is urgent or the patient is suspected of having a full stomach and at increased risk of aspiration (see Chapter 79).

Once adequate sedation and/or paralysis has been achieved, ventilation should be assisted with a **bag-mask device**. After optimal preoxygenation, intubation can be performed. The clinician uses the dominant hand to open the patient's mouth and insert the laryngoscope blade gently along the tongue to its base. The airway opening can be visualized by lifting up and away from the clinician, along the axis of the laryngoscope handle. When a *straight* (Miller) laryngoscope blade is used to visualize the glottis, the tip of the blade lifts the epiglottis anteriorly. When a *curved* (Macintosh) blade is used to visualize the glottis, the tip of the blade should be advanced into the vallecula and then lifted. Secretions often obscure visualization at this step and should be suctioned clear. Once clear visualization of the vocal cords is accomplished, the ETT can be placed through the vocal cords. Rapid confirmation of ETT placement is essential and should be assessed by as many of the following steps as possible: (1) presence of exhaled CO_2 determined by a colorimetric device, capnometry, or, preferably, capnography, attached in-line with the ETT; (2) auscultation of both lung fields for equal breath sounds and the epigastrium; (3) bilateral chest wall expansion; and (4) condensation (misting) inside the ETT. An increasing heart rate, if heart rate had decreased before or during

Table 86.10 Average Size and Depth Dimensions for Tracheal Tubes

PATIENT AGE	INTERNAL DIAMETER (mm)	OROTRACHEAL DEPTH (cm)	NASOTRACHEAL DEPTH (cm)
Premature	2.0-3.0	8-9	9-10
Full-term neonate	3.0-3.5	10	11
6 mo	4.0	11	13
12-24 mo	4.5	13-14	16-17

Table 86.11 Medications Commonly Used for Intubation

DRUG	DOSE	ONSET (min)	DURATION (min)	COMMENTS
SEDATIVES/ANESTHETICS				
Midazolam	0.1 mg/kg IV	3-5	60-120	Amnesia Respiratory depression
Lorazepam	0.1 mg/kg IV	3-5	120-240	Amnesia Respiratory depression
Ketamine	1-2 mg/kg IV 4-6 mg/kg IM	2-3	10-15	↑ HR, BP, and ICP Bronchodilation, sialorrhea
Propofol	1-3 mg/kg IV	0.5-2	10-15	↓ BP Apnea
Thiopental	4-7 mg/kg IV	0.5-1	5-10	↓ BP Apnea
ANALGESICS				
Fentanyl	2-5 µg/kg IV	3-5	30-90	Respiratory depression Chest wall rigidity
Morphine	0.1 mg/kg IV	5-15	120-240	↓ BP Respiratory depression
NEUROMUSCULAR BLOCKING AGENTS				
Vecuronium	0.1 mg/kg IV	1.5-2	30-75	↑ HR Renal elimination
Rocuronium	0.6-1.2 mg/kg IV 1 mg/kg IM	1-1.5	15-60	↑ HR Renal elimination
Cisatracurium	0.1 mg/kg IV	3-5	25-30	Histamine release Nonrenal elimination

BP, Blood pressure; HR, heart rate; ICP, intracranial pressure; IM, intramuscularly; IV, intravenously.

the attempt, and a rising or normal Spo_2 reading are suggestive of successful tube placement. Preoxygenation may significantly delay any drop in Spo_2 with improper tube placement, leading to a delay in its recognition. A properly placed ETT should be well secured to avoid displacement or dislodgement. As soon as feasible, a chest radiograph should also be obtained to confirm proper position of the ETT, which should lie with the tip about halfway between the thoracic inlet and the carina (see Chapter 79).

Transient Manual Ventilation in Immediate Preintubation and Postintubation Periods

Establishment of supportive ventilation via bag-mask or bag-ETT is required before transport of the patient to a setting of continued critical care. The technique of manual ventilation should take into account the underlying pathology. Mechanical ventilation of patients with diseases characterized by low FRC (e.g., pneumonia, pulmonary edema, ARDS) should include the application of PEEP to prevent alveolar derecruitment. Lung volume recruitment can be accomplished with a PEEP valve on a self-inflating ventilation bag or by careful manipulation of exhaust gas using an anesthesia bag. Such diseases are also characterized by a short time constant for lung deflation and therefore are best managed with relatively small tidal volumes and high ventilation rates.

In contrast, diseases characterized by airway obstruction, such as critical asthma, have prolonged deflation time constants and are therefore best managed with relatively slow rates and high tidal volumes.

86.1 Mechanical Ventilation

Martin C.J. Kneyber, Ashok P. Sarnaik, and Alexandre T. Rotta

The decision to institute mechanical ventilation is based mainly on the need to assist native pulmonary function in patients with acute respiratory failure; supporting performance of the left ventricle (LV), decreasing metabolic demand, and modulating of cerebral blood flow in intracranial hypertension are additional indications. Respiratory distress leading to fatigue and impending exhaustion are also indications for respiratory support, even in the presence of adequate gas exchange. Although there are no absolute criteria for derangement of gas exchange, Pao_2 <60 mm Hg while breathing >60% oxygen, $Paco_2$ >60 mm Hg, and pH <7.25 are often used in the decision-making to institute respiratory support. Positive pressure ventilation is a powerful means of decreasing LV afterload, and it is used for this purpose in patients with cardiogenic shock resulting from LV dysfunction. Mechanical ventilation is also used in patients whose breathing is unreliable (e.g., unconscious patients, those with neuromuscular dysfunction) and when deliberate hyperventilation is desired, such as in patients with intracranial hypertension.

Mechanical ventilation is not intended to normalize gas exchange. The goals are to maintain sufficient oxygenation and ventilation to ensure tissue viability until the disease process that has compromised the patient's lung function has resolved, while minimizing excessive work of breathing and complications. When precisely employed, mechanical ventilation is a lifesaving intervention, yet care must be taken to avoid ventilator-induced lung injury (VILI). Several factors have been identified as contributors to VILI. These include lung strain from the delivery of excessive tidal volume **(volutrauma)**, injury from the repetitive opening and closing of alveoli **(atelectrauma)**, injury from excessive pressure delivery **(barotrauma)**, local and systemic cytokine release **(biotrauma)**, and damage caused by oxygen toxicity (Figs. 86.2 and 86.3).

BASIC CONCEPTS OF VENTILATOR MANAGEMENT

Equation of Motion

A pressure gradient is required for air to move from one place to another. During natural spontaneous ventilation, inspiration results from generation of negative intrapleural pressure from contraction of the diaphragm and intercostal muscles, drawing air from the atmosphere across the airways into the alveoli. During mechanical ventilation, inspiration results from positive pressure created by compressed gases through the ventilator, which pushes air across the airways into alveoli. In both spontaneous and mechanical ventilation, exhalation results from alveolar pressure generated by the elastic recoil of the lung

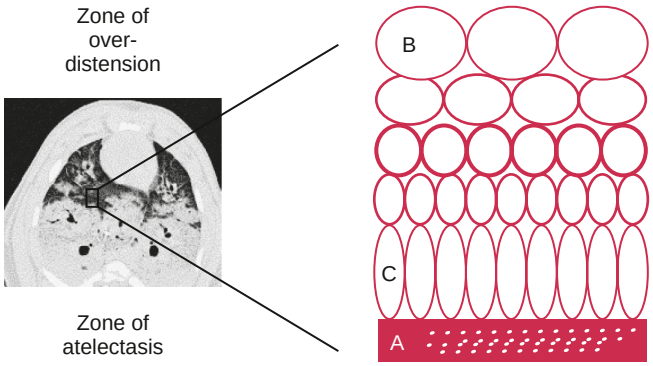

Fig. 86.2 Atelectrauma. The interface between collapsed and consolidated lung *(A)* and overdistended lung units *(B)* is heterogeneous and unstable. Depending on ambient conditions, this region is prone to cyclic recruitment and derecruitment and localized asymmetric stretch of lung units *(C)* immediately apposed to regions of collapsed lung. *(From Pinhu L, Whitehead T, Evans T, et al. Ventilator-associated lung injury.* Lancet. *2003;361:332-340.)*

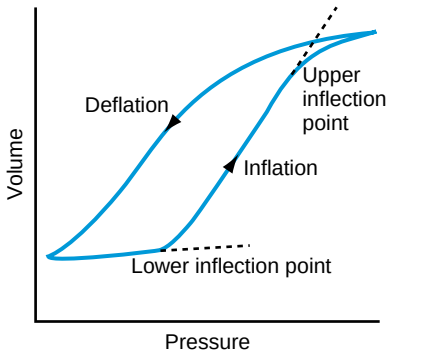

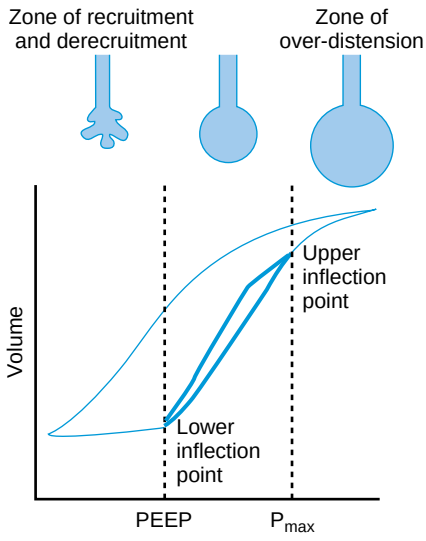

Fig. 86.3 Pulmonary pressure-volume relation in a patient with acute lung injury. *Top,* The lower inflection point is typically 12-18 cm H_2O and the upper inflection point 26-32 cm H_2O. *Bottom,* Specific protective ventilation strategies require that positive end-expiratory pressure (PEEP) is set just above the lower inflection point and the pressure limit (P_{max}) just below the upper inflection point. Thus the lung is ventilated in the safe zone between the zone of recruitment and derecruitment and the zone of overdistention, and both high-volume and low-volume injuries are avoided. This zone is located on the deflation limb of the pressure-volume curve, making use of the pulmonary hysteresis. *(From Pinhu L, Whitehead T, Evans T, et al. Ventilator-associated lung injury.* Lancet. *2003;361:332-340.)*

1. Pressure gradient is required to move air from one place to another
2. Movement of air is opposed by flow-resistive and elastic properties of the system

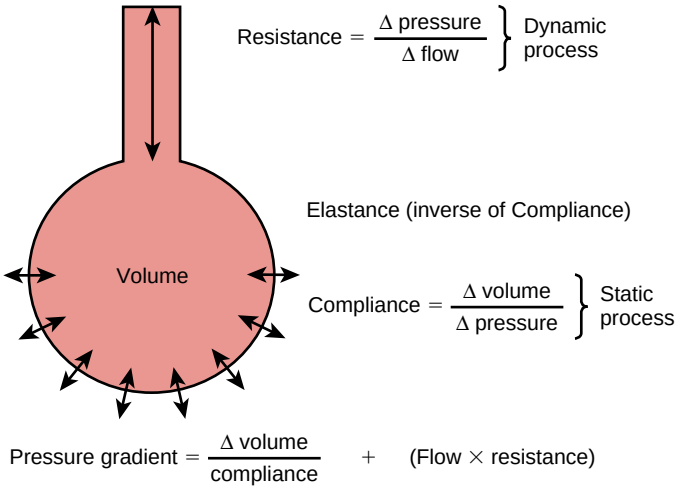

Fig. 86.4 Equation of motion. A pressure gradient is required to move air from one place to another. In the lungs, the required pressure gradient must overcome the lung and chest wall elastance (static component) and the flow-resistive properties (dynamic component). The static component is increased in alveolar interstitial diseases and stiff chest wall, whereas the dynamic component is increased with airway obstruction.

and the chest wall. Pressure necessary to move a given amount of air into the lung is determined by two factors: lung and chest wall elastance and airway resistance. Figure 86.4 describes the relationship in pressure gradient, compliance, and resistance. *Elastance*—defined as the change in pressure (ΔP) divided by the change in volume (ΔV)—refers to the property of a substance to oppose deformation. It is opposite of *compliance* (ΔV ÷ ΔP), the property of a substance to allow distention or lengthening when subjected to pressure. Compliance (C) is therefore expressed as 1/elastance.

The pressure needed to overcome tissue elastance is measured in conditions in which there is no flow (at end inspiration and end expiration) and is therefore a reflection of static conditions in the lung. It is influenced by tidal volume (Vt) and compliance (P = ΔV ÷ C). It is increased with high Vt and low compliance. This pressure gradient is used to calculate the static compliance of the respiratory system (C_{STAT}).

Resistance (R) refers to the opposition to generation of flow. It is measured as the amount of pressure needed to generate a unit of flow (ΔP ÷ ΔFlow). Pressure needed to overcome airway resistance is calculated as flow multiplied by resistance. Because this pressure is needed only when the flow is occurring through the airways, it is referred to as the *dynamic component*. Pressure to overcome flow-resistive properties is measured when there is maximum flow and is therefore under dynamic conditions. It is increased in conditions with greater airway resistance and flow rate. Flow rate depends on the time allowed for inspiration and expiration. At higher respiratory rates, there is less time available for each inspiration and expiration, necessitating higher flows; therefore higher pressure is required to overcome flow-resistive properties. The pressure gradient necessary to move air from one place to another is the sum of pressure needed to overcome the elastic and flow-resistive properties of the lung. This pressure gradient is taken into account to calculate the dynamic compliance of the respiratory system (C_{DYN}). The difference in change in pressure between static conditions and dynamic conditions is attributable to airway resistance.

Functional Residual Capacity

During inspiration, oxygen-enriched gas enters alveoli. During exhalation, oxygen continues to be removed by the pulmonary capillary

circulation. Functional residual capacity (FRC) is the volume of gas left in the alveoli at end expiration; in mechanically ventilated patients, it is generally referred to as *end-expiratory lung volume* (EELV). It is the only source of gas available for gas exchange during exhalation. In diseases with decreased FRC (e.g., pediatric acute respiratory distress syndrome [PARDS], pulmonary edema), P_{AO_2} declines sharply throughout expiration, resulting in hypoxemia. Two ventilator strategies used to improve oxygenation in such situations are the application of PEEP and increasing the *inspiratory time* (TI) (Fig. 86.5). Positive end-expiratory pressure (PEEP) increases EELV by stabilizing recruited alveoli, whereas a longer TI allows longer exposure of pulmonary capillary blood to a higher concentration of O_2 during inspiration (see also Chapter 421).

Time Constant

At the beginning of inspiration, the atmospheric pressure is higher than the pressure in the alveoli, resulting in movement of air into the alveoli. During mechanical ventilation, the ventilator circuit serves as the patient's atmosphere. As alveoli expand with air, the alveolar pressure rises throughout inspiration until it equilibrates with the ventilator pressure, at which time airflow ceases. Expiration starts when the ventilator pressure falls below the alveolar pressure. Alveolar pressure decreases throughout expiration until it reaches the ventilator pressure, at which time no further egress of air from the alveoli occurs. If inspiration or expiration is terminated before pressure equilibration between alveoli and the ventilator is allowed to occur, alveolar expansion during inspiration or alveolar emptying during expiration is incomplete. Incomplete inspiration results in delivery of decreased VT, whereas incomplete expiration is associated with air trapping and the presence of residual PEEP in the alveoli that is greater than the PEEP set at the ventilator, referred to as **auto-PEEP**. Some time is required for pressure equilibration to occur between alveoli and the atmosphere, which is reflected in the *time constant* (TC). It takes 3 TCs for 95% (and 5 TCs for 99%) of pressure equilibration to occur. The TC depends on compliance (C) and resistance (R), and their relationship is depicted in Figure 86.6. TC is calculated as compliance multiplied by resistance (C × R) and is measured in seconds.

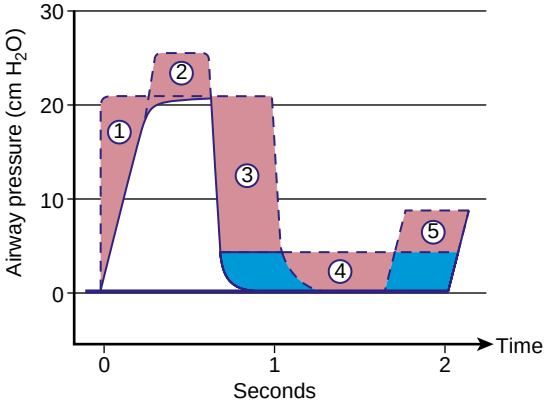

Fig. 86.5 Five different ways to increase mean airway pressure. *(1)* Increase the respiratory flow rate, producing a square wave inspiratory pattern; *(2)* increase the peak inspiratory pressure; *(3)* reverse the inspiratory-expiratory ratio or prolong the inspiratory time without changing the rate; *(4)* increase positive end-expiratory pressure; and *(5)* increase the ventilatory rate by reducing the expiratory time without changing the inspiratory time. *(From Harris TR, Wood BR. Physiologic principles. In Goldsmith JP, Karotkin EH, eds.* Assisted Ventilation of the Neonate, *3rd ed. Philadelphia: Saunders;1996.)*

Diseases with decreased compliance (increased elastance) are characterized by high elastic recoil pressure, which results in more rapid equilibration of alveolar and ventilator pressures, thereby decreasing TC. Diseases with increased airway resistance are associated with slower flow rates, require longer time for movement of air from one place to another, and therefore have increased TC. Airways expand during inspiration and narrow during expiration. Therefore expiratory time constant (TCE) is longer than inspiratory time constant (TCI). In intrathoracic airway obstruction (e.g., asthma, bronchiolitis, aspirated foreign body), airway narrowing is much more pronounced during expiration. Therefore although both TCE and TCI are prolonged in such diseases, TCE is much more prolonged than TCI. Patients with such diseases therefore are best ventilated with slower rates, larger VT, and longer expiratory time than inspiratory time. In diseases characterized by decreased compliance, both TCE and TCI are short; however, the TCE is closer to TCI than in normal lungs because the stiffer alveoli recoil with greater force. Patients with these diseases are best ventilated with smaller VT to prevent VILI, increased respiratory rate, and a relatively longer inspiratory time in each breath to improve oxygenation.

Critical Opening Pressure

Collapsed or atelectatic alveoli require a considerable amount of pressure to open. Once open, the alveoli require relatively less pressure for continued expansion. The process of opening atelectatic alveoli is called **recruitment**. In a normal lung, alveoli remain open at end expiration, and therefore the lung requires relatively less pressure to receive its VT. In a disease process in which alveoli collapse at end expiration (e.g., PARDS), a substantial amount of pressure is required to open the alveoli during inspiration. This pressure causes VILI by two mechanisms: *barotrauma* at the terminal airway-alveolar junction and *volutrauma* as a result of overdistention of alveoli that are already open (see Figs. 86.2 and 86.3). Although pulmonary parenchymal disease is rarely uniform and each of the millions of alveoli may have its own mechanical characteristics, a composite volume-pressure relationship could be conceptualized for the whole lung (Fig. 86.7).

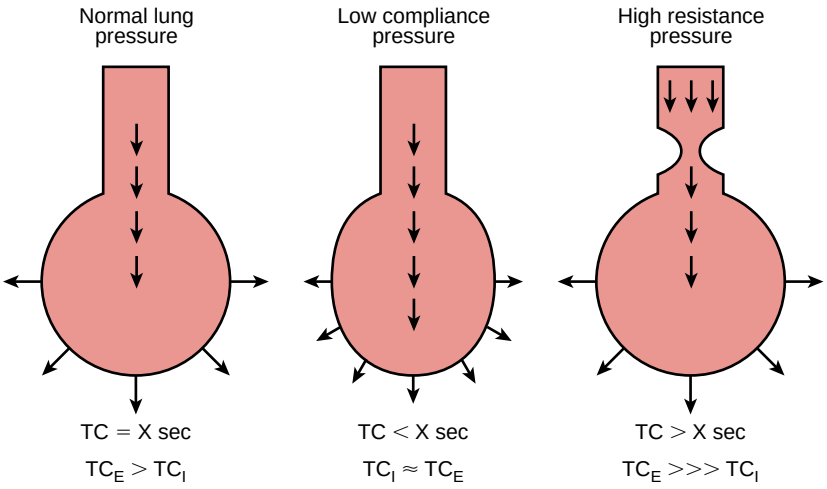

Fig. 86.6 Time constant (TC). A certain amount of time is necessary for pressure equilibration (and therefore completion of delivery of gas) to occur between the proximal airway and alveoli. TC, a reflection of time required for pressure equilibration, is a product of compliance and resistance. In diseases of decreased lung compliance, less time is needed for pressure equilibration to occur, whereas in diseases of increased airway resistance, more time is required. Expiratory TC (TC_E) is increased much more than inspiratory TC (TC_I) in obstructive airway diseases because airway narrowing is exaggerated during expiration.

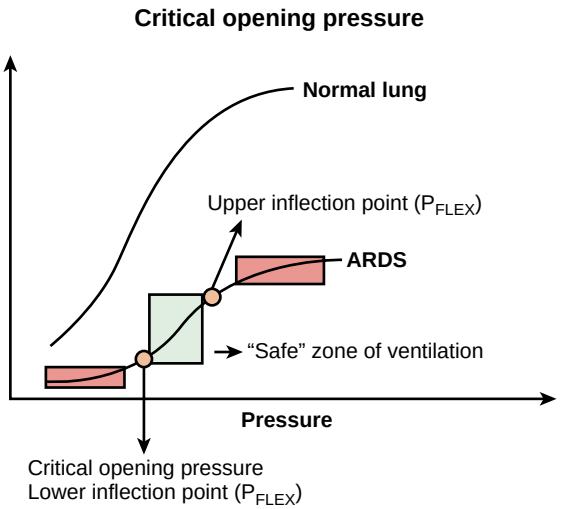

Fig. 86.7 Volume-pressure relationship in normal lung and in acute respiratory distress syndrome (ARDS). In ARDS, atelectatic alveoli require a considerable amount of pressure to open. Critical opening pressure, also referred to as lower P_{FLEX}, is the airway pressure above which further alveolar expansion occurs with relatively less pressure. Upper P_{FLEX} is the airway pressure above which further increase in pressure results in less alveolar expansion; this is the area of alveolar overdistention. Keeping tidal volume between upper and lower P_{FLEX} values is considered less injurious to the lung.

In these situations, the lower and upper portions of the curve are relatively horizontal and the middle portion is more vertical. At the beginning of inspiration, atelectatic alveoli are being recruited, requiring high pressure for a relatively small increase in volume. Once they are recruited, further increase in volume requires relatively less pressure. The pressure at which most alveoli are open is called *critical opening pressure;* this point is also referred to as the *lower inflection point* (lower P_{FLEX}). After the lower P_{FLEX}, greater volume can be delivered for relatively less pressure until the upper P_{FLEX} is reached, at which point the volume-pressure curve again becomes relatively horizontal. The goal of mechanical ventilation in alveolar interstitial pathology is to deliver a VT between the lower and upper inflection points, the so-called *safe zone of ventilation.* If VT is delivered with a change in inflation pressure that includes the lower P_{FLEX}, alveoli are likely to open *and* close during every breath, a process termed **tidal recruitment** that is injurious to the lung (atelectrauma), especially at the terminal airway-alveolar junction. If VT is delivered with a change of pressure that includes the upper P_{FLEX}, overdistention of alveoli is likely to occur, resulting in volutrauma and barotrauma. Keeping tidal ventilation between the upper and lower P_{FLEX} values is accomplished by maintaining a level of PEEP to produce baseline alveolar recruitment and delivering a relatively small VT. This lung-protective ventilation is also known as "open lung" strategy and is the preferred approach in diffuse alveolar interstitial diseases such as PARDS.

Mechanical ventilation may be delivered either noninvasively with a patient-machine interface other than an ETT or invasively after endotracheal intubation.

NONINVASIVE MECHANICAL VENTILATION

Delivering positive pressure mechanical respiratory support without the use of endotracheal intubation is called noninvasive positive pressure ventilation **(NIPPV)**. This type of respiratory support has been increasingly used in the pediatric intensive care setting.

The most common techniques applied are continuous positive airway pressure **(CPAP)** or biphasic (inspiratory and expiratory) positive airway pressure **(BiPAP)**. Of note, CPAP is only the delivery of a continuous airway pressure; therefore by definition, it is not a true form of noninvasive ventilation because a minute volume is generated exclusively by the patient, not by the device. A variety of devices with increasing sophistication has been developed in recent years, and different interfaces are available, such as nasal prongs, nasal and full-face masks, and helmets. Especially in the pediatric population, an age-appropriate, properly sized, and comfortable interface that minimizes air leak is critical for the successful application of NIPPV. NIPPV has been successfully used in acute and chronic hypoxic and/or hypercarbic respiratory failure. Indications range from acute lower airway obstruction, such as asthma, or acute upper airway obstruction, including postextubation airway swelling, to parenchymal lung diseases such as pneumonia and mild to moderate PARDS. Acute and chronic respiratory failure from neuromuscular weakness or chest wall deformities have been the classic indication for its use. NIPPV can also be used to help prevent reintubation after prolonged mechanical ventilation.

BiPAP provides positive airway pressure during exhalation and additional positive pressure during inspiration. These pressures can be adjusted independently to suit individual needs and comfort, and a respiratory rate can be delivered. The additional positive pressure during inspiration helps improve alveolar ventilation in low compliance and obstructive lung disease. During exhalation, expiratory positive airway pressure can decrease the effects of airway closure by raising intraluminal pressure and ameliorating intrathoracic airway collapse. During inspiration, inspiratory positive airway pressure unloads inspiratory muscle work.

These mechanics may explain many of the physiologic benefits of NIPPV, including an increase in lung compliance and FRC, a decrease of dynamic airway narrowing, augmentation of VT and alveolar ventilation, and decreased work of breathing. Physiologic benefits of NIPPV in obstructive (e.g., asthma) and restrictive (e.g., PARDS) lung disease are schematically presented in Figures 86.8 and 86.9. Additional benefits result from improving cardiopulmonary interactions, especially LV afterload reduction, thereby improving cardiac output in patients with acute or chronic LV dysfunction.

NIPPV is often well tolerated and may be associated with fewer complications compared to invasive mechanical ventilation; airway trauma from endotracheal intubation can be avoided, and less sedation is required. Breaks can be given for the administration of oral medications and clearance of respiratory secretions, and selected stable patients can be fed by mouth. The rate of nosocomial infections, ventilator-associated pneumonia, and VILI is expected to decrease as well. In addition, aerosol therapy delivered by NIPPV appears to be more effective.

Complications of NIPPV include pressure injury, upper airway mucosal irritation, abdominal distention, aspiration, feeding intolerance, and pulmonary hyperinflation with resulting interstitial emphysema, pneumomediastinum, and pneumothorax. Patients initiated on NIPPV need close cardiorespiratory monitoring because the respiratory failure may progress, leading to the need for endotracheal intubation. Patients with more severe respiratory distress and those who do not show improvement of respiratory indices (i.e., respiratory rate, SpO_2/FIO_2 ratio, reduction in FIO_2) within 2 hours of initiation are more likely to require invasive ventilation. Patients with underlying severe systemic diseases such as sepsis, multiorgan dysfunction, and malignancies are less likely to respond favorably to NIPPV. Absolute contraindications include loss of airway reflexes, acute severe neurologic insults, cardiorespiratory arrest, and severe hemodynamic instability. Patients with midface abnormalities or facial trauma and burns should not be considered candidates for NIPPV. Other contraindications include the immediate postoperative period after facial and upper airway surgery, recent gastrointestinal surgery, or patients with bowel obstruction and vomiting. Patients who are severely agitated and confused should not be initiated on NIPPV. NIPPV has been shown to decrease intubation rates and reintubation rates after liberation from invasive mechanical ventilation, and has been increasingly used to treat acute or chronic respiratory failure in pediatric patients.

INVASIVE MECHANICAL VENTILATION

Mechanical ventilation involves considering the four phases of the respiratory cycle: (1) initiation of respiration and a variable that is controlled, often referred to as *mode;* (2) inspiratory phase characteristics, which determine the duration of inspiration and how the pressure or

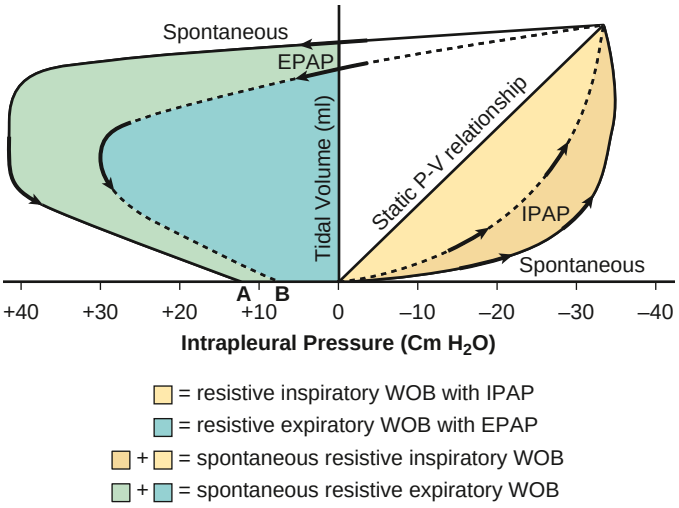

Fig. 86.8 Work of breathing (WOB) in status asthmaticus with and without noninvasive positive pressure ventilation. In the expiratory limb of the respiratory cycle, the equal pressure point is displaced distally, causing airways to begin to close at a higher lung volume (increased closing capacity), leading to dynamic hyperinflation, and auto–positive end-expiratory pressure (auto-PEEP). *(A),* Application of expiratory positive airway pressure (EPAP) stents the airways, reducing intrathoracic airway collapse, dynamic hyperinflation, auto-PEEP *(B),* and WOB. In the inspiratory limb, the patient needs to generate less negative pressure to initiate inspiration because of lower auto-PEEP. Inspiratory muscles are further unloaded by inspiratory positive airway pressure (IPAP) throughout inspiration for the given tidal volume. Both expiratory and inspiratory WOB are thus reduced by application of noninvasive positive pressure ventilation. P-V, Pressure-volume. *(From Sarnaik AA, Sarnaik AP. Noninvasive ventilation in pediatric status asthmaticus: Sound physiologic rationale but is it really safe, effective, and cost-efficient?* Pediatr Crit Care Med. *2012;13:484-485.)*

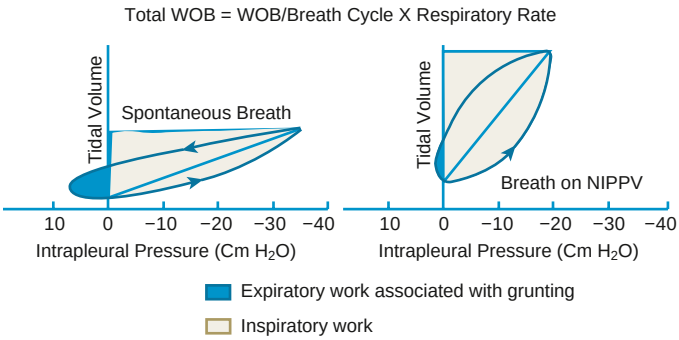

Fig. 86.9 Beneficial physiologic pulmonary effects of noninvasive positive pressure ventilation (NIPPV) in restrictive lung disease (e.g., ARDS). *Left,* Without NIPPV, the slope of pressure-volume relationship is flatter, resulting in lower tidal volume for a given inflation pressure and necessitating an increased respiratory rate to maintain required minute alveolar ventilation. Start of inspiration is at a lower lung volume, indicating decreased functional residual capacity (FRC). Expiration is active toward the end as a result of grunting aimed at increasing FRC. *Right,* On institution of NIPPV, the slope of the pressure-volume relationship is increased, resulting in greater tidal volume for a given inflation pressure, with a subsequent decrease in respiratory rate and inspiratory work of breathing (WOB). FRC is increased because of expiratory positive airway pressure (EPAP), resulting in improved oxygenation and decreased expiratory work associated with grunting.

volume is delivered; (3) termination of inspiration, often referred to as *cycle;* and (4) expiratory phase characteristics. Ventilation should not completely take over the work of breathing unless indicated in specific clinical conditions, such as in severe traumatic brain injury or pulmonary hypertensive crisis, but rather should assist the patient's own respiratory effort, if present.

Initiation of Inspiration and the Control Variable (Mode)

The initiation of inspiration may be set to occur at a predetermined rate and interval regardless of patient effort, or it could be timed in response to patient effort. Once inspiration is initiated, the ventilator breath either is controlled entirely by the ventilator *(control mode)* or supports the patient's inspiratory effort to a predetermined inspiratory volume or pressure target *(support mode).* Advances in technology allow for greater patient-ventilator synchrony to occur. The ventilator may be set to be *triggered* by the signal it receives as a result of patient effort. This feature may be in the form of lowering of either pressure *(pressure trigger)* or airflow *(flow trigger)* in the ventilator circuit generated by the patient's inspiratory effort. If no such signal is received because of lack of patient effort, the ventilator delivers a breath at an interval selected by the operator. Most ventilators make use of flow triggering.

Control Modes

Intermittent Mandatory Ventilation Mode. In intermittent mandatory ventilation **(IMV)**, inspiration is initiated at a set frequency with a timing mechanism independent of patient effort. In between machine-delivered breaths, the patient can breathe spontaneously from a fresh source of gas. IMV allows for adjustment of ventilator support according to the patient's needs, making it useful in the weaning process. Lack of synchrony between machine-delivered breaths and patient efforts may result in ineffective ventilation and patient discomfort, especially when IMV is delivered at a high rate. In such cases the patient may require sedation and pharmacologic neuromuscular blockade for efficient delivery of VT. To obviate this problem, **synchronized IMV (SIMV)** is preferred, whereby the machine-delivered breaths are triggered by the patient's inspiratory efforts (Fig. 86.10). In between the machine-delivered breaths, a fresh source of gas is available for spontaneous patient breaths. In the absence of patient effort, the patient receives a predetermined backup rate. Even with SIMV, ventilator-patient asynchrony can occur because VT, inflation pressure, and inspiratory time are determined by the ventilator alone.

Assist-Control Mode. In assist-control (AC) mode, every patient breath is triggered by pressure or flow generated by patient inspiratory effort and "assisted" with either preselected inspiratory pressure or volume. The rate of delivered breaths is therefore determined by the patient's inherent respiratory rate. A backup total (patient and ventilator) obligatory rate is set to deliver a minimum number of breaths. For illustration, on AC mode with a backup rate of 20 breaths/min and a patient's inherent rate of 15 breaths/min, the ventilator will assist all the patient's breaths and the patient will receive 5 additional breaths/min. On the other hand, a patient with an inherent rate of 25 breaths/min will receive all 25 breaths assisted. Although useful in some patients, the AC mode cannot be used in the weaning process, which involves gradual decrease in ventilator support.

Control Variable

Once initiated, either the VT or the pressure delivered by the machine can be controlled. The machine-delivered breath is thus referred to as either volume controlled or pressure controlled (Table 86.12). With **volume-controlled ventilation (VCV)**, machine-delivered volume is the primary control, and the inflation pressure generated depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance are therefore easily detected from changes observed in inflation pressure. In **pressure-controlled ventilation (PCV)**, the pressure change above the baseline is the primary control, and the VT delivered to the lungs depends on the respiratory system's C and R. Changes in respiratory system C and R do not affect inflation pressure and may therefore go undetected unless the exhaled VT is closely monitored. VCV and PCV have their own advantages and disadvantages (see Table 86.12). Favoring one mode over the other is largely driven by institutional preference and personal beliefs. VCV is characterized by a constant inspiratory flow with

a constant, preset VT, whereas PCV makes use of a decelerative flow pattern, with a variable delivered VT. A potential benefit of PCV is that the inspiratory pressures are limited, making it a more attractive mode in disease conditions where there is airway obstruction, preventing the normally compliant alveolus from being exposed to large VT. Generally speaking, PCV is more efficient than VCV in terms of amount of VT delivered for a given inflation pressure during ventilation of a lung that has nonuniform TC, as in asthma. In VCV, relatively less-obstructed airways are likely to receive more of the machine-delivered volume throughout inspiration than relatively more obstructed airways with longer TC (Fig. 86.11A). This situation would result in uneven ventilation, higher peak inspiratory pressure (PIP), and a decrease in C_{DYN}. In PCV, because of a constant inflation pressure that is held throughout inspiration, relatively less obstructed lung units with shorter TC would achieve pressure equilibration earlier during inspiration than the relatively more obstructed areas. Thus units with shorter TCs would attain their final volume earlier in inspiration, and those with longer TCs would continue to receive additional volume later in inspiration (see Fig. 86.11B). This situation would result in more uniform distribution of inspired gas, delivery of more VT for the same inflation pressure, and improved C_{DYN} compared with VCV.

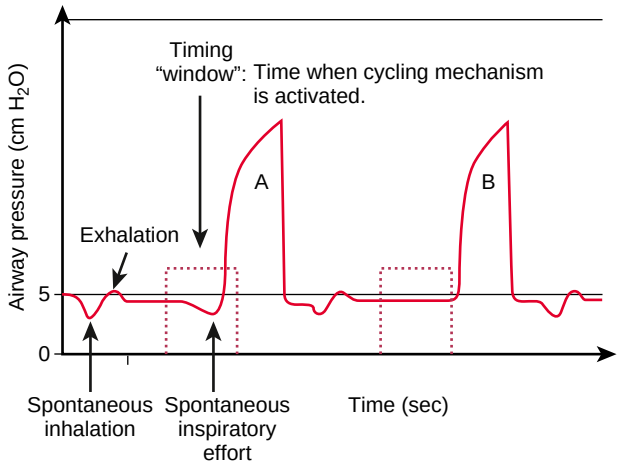

Fig. 86.10 Synchronized intermittent mandatory ventilation. At set intervals, the ventilator's timing circuit becomes activated and a timing "window" appears *(dashed line area)*. If the patient initiates a breath in the timing window, the ventilator delivers a mandatory breath *(A)*. If no spontaneous effort occurs, the ventilator delivers a mandatory breath at a fixed time after the timing window *(B)*. *(From Banner MJ, Gallagher TJ. Respiratory failure in the adult: Ventilatory support. In: Kirby RR, Smith RA, Desautels DA, eds.* Mechanical Ventilation. *New York: Churchill Livingstone;1985.)*

Pressure-regulated volume control (PRVC) combines the characteristics of VCV and PCV. In this mode, VT and TI are controlled as primary variables, but the ventilator determines the lowest amount of pressure needed to deliver the desired VT. Inflation pressure is thus continuously adjusted to deliver the prescribed VT over the TI, depending on the patient's respiratory C and R.

Support Modes

Pressure-support ventilation (PSV) and **volume-support ventilation (VSV)** are designed to support the patient's spontaneous respirations. With PSV, initiation of inspiration is triggered by the patient's spontaneous breath, which is then "supported" by a rapid rise in ventilator pressure to a preselected level. The inspiration is continued until the inspiratory flow rate falls to a set level (generally 25% of peak flow rate) as the patient's lungs inflate. Each inspiration is initiated and terminated by the patient, thus TI is controlled by the patient's own efforts. PSV has no backup rate, so a ventilator breath will not be delivered to the apneic patient. PSV can be combined with SIMV so that any breath above the SIMV rate is supported by PSV. Allowing the patient to control as much of the rate, VT, and inspiratory time as possible is considered to be a more comfortable form of mechanical ventilation than those in which the VT (or inflation pressure) and TI are preset. PSV as the sole source of mechanical ventilator support is often inadequate for patients with severe lung disease and those with a depressed respiratory drive, but may be especially useful in patients being weaned and in those who require mechanical ventilation for relatively minor lung disease or for neuromuscular weakness.

VSV is similar to PSV, in that all the spontaneous breaths are supported. In VSV, inspiratory pressure to support spontaneous breaths is adjusted to guarantee a preset VT goal. If there is a change in respiratory mechanics or patient effort, the inspiratory pressure to support the breath initiated by patient effort is automatically adjusted to achieve the set VT.

Inspiratory Phase Characteristics

Inspiratory flow waveform, TI, and pressure rise time can be adjusted in the inspiratory phase to suit the patient's respiratory mechanics.

In PCV the duration of TI is directly set in seconds. In VCV the TI can be adjusted by adjusting the inspiratory flow (volume/time) and/or setting an inspiratory pause before exhalation starts. Irrespective of ventilator mode, the choice of TI value depends on the respiratory rate, which determines the total duration of each breath, and on the estimation of inspiratory and expiratory TCs. Decreasing the flow rate delivery increases TI, and vice versa. With an increase in TI, the pulmonary capillary blood is exposed to a higher level of P_{AO_2} for a longer time. This feature is beneficial in diseases with decreased EELV, such as PARDS and pulmonary edema. An increase

Table 86.12 Characteristics of Pressure-Controlled and Volume-Controlled Methods of Ventilation

	PRESSURE-CONTROLLED VENTILATION	VOLUME-CONTROLLED VENTILATION
Control setting(s)	Inflation pressure Inspiratory time Rise time	Tidal volume Flow rate Inspiratory flow pattern (constant vs decelerating)
Machine-delivered volume	Depends on respiratory system compliance and resistance	Constant
Inflation pressure	Constant	Depends on respiratory system compliance and resistance
Endotracheal tube leak	Somewhat compensated	Leaked volume part of tidal volume
Distribution of ventilation	More uniform in lungs with varying time constant units	Less uniform in lungs with varying time constant units
Patient comfort	Possibly compromised	Possibly enhanced
Weaning	Inflation pressure adjustment required to deliver desired tidal volume	Tidal volume remains constant; inflation pressure automatically weaned

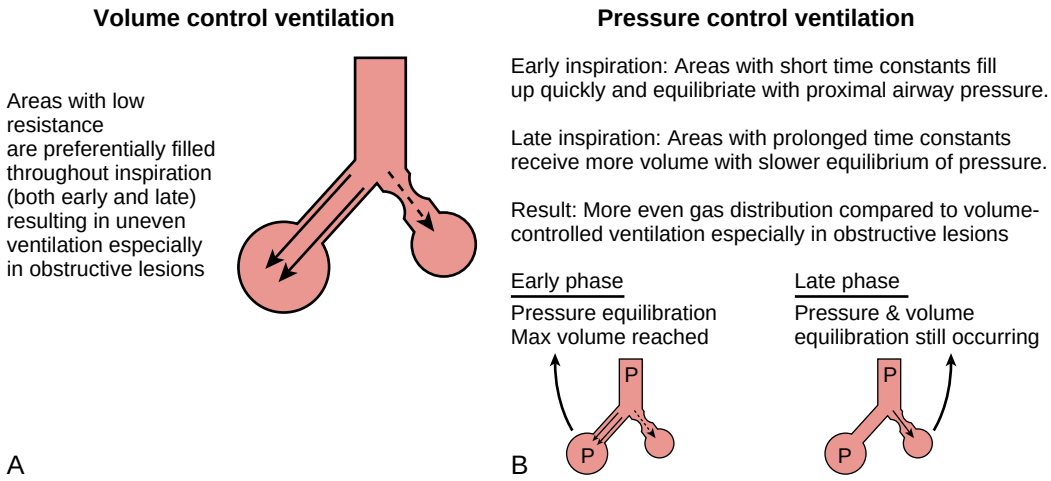

Fig. 86.11 A, In volume-controlled ventilation (VCV), tidal volume (V_T) is delivered to the less obstructed areas throughout inspiration. Obstructed areas of the lung therefore receive a lower proportion of V_T, resulting in uneven ventilation. B, In pressure-controlled ventilation (PCV), less obstructed areas equilibrate with inflation pressure and therefore receive most of their V_T early during inspiration. More obstructed areas, with prolonged time constants, require longer time for pressure equilibration and therefore continue to receive a portion of their V_T later during inspiration. The entire V_T is more evenly distributed than with volume-cycled ventilation.

in T_I also increases V_T without increasing inflation pressure in PCV if inspiratory flow is still occurring at end expiration. It must be recognized that at a given ventilator rate, an increase in T_I decreases expiratory time (T_E). Therefore any strategy that employs an increase in the inspiratory component of the respiratory cycle should ensure that the decreased T_E is still sufficient for complete exhalation.

Inspiratory flow waveform can be adjusted in VCV mode as either a constant flow (square waveform) or a decelerating flow (descending ramp waveform). With a square waveform, flow is held constant throughout inspiration. In a descending ramp waveform, flow is maximal at the start of inspiration and declines throughout its duration. It is debatable which flow pattern is better for a given disease.

In PCV and PSV, the prescribed PIP is reached through delivery of airflow. *Pressure rise time* reflects the time required for the ventilator to reach PIP and can be adjusted by control of flow at the beginning of the inspiratory phase. The inspiratory flow rise time may be adjusted to prevent too rapid a rise in inspiratory pressure, which can be uncomfortable for a patient who is awake and lead to dyssynchrony.

Termination of Inspiration (Cycle)

The two most commonly used inspiratory terminating mechanisms in control modes are time-cycled and volume-cycled. With a **time-cycled** mechanical breath, inspiration is terminated after a preselected T_I has elapsed, whereas with **volume-cycled** breath, the inspiration ends after a preselected volume has been delivered by the machine into the ventilator circuit. A time-cycled breath is almost always pressure-limited, with the PIP held constant for the duration of inspiration. A volume-cycled breath can be pressure-limited as a safety mechanism to avoid barotrauma. The inspiration-terminating mechanism is set somewhat differently in support modes. In PSV the inspiration is set to end after the inspiratory flow decreases below a certain percentage (usually 25%) of peak inspiratory flow. This happens when the patient no longer desires to receive additional V_T. Such a breath is termed **flow-cycled**. In VSV the inspiration is terminated when the patient has received the selected V_T.

Expiratory Phase Maneuvers

The most useful expiratory phase maneuver is the application of PEEP, which is applied to both the control breath and the assisted breath. The most important clinical benefits of PEEP are to stabilize recruited alveoli to increase EELV in patients with alveolar-interstitial diseases and thereby improve oxygenation. Any situation where there is zero end-expiratory pressure (ZEEP), as is the case when the patient is disconnected from the ventilator circuit (even if briefly), will result in alveolar **derecruitment** and decline in oxygenation. In patients with obstructive lesions in which insufficient exhalation results in air trapping and auto-PEEP, extrinsic PEEP (applied through a mechanical device) can prevent airway closure during expiration and improve ventilation. Other salutary effects of PEEP include redistribution of extravascular lung water away from gas-exchanging areas, improved $\dot{V}/\dot{Q}$ relationship, stabilization of the chest wall, and reduction in work of breathing in patients with intrinsic PEEP. The effect of PEEP on lung C is variable, depending on the level of PEEP provided and the patient's pulmonary mechanics. By shifting tidal ventilation to a more favorable part of the pressure-volume curve, PEEP may maintain more recruited alveoli, delay airway closure, and improve lung C. Excessive PEEP, on the other hand, may lead to overdistention of alveoli and reduced C. The effect of PEEP in individual patients can be ascertained by measuring exhaled V_T and calculating C_{DYN}. Other potentially deleterious effects of PEEP include decreased venous return, increased pulmonary vascular resistance, and decreased cardiac output.

ADDITIONAL VENTILATORY MODALITIES

Airway Pressure Release Ventilation

Airway pressure release ventilation (**APRV**) aims to improve oxygenation in patients with preserved respiratory drive suffering from severe hypoxemic respiratory failure due to alveolar-interstitial disease. This modality applies a CPAP, designated $CPAP_{HIGH}$, to recruit and maintain EELV with brief intermittent release phases of $CPAP_{LOW}$ to allow alveolar gas to escape. $CPAP_{HIGH}$ is analogous to PIP, and $CPAP_{LOW}$ is similar to setting PEEP. In contrast to the patient receiving conventional mechanical ventilation, a patient receiving APRV spends the majority of time in the $CPAP_{HIGH}$ phase, which may last as long as 3-5 seconds with a brief (0.3-0.5 seconds) time in the $CPAP_{LOW}$ phase. These atypically long T_Is are tolerated because of a floating expiratory valve in the ventilator circuit that permits spontaneous breathing during $CPAP_{HIGH}$ phase. Therefore even if the $CPAP_{HIGH}$ phase can be considered "inspiratory" and the $CPAP_{LOW}$ phase "expiratory" in regard to the ventilator, the patient is able to breathe spontaneously during both these phases. The longer ventilator T_I recruits lung units, and the ability to breathe spontaneously during this phase allows distribution of gas flow to atelectatic lung regions. The outcome benefit of APRV in pediatric hypoxemic respiratory failure has not been proven.

High-Frequency Ventilation

Mechanical ventilation at supraphysiologic rates and low V_T, known as high-frequency ventilation (**HFV**), improves gas exchange in a select group of patients who show no response to more traditional ventilatory modalities. The mechanism of alveolar ventilation in HFV is very different from that in conventional ventilation, in that HFV is less dependent

on VT and more dependent on asymmetric velocities and convective dispersion of inspired gas. Patients with severe persistent hypoxic failure are most likely to benefit from HFV. HFV is also helpful in patients with bronchopleural fistula and persistent air leaks. The main tenet of HFV is to recruit lung volume with a high mean airway pressure (MAP) and produce smaller fluctuations in alveolar pressure during inspiration and expiration, thus maintaining a satisfactory EELV and reducing alveolar stretch. The two most investigated techniques of HFV are HFOV and HFJV.

The most commonly used HFV modality is **high-frequency oscillatory ventilation (HFOV)**, which employs a mechanism to generate to-and-fro air movement. Additional air is drawn in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively pulled out during expiration. The main determinants of oxygenation are F_{IO_2} and MAP, whereas ventilation is determined by changes in pressure (amplitude) around the MAP and frequency. The optimal frequency varies for the individual patient and disease process and depends on the so-called *corner frequency,* where the pressure cost of ventilation is the lowest. In PARDS this usually means frequency >8 Hz, irrespective of age.

In **high-frequency jet ventilation (HFJV)**, a high-frequency interrupter is interposed between a high-pressure gas source and a small cannula that is incorporated in the ETT. The cannula propels tiny amounts of gas (jets) at high velocity and high frequency through the ETT. An additional amount of gas is entrained from a parallel circuit. Unlike in HFOV, expiration occurs passively in HFJV as a result of elastic recoil of the lung and the chest wall. PEEP is set through the parallel circuit by a conventional ventilator in-line. Respiratory rate is generally set at 420 breaths/min. Major determinants of oxygenation are F_{IO_2} and PEEP, and the major determinant of ventilation is PIP.

CONVENTIONAL VENTILATOR SETTINGS

Fraction of Inspired Oxygen

The shape of the hemoglobin-O_2 dissociation curve dictates that oxygen content in the blood is not linearly related to P_{AO_2}. A P_{AO_2} value that results in an oxyhemoglobin saturation of ≤97% is reasonable in most situations, because a higher P_{AO_2} would cause minimal increase in arterial oxygen content, and a modest (10 mm Hg) drop in P_{AO_2} would result in minimal decrease in oxyhemoglobin saturation. In most cases, a P_{AO_2} value of >60 mm Hg is a reasonable goal. F_{IO_2} values that are higher than those necessary to attain oxyhemoglobin saturations of approximately 95% expose the patient to unnecessary oxygen toxicity. Whenever possible, F_{IO_2} values should be decreased to a level ≤0.40 as long as oxyhemoglobin saturation remains ≥92%. In patients with severe lung disease, oxyhemoglobin saturation of 88–92% may be acceptable.

Mode

The choice of mode of ventilation depends on the disease entity that is being treated and how much ventilator-patient interaction is desired. SIMV or AC is chosen as the control mode; PCV, VCV, or PRVC as the variable that is to be controlled; and pressure support and volume support are the choices for support modes. SIMV pressure-controlled modes are most commonly used in children.

Tidal Volume and Rate

As previously discussed, alveolar ventilation, the chief determinant of P_{ACO_2}, is calculated using VT, respiratory rate, and VD. A change in VT results in a corresponding change in alveolar ventilation without affecting VD-ventilation. A change in respiratory rate will affect alveolar ventilation and the VD-ventilation. Choice of VT and rate depends on the TC. In a patient with relatively normal lung compliance, an age-appropriate ventilator rate and a VT of 5-8 mL/kg would be appropriate initial settings. Diseases associated with decreased TC (decreased static compliance; e.g., PARDS, pneumonia, pulmonary edema) are best treated with small (4-6 mL/kg) VT and relatively rapid rates (e.g., 25-40 breaths/min). Diseases associated with prolonged TCs (increased airway resistance; e.g., asthma, bronchiolitis) are best treated with relatively slow rates and higher (10-12 mL/kg) VT. In PCV the delivered VT depends on the C and R of the patient's respiratory system and needs to be monitored to ensure the appropriate amount for a given situation. The operator titrates the inflation pressure, depending on the volume of exhaled VT. It should be emphasized that achieving a *normal* P_{ACO_2} value is not a goal of mechanical ventilation. Some degree of hypercapnia (permissive hypercapnia) should be accepted, especially when one is attempting to limit injurious inflation pressures or VT.

Inspiratory Time and Expiratory Time

TI and TE are adjusted by setting inspiratory flow rate and/or inspiratory pause in VCV and by setting the precise TI in PCV. Increasing the TI results in increased MAP, improved oxygenation in diseases with decreased EELV, and potentially a better distribution of VT in obstructive lung disease. Sufficient expiratory time must be provided to ensure adequate emptying of the alveoli.

Positive End-Expiratory Pressure

The best level of PEEP depends on the disease entity that is being treated, and it may change in the same patient from time to time. Decisions are often based on the P_{AO_2}/F_{IO_2} ratio and the measurement of C_{DYN}. For patients with PARDS, the adult-based $PEEP/F_{IO_2}$ grid may be useful.

PATIENT-VENTILATOR ASYNCHRONY

Patient-ventilator asynchrony occurs when the patient's respiratory pattern does not match that of the ventilator. This can occur during all phases of respiration. Adverse effects of patient-ventilator asynchrony include wasted effort, ineffective delivery of desired VT, excessive generation of intrathoracic pressure resulting in injury and adverse effects on cardiac output, increased work of breathing, and patient discomfort. Although several mechanisms exist to facilitate patient-ventilator synchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.

Triggering the Ventilator

The patient must be able to trigger the ventilator without excessive effort. Ventilators can be pressure-triggered or flow-triggered. With **pressure triggering**, the inspiratory valve opens and flow is delivered when a set negative pressure is generated within the patient-ventilator circuit during inspiration. The amount of pressure required to trigger an inspiration depends on the pressure trigger sensitivity. In **flow triggering**, the ventilator provides a base flow of gas through the ventilator-patient circuit. When a flow sensor on the expiratory limb of the patient-ventilator circuit detects a decrease in flow as a result of the patient's inspiratory effort, the inspiratory valve opens and a ventilator breath is delivered. The degree of change in flow required to trigger an inspiration depends on the flow trigger sensitivity. Flow triggering is considered to be more comfortable, primarily because the patient receives some flow before triggering the ventilator, in contrast to pressure triggering, in which no flow is provided until the ventilator breath is triggered through generation of negative pressure. Increasing the trigger sensitivity by decreasing the change in either pressure or flow needed to trigger an inspiration decreases the work of breathing and may improve comfort. However, reducing the required pressure or flow excessively could result in accidental triggering and unwanted breaths by turbulence, caused by condensation in the ventilator circuit, endotracheal tube (ETT) air leaks, or cardiac oscillations.

Selection of Appropriate Inspiratory Time

The duration of TI should match the patient's own inspiratory phase. If TI is too long, the patient's drive to exhale may begin before the ventilator breath has cycled off. When this occurs, exhalation occurs against inspiratory flow and a closed exhalation valve, resulting in increased work of breathing, excessive rise in intrathoracic pressure, and discomfort. If TI is too short, the patient may be still inhaling without respirator support. In general terms, TI is usually initiated at 0.5-0.7 second for neonates, 0.8-1 second in older children, and 1-1.2 second for adolescents and adults, but should really be driven by the inspiratory TC. Adjustments need to be made through individual patient observations and according to the type of lung disease present. In patients with severe lung disease (both obstructive and restrictive), unnatural TI and TE values may have to be selected, as discussed earlier. In such situations, adequate analgesia, sedation, and, in extreme cases, neuromuscular blockade may be needed.

Selection of Inspiratory Flow Pattern

In VCV, inappropriate flow may be another source of patient-ventilator dyssynchrony. After initiation of inspiration, if the set amount of flow is

inadequate to meet patient demand, a state of **flow starvation** occurs, resulting in excessive work of breathing and discomfort. Such patients may require a decelerating inspiratory flow pattern, in which a higher flow is provided in the beginning of inspiration and less toward the end as the lungs fill up. On the other hand, such a pattern may be uncomfortable for a patient who desires more gradual alveolar filling. The selection of inspiratory flow pattern should be based on the individual patient's respiratory mechanics. In PCV and PSV, the inspiratory rise time determines the manner in which the airway pressure is raised and VT delivered. Considerations for choosing the appropriate rise time in PCV and PSV are similar to those for choosing the inspiratory flow pattern in VCV.

Use of Support Modes

A conscious patient should be allowed to have spontaneous breaths that are supported by either PSV or VSV. This approach minimizes the mandatory breaths generated by the ventilator that are beyond the patient's control to modulate. Therefore continued assessments should be made to determine whether the patient is able to maintain ventilatory requirements more in support modes and less in control modes.

Use of Sedation and Neuromuscular Blockade

Having a conscious yet comfortable patient is a desirable goal during mechanical ventilation. Spontaneous breaths with good muscle tone and presence of cough are important for adequate clearance of tracheobronchial secretions. The patient's ability to indicate distress is also important in identifying and preventing potential injurious factors. In certain situations, management of patient-ventilator asynchrony assumes much greater importance when the asynchrony is causing unacceptable derangement of gas exchange and VILI. Both alveolar interstitial lung pathology and obstructive airway diseases may necessitate unnatural and uncomfortable settings for respiratory rate, TI, and inflation pressures. In such patients, deep sedation is often necessary; dexmedetomidine, benzodiazepines, and opiates are the agents most commonly used for this purpose. In extreme situations, pharmacologic neuromuscular blockade is required to abolish any patient effort and respiratory muscle tone. When such pharmacologic paralysis is used, deep sedation must be ensured so that the patient does not sense pain and discomfort. Pharmacologic sedation and paralysis can ensure total control of the patient's ventilation by mechanical means and may result in lifesaving improvement in gas exchange with reduction in inflation pressures. However, long-term use of such agents may be associated with undesirable consequences and higher morbidity. The risk of inadequate clearance of tracheobronchial secretions and atelectasis is potentially greater. Long-term use of pharmacologic sedation may be associated with chemical dependency and withdrawal manifestations, and prolonged neuromuscular blockade is associated with neuromyopathy in critically ill patients. The benefits of sedation and pharmacologic paralysis therefore should be carefully balanced with the risks, and periodic assessments should be made to determine the need for their continuation.

Cardiopulmonary Interactions

Mechanical ventilation can have salutary and adverse effects on cardiac performance. By decreasing oxygen consumption necessary for work of breathing, oxygen supply to vital organs is improved. Positive pressure breathing decreases LV afterload, thus enhancing stroke volume and cardiac output in patients with a failing myocardium (e.g., myocarditis). On the other hand, the decreased systemic venous return may further compromise stroke volume in hypovolemic (preload-dependent) patients. Such patients will require intravascular fluid loading when subjected to positive pressure ventilation. Also, an increase in pulmonary vascular resistance (PVR) caused by positive intrathoracic pressure may result in further decompensation of a poorly performing right ventricle. PVR is at its lowest value at an optimum FRC. When FRC is too low or too high, PVR (and therefore the right ventricular afterload) is increased. Both desirable and undesirable effects of cardiopulmonary interactions may coexist and require ongoing assessment and necessary interventions (Table 86.13).

Table 86.13 Suggested Mechanical Ventilation Strategies in Various Clinical Situations

SITUATION	DISEASE	STRATEGY
Low compliance, normal resistance	ARDS	PCV, APRV, HFOV
Normal compliance, high resistance	Asthma	PCV, PRVC
Normal compliance, normal resistance, for weaning	Head trauma, drug overdose, subglottic stenosis	VCV

APRV, Airway pressure release ventilation; ARDS, acute respiratory distress syndrome; HFOV, high-frequency oscillatory ventilation; PCV, pressure-controlled ventilation; PRVC, pressure-regulated volume control; VCV, volume-controlled ventilation.

MONITORING RESPIRATORY MECHANICS

Exhaled Tidal Volume

Exhaled tidal volume (VTE) is measured by a pneumotachometer in the ventilator circuit during exhalation; in small children, it is preferably measured near the connection of the ETT. Measurement of VTE more accurately describes the VT that is contributing to the patient's alveolar ventilation. In PCV the VTE depends on the patient's respiratory system compliance and resistance and therefore offers valuable diagnostic clues. A decrease in VTE during PCV is indicative of either decrease in compliance or increase in resistance and is helpful in directing the clinician to appropriate investigation and management. An increase in VTE is indicative of improvement and may require weaning of inflation pressures to adjust the VTE.

Peak Inspiratory Pressure

In VCV and PRVC, the PIP is the secondary variable determined by the patient's respiratory system compliance and resistance. An increase in PIP in these modes is indicative of decreased C (e.g., atelectasis, pulmonary edema, pneumothorax) or increased R (e.g., bronchospasm, obstructed ETT). During VCV and PRVC, decreasing the respiratory rate or prolonging the TI will result in a lower PIP in patients with prolonged TCs because more time will be available for alveoli to fill. In such patients, a decrease in PIP (or plateau pressure when an inspiratory pause is set during VCV) suggests increased C or decreased R of the respiratory system.

Respiratory System Dynamic Compliance and Static Compliance

The changes in PIP (or plateau pressure) during VCV and PRVC, and in VTE during PCV, are determined by C_{DYN} of the respiratory system (lung and chest wall). C_{DYN} is calculated as follows

$$C_{DYN} = V_{TE} \div (PIP - PEEP)$$

C_{DYN} takes into account both the flow-resistive and the elastic properties of the respiratory system. Changes in C_{DYN} can be used to assess effects of different levels of PEEP as tidal ventilation is shifted along the slope of the volume-pressure curve (see Fig. 86.7). An increase in PEEP in alveolar-interstitial diseases (increased elastance), resulting in an increase in C_{DYN}, suggests alveolar recruitment, whereas a decrease in C_{DYN} may indicate overdistention. Similarly, in obstructive diseases (increased R), adjustment in PEEP levels to ameliorate airway collapse during exhalation can be guided by monitoring C_{DYN}. To assess only the elastic recoil of the lung, measurement of C_{STAT} when there is no airflow is required. This measurement is performed by using an inspiratory hold maneuver with the patient under neuromuscular blockade and observing pressure-time and flow-time waveforms (Fig. 86.12). During this maneuver, inspiratory flow ceases while the expiratory valve continues to remain closed, thus allowing pressure to equilibrate throughout the ventilator circuit and the patient's lungs. This pressure, referred to as the *plateau pressure* (P_{plat}), reflects alveolar pressure. C_{STAT} is calculated as follows:

$$C_{STAT} = V_{TE} \div (P_{plat} - PEEP)$$

The difference between C_{DYN} and C_{STAT} is attributable to airway resistance. This difference is minimal in alveolar-interstitial diseases but substantial in airway obstruction.

Assessment of Auto-PEEP

Auto-PEEP is assessed with the use of an expiratory pause maneuver in which inspiration is delayed and alveolar pressure is allowed to

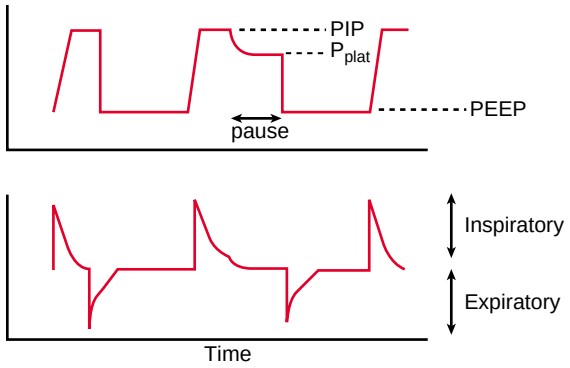

Fig. 86.12 Alveolar pressure is best determined by measurement of plateau pressure (P_{plat}). Inspiration is paused for an extended period, and alveolar gas pressure is allowed to equilibrate with the ventilator circuit pressure. Airway pressure at the end of the inspiratory pause is P_{plat}. The difference between peak inspiratory pressure (PIP) and P_{plat} is meant to overcome flow-resistive properties of the lung, whereas P_{plat} reflects the pressure needed to overcome elastic properties of the lung and chest wall. PEEP, Positive end-expiratory pressure.

equilibrate with the airway. In diseases with airway obstruction, insufficient alveolar emptying may occur if exhalation time is not adequate. The alveolar pressure in excess of the set PEEP at the completion of the expiratory pause is measured as auto-PEEP or intrinsic PEEP. Auto-PEEP can have adverse effects on ventilation and hemodynamic status. It can be managed by decreasing the respiratory rate or TI and thus allowing longer time for exhalation. Auto-PEEP may also be managed by increasing the set PEEP (*extrinsic* PEEP), thereby delaying airway closure during exhalation and improving alveolar emptying.

Assessment of Dead Space Ventilation

Positive pressure ventilation and application of PEEP may result in a decrease in venous return, cardiac output, and therefore pulmonary perfusion. Ventilation of poorly perfused alveoli results in dead space ventilation, which does not contribute to gas exchange. The VD/VT fraction can be calculated (see Chapter 86). Normal VD/VT is 0.33. Increased VD/VT is indicative of poorly perfused alveoli. Patients with increased VD/VT may require intravascular volume infusion or other means of augmenting the cardiac output to improve pulmonary perfusion. The VD/VT fraction is calculated and displayed by commercially available capnographs, which measure endotracheal $PetCO_2$ continuously.

VENTILATOR-INDUCED LUNG INJURY (VILI)

As with most medical therapies, mechanical ventilation can be harmful. Pathophysiology of VILI can be multifactorial. Large tidal volumes and high inspiratory pressures delivered with increased frequency cause cyclic strain, which may lead to disruption of the tight junctions between the alveolar epithelial and capillary endothelial cells, with intracapillary blebs resulting in alveolar and interstitial edema. This may cause the release of proinflammatory mediators (**biotrauma**) that further injure the lung and travel in the blood outside the lung, contributing to the development of multiorgan failure. Evidence shows that in patients with ARDS, avoidance of VT ≥10 mL/kg and P_{plat} ≥30 cm H_2O limits diffuse alveolar damage.

Atelectrauma is shear stress on the alveolar walls caused by cyclic opening and closing of the alveoli. PEEP can be used to prevent collapse and keep alveoli open. It is important that alveolar units are neither overdistended nor collapsed. Careful adjustments of PEEP may also permit the clinician to wean a patient from a high FIO_2, another potential source of lung injury, through exposure to reactive oxygen species (**oxytrauma**). Although most patients receive an FIO_2 of 1.0 at the time of endotracheal intubation and at the beginning of mechanical ventilation, increasing PEEP to recruit alveoli without overdistention should be quickly instituted to improve oxygenation and permit weaning of the FIO_2. Although the FIO_2 value below which there is no risk of oxygen toxicity is unknown, most clinicians aim for a value <0.6. Regional mechanics may play a role in lung injury.

Ventilator-Associated Pneumonia

The pathophysiology of ventilator-associated pneumonia (VAP) is multifactorial. Aspiration of oral and/or gastric secretions, colonization of the ETT, and suppression of cough reflexes from sedation all play a role. New-onset fever and leukocytosis accompanied by demonstration of an infiltrative process on chest radiography are consistent with a diagnosis of VAP. This complication can lead to worsened gas exchange, increased duration of ventilation, and even death. Elevation of the head of the bed to 30 degrees after initiation of mechanical ventilation and use of a protocol for oral decontamination during mechanical ventilation are common means of reducing the risk for VAP. The most effective strategy to minimize any of the aforementioned complications is regular assessment of extubation readiness and liberation from mechanical ventilation as soon as clinically possible.

Weaning

Weaning from mechanical ventilation should be considered as a patient's respiratory insufficiency begins to improve. Most pediatricians favor gradual weaning from ventilator support. With SIMV, the ventilator rate is slowly reduced, allowing the patient's spontaneous breaths (typically assisted with pressure or volume support) to assume a larger proportion of the minute ventilation. When the ventilator rate is low (<5 breaths/min) such that its contribution to minute ventilation is minimal, assessment of extubation readiness is performed. An alternative method of gradual weaning is transition to PSV. In this mode, no ventilator rate is set, allowing all triggered breaths to be assisted with pressure support. The clinician reduces the pressure support slowly to a low value (<5-10 cm H_2O), at which point assessment of extubation readiness is performed. During either technique, weaning should be halted if tachypnea, increased work of breathing, hypoxemia, hypercapnia, acidosis, diaphoresis, tachycardia, or hypotension occurs.

The most objective means of assessing extubation readiness is a **spontaneous breathing trial (SBT)**. Before performance of an SBT, a patient should be awake with intact airway reflexes, capable of handling oropharyngeal secretions, and with stable hemodynamic status. In addition, gas exchange should be adequate, defined as PaO_2 >60 mm Hg while receiving FIO_2 <0.4 and PEEP ≤5 cm H_2O. If these criteria are present, a patient should be started on CPAP with minimal (≤5 cm H_2O) or no pressure support. If this SBT is tolerated with no episodes of respiratory or cardiovascular decompensation, successful extubation is likely.

Some neonates and small children cannot be calmed or consoled long enough to complete the SBT. In this situation, extubation readiness must be assessed on a low level of ventilator support. Data suggest a low risk of extubation failure if the patient is comfortable and has stable hemodynamic status, with adequate gas exchange and spontaneous VT >6.5 mL/kg while receiving <20% of total minute ventilation from the ventilator. Certain patient populations are at increased risk for extubation failure, such as young infants, children mechanically ventilated for longer than 7 days, and patients with chronic respiratory or neurologic conditions. These children often benefit from transition to a noninvasive form of respiratory support (e.g., high-flow nasal cannula, CPAP, or BiPAP) upon liberation from mechanical ventilation to increase the odds of successful extubation.

The likelihood of **postextubation upper airway obstruction**, the most common cause of extubation failure in children, cannot be predicted by the results of an SBT or bedside measurements of physiologic variables. Traumatic endotracheal intubation and subglottic swelling from ETT irritation, especially in patients who exhibit agitation while receiving mechanical ventilation, are common causes of airway narrowing after extubation. Administration of intravenous corticosteroids (dexamethasone 0.5 mg/kg every 6 hr for four doses before extubation) has been shown to decrease the incidence of postextubation airway obstruction. In patients in whom postextubation airway obstruction develops, the need for reintubation may be obviated by administration of nebulized racemic epinephrine and helium-oxygen mixtures.

blood cells, which begin to appear in the circulation in 4 or 5 days. Hypoxemia also increases 2,3-DPG, resulting in a rightward shift of the oxyhemoglobin dissociation curve and favoring release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the oxyhemoglobin dissociation curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin curve and an increase in oxygen-hemoglobin binding in the lung, raising Sao_2. Climbers at extreme altitude respond with marked hyperventilation, alkalosis, and leftward shift. This leftward shift favors oxygen loading in a hypoxic environment and increases Sao_2.

ACUTE MOUNTAIN SICKNESS

Epidemiology and Risk Factors

The incidence of high-altitude illness depends on several variables, including the rate of ascent, previous altitude exposure, and individual genetic susceptibility. Sleeping altitude, final altitude reached, and duration of stay at altitude are also risk factors for AMS development. Individual susceptibility for the development of AMS plays a significant role in risk assessment. Most individuals with previous histories of AMS after acute ascent are likely to experience similar symptoms with repeated visits to altitude. Gender and age do not affect the incidence of AMS.

AMS is very common with **rapid ascent**. Climbers around the world who ascend quickly (1 or 2 days) from sea level to altitudes of 4,000-6,000 m (~13,000-20,000 ft) have a very high incidence of AMS (27–83%). The rapid ascent profile associated with air travel to high altitude locations also results in high AMS rates. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively moderate altitudes: 2,000-3,000 m (~6,500-9,800 ft). Among this population, AMS occurs in approximately 25%.

Pathophysiology

The symptoms of AMS develop several hours after arrival at high altitude, whereas the development of HAPE and HACE generally require several days of altitude exposure. Because hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness, but rather the initiating factor for a cascade of events that lead to the development of the altitude clinical syndromes.

The clinical manifestations of AMS/HACE are primarily the result of central nervous system (CNS) dysfunction caused by hemodynamic mechanical factors and biochemical mediators of permeability. The CNS vasodilatory response to hypoxemia causes an increase in cerebral blood flow and volume. Significant elevation of brain volume is observed in moderate to severe AMS and HACE but has not been demonstrated in mild AMS. Hypoxic alteration of CNS vascular autoregulation and hypertension from exercise may increase pressure transmission to the brain's capillary beds, resulting in transcapillary leakage and vasogenic edema. Inflammatory mediators also contribute to vascular permeability and edema formation. HIF-mediated vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation can increase permeability. Both mechanical and biochemical activation of the trigeminovascular system have been proposed as the cause of *high-altitude headache*, the primary symptom of AMS. Although vasogenic edema has been implicated in severe AMS and HACE, MRI reveals signal changes in subjects with and without clinical AMS.

Many of these responses to hypoxia and altitude exposure occur both in individuals who develop symptoms and those who remain free of AMS. To address the discrepancy in symptomatic illness, the "tight fit" hypothesis was proposed. This theory suggests that the development of AMS/HACE is due to a lack of intracranial space to accommodate increasing volume from brain swelling and edema that develop at altitude. The adequacy of the intracranial and intraspinal space to buffer changes in brain and cerebrospinal fluid (CSF) volume is the central concept. Buffering occurs as the intracranial CSF is displaced via the foramen magnum into the space available in the spinal canal, followed by increased CSF absorption and decreased CSF production. Individuals with less CSF buffering capacity have less compliance and are hypothesized to become more symptomatic (develop AMS).

Diagnosis

The diagnosis of AMS in older children and adults requires the history of a recent gain in altitude, presence at the new altitude for at least several hours, and the report of a headache plus one or more of the following symptoms: gastrointestinal (GI) upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness, or lightheadedness. The **2018 Lake Louise Acute Mountain Sickness Score** is based on self-report of symptoms and aids clinicians in making the diagnosis and quantifying AMS severity in older children and adolescents (Table 87.1). Symptoms develop within a few hours after ascent and generally reach maximum severity between 24 and 48 hours, followed by gradual resolution. Sleep disturbance caused by periodic breathing is common in all visitors to high altitudes and is not part of the adult diagnostic criteria; sleep disturbance is likely the result of hypoxia rather than AMS. There are no diagnostic physical signs in cases of mild AMS. Any evidence of CNS dysfunction, such as mild ataxia or altered mentation, is early evidence of HACE. Similarly, whereas shortness of breath on exertion is common at high altitudes, dyspnea at rest is an early indicator of HAPE.

Table 87.1 2018 Lake Louise Acute Mountain Sickness Score

HEADACHE
0 – None at all
1 – Mild headache
2 – Moderate headache
3 – Severe headache, incapacitating
GASTROINTESTINAL SYMPTOMS
0 – Good appetite
1 – Poor appetite or nausea
2 – Moderate nausea or vomiting
3 – Severe nausea and vomiting, incapacitating
FATIGUE AND/OR WEAKNESS
0 – Not tired or weak
1 – Mild fatigue/weakness
2 – Moderate fatigue/weakness
3 – Severe fatigue/weakness, incapacitating
DIZZINESS/LIGHTHEADEDNESS
0 – No dizziness/lightheadedness
1 – Mild dizziness/lightheadedness
2 – Moderate dizziness/lightheadedness
3 – Severe dizziness/lightheadedness, incapacitating
AMS CLINICAL FUNCTIONAL SCORE
Overall, if you had AMS symptoms, how did they affect your activities?
0 – Not at all
1 – Symptoms present, but did not force any change in activity or itinerary
2 – My symptoms forced me to stop the ascent or to go down on my own power
3 – Had to be evacuated to a lower altitude
To obtain the AMS score, add number from each category earlier. Although no official severity rankings exist, many consider mild AMS to be 3-5 points, moderate AMS 6-9 points, and severe AMS 10-12 points.

From Roach RC, Hackett PH, Oelz O, et al. The 2018 Lake Louise Acute Mountain Sickness Score. *High Alt Med Biol.* 2018;19(1):4–6, Table 1.

The diagnosis of AMS in children with early language skills (age 4-11 years) may be made with cautious use of the 2018 Lake Louise criteria (see Table 87.1). The language used in this adult questionnaire may be too complex and may underestimate AMS if not understood by the child. This is particularly true for questions regarding headache (the key symptom of AMS) and GI symptoms.

In preverbal young children and infants, recognition of AMS relies on observable signs and exclusion of other causes. In this age range, AMS is manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance. In most cases of AMS in very young children, all these symptoms are present. Fussiness is defined as a state of irritability that is not easily explained by another cause, such as tiredness, wet diaper, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Decreased playfulness may be profound. Alterations of appetite may progress to frank vomiting. Sleep disturbance can manifest with either increased or decreased sleep when compared with normal patterns. Most often, decreased sleep and the inability to nap are noted.

The Children's Lake Louise Score (CLLS) has been successfully tested in preverbal children <4 years old by parents briefed on the use of the scoring system. The CLLS combines a score for the amount and intensity of unexplained fussiness with a symptom score of how well the child has eaten, played, and slept in the past 24 hours. Evaluating for the presence of headache can be accomplished by asking if the "head hurts" or by using a visual "faces" pain scale. GI symptoms are evaluated by asking children if they are "hungry" rather than trying to evaluate their appetite. A combined score of ≥7 is indicative of AMS (Fig. 87.1). Many of the symptoms manifested by AMS in children may also result from the disruption of the normal routine with travel. A change in environment, sleeping accommodation, or eating options can result in a fussy child. The threshold scores for AMS diagnostic criteria are modified to account for these baseline variations. Educating parents to recognize the symptoms of AMS in themselves is also important, as an ill parent can indirectly compromise a child's safety.

Other acute illnesses can mimic AMS in young children. *It must be emphasized that altered mental status, neurologic abnormalities, breathing difficulty, and cyanosis are not part of uncomplicated AMS.* **Any of these signs warrant immediate medical attention.** If serious bacterial illness, a surgical condition, or another problem meriting specific intervention is suspected in a child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

Periodic Breathing

Periodic breathing at altitude is common at all ages during sleep, resulting in brief repeated episodes of oxyhemoglobin desaturation. Prepubertal children (9-12 years old) have similar nighttime oxygen desaturations as their parents; however, they have somewhat more stable breathing patterns with less periodicity. Although periodic breathing is not a sign of AMS, the exacerbation of hypoxia during sleep plays a role in AMS development. Newborn infants normally have periodicity in their respiratory pattern, and this periodicity is increased by high-altitude exposure and sleep. Oxygen saturations of awake neonates born at 3,100 m (~10,100 ft) in Colorado range from 88% to 91%. During sleep with increased periodic breathing, oxygen saturation may drop to 81% during the first week of life. The amount and magnitude of respiratory periodicity decrease as the child matures, and saturation during sleep increases to 86% after 2 months. A stable mature pattern is usually reached by 6 months of age. Preterm babies may demonstrate marked periodicity with prolonged desaturation because of their immaturity. Acute ascent with a child born preterm is best delayed until maturity, when normal pulmonary function and respiratory drive can be demonstrated. Parents of normal young babies may become distressed as they note marked periodic breathing patterns in their child after ascent to moderate altitude. Clinicians can reassure parents that this is generally not a precursor of true apnea; desaturation can occur with periodic breathing in sleep, especially at higher altitudes.

Management

The management of AMS must include strict adherence to the principle that further ascent to a higher sleeping altitude is contraindicated after the symptoms of altitude illness occur. Halting ascent or activity to allow further acclimatization may reverse the symptoms; however, continuing the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. Stopping further ascent and waiting for acclimatization treats most AMS in 1-4 days. Mild cases of AMS may be treated without descent if monitoring by a reliable caregiver is available. Conservative treatment may be provided, including rest, analgesics for headache, and antiemetics for nausea. When conservative measures are inadequate, acetazolamide and/or oxygen titrated to maintain Sao_2 >94% are generally effective. Although no studies have formally assessed its use in pediatric patients, anecdotal reports have demonstrated efficacy of acetazolamide in treating mild AMS in this population. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention mandates descent. Descent (500-1,000 m, ~1,600-3,300 ft) is effective treatment for all forms of altitude illness and should be tailored to the individual response. The presence of neurologic abnormalities (e.g., ataxia or altered mentation) mandates descent because these signs indicate a progression of AMS to severe altitude illness (HACE).

Supplemental oxygen administration relieves AMS symptoms, including small amounts (1-2 L/min) given during sleep. In the wilderness, oxygen tanks are impractically heavy and are usually unavailable in adequate amounts; therefore oxygen therapy is usually reserved for the more serious manifestations of high-altitude illness. Hyperbaric therapy that simulates descent is also effective.

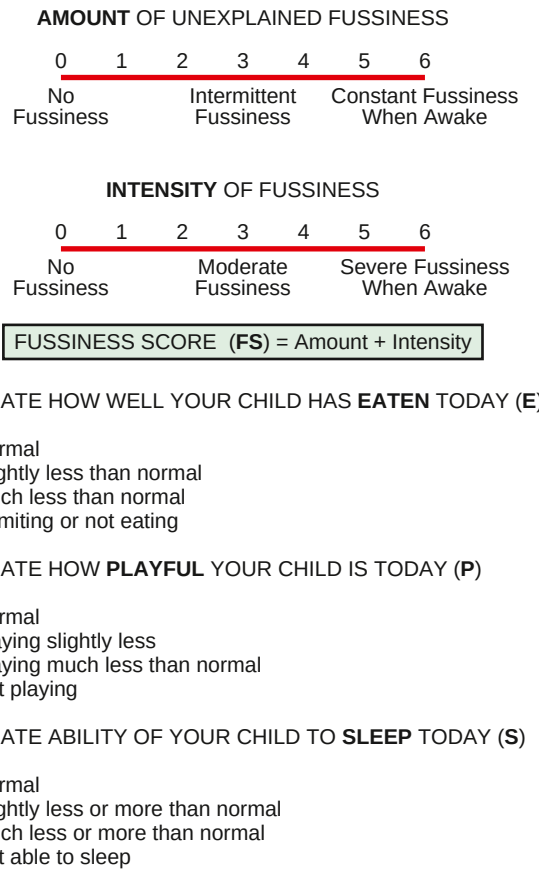

Fig. 87.1 Children's Lake Louise Score (CLLS). Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Please rate your child's typical fussy behavior *during the last 24 hours* without the benefit of your intervention.

Treatment of headache and nausea can be beneficial for mild AMS, and in many cases this may be all that is necessary. Evidence supports the use of ibuprofen and acetaminophen for the treatment of high-altitude headache in children; aspirin and combination products containing aspirin should be avoided in children because of possible association with Reye syndrome. For nausea and vomiting, ondansetron may be used.

Acetazolamide is a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. This respiratory stimulation improves sleep when the hypoxemia caused by periodic breathing is eradicated by acetazolamide. Acetazolamide accelerates acclimatization and, if given early in the development of AMS, rapidly resolves symptoms. Anecdotal experience supports the use of acetazolamide in children, particularly when conservative measures have been insufficient (Table 87.2). Treatment for 48 hours is usually adequate for resolution of symptoms. Acetazolamide may be prepared as a solution by a compounding pharmacy.

Adverse reactions to acetazolamide in adults include paresthesias, polyuria, and taste alterations for carbonated beverages. Less common reactions include nausea, drowsiness, tinnitus, transient myopia, and rarely, rash. Acetazolamide is a nonantibiotic sulfa compound that carries a low risk of cross-reactivity for individuals with an allergy to sulfa antibiotics. A history of anaphylaxis or severe skin reactions to any sulfa-containing medication contraindicates the use of acetazolamide. Acetazolamide should be avoided in breastfeeding mothers and pregnant women.

Dexamethasone is an effective alternative treatment for AMS in adults. Although dexamethasone can resolve the symptoms of AMS, it does not play a role in acclimatization, and symptoms may recur when the treatment is withdrawn. Adverse reactions to dexamethasone of concern in the pediatric population are pancreatitis, pseudotumor cerebri, and interference with normal growth. Although these reactions are generally seen with prolonged use, dexamethasone should be used for treatment in children only in extreme situations where alternatives such as descent or oxygen therapy are unavailable.

Prevention

Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical may consider prophylactic medication. *Acetazolamide remains the compound of choice for AMS prophylaxis.* Numerous studies have demonstrated its effectiveness in adults starting 24 hours before ascent and continuing for the first 2 days at high altitude. Controlled studies for prophylaxis with acetazolamide in children are unavailable; however, anecdotal evidence supports its use (see Table 87.2). Ibuprofen, when compared with acetazolamide, has been found to be equally efficacious in preventing headache in adults. Dexamethasone also prevents AMS; however, the potential adverse effects in children preclude its use for prophylaxis in this age group. Recommendations for hyperhydration are frequently given in the lay literature, yet no evidence supports this advice. Drinking excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness.

HIGH-ALTITUDE CEREBRAL EDEMA

Epidemiology and Risk Factors

HACE is rare and may occur in children. Prompt recognition and treatment are necessary, because if unrecognized, it is rapidly fatal. HACE is generally seen in adults with prolonged stays above 4,000 m (~13,000 ft), but in rare cases has been reported as low as 2,100 m (~6,900 ft). HACE is usually associated with concurrent AMS or HAPE, but can occur on its own.

Pathophysiology

HACE is regarded as the extreme expression of the same pathophysiology underlying AMS. The edema and increased intracranial pressure are believed to be primarily caused by a vasogenic process where fluid moves from the vascular to the interstitial space due to a combination of increased hydrostatic pressure and increased vascular permeability. In the later stages of HACE, a cytotoxic component may contribute to the edema. These proposed mechanisms are supported by MRI studies revealing white matter changes consistent with vasogenic and cytotoxic edema.

Diagnosis

HACE is differentiated from severe AMS by the presence of **neurologic signs**. Most common are ataxia and altered mental status, including confusion, progressive decrease in responsiveness, and eventually coma. Less common are focal cranial nerve palsies, motor and sensory deficits, and seizures. CT imaging is consistent with edema and increased intracranial pressure. MRI shows a high T2 signal in the white matter, specifically in the splenium of the corpus callosum, with diffusion-weighted technique.

Management

Descent remains the most effective treatment for HACE. Supplemental oxygen, if available, is useful, especially if descent is not possible or

Table 87.2 Medications for Treatment of Altitude-Associated Illness in Children*

MEDICATION	CLASSIFICATION	INDICATION	DOSE AND ROUTE	ADVERSE EFFECTS
Acetazolamide	Carbonic anhydrase inhibitor	AMS treatment	2.5 mg/kg PO every 12 hours; maximum 250 mg/dose	Collateral effects include paresthesias, altered taste and visual acuity, electrolyte disturbance
		AMS or re-entry HAPE prevention[1]	1.25 mg/kg PO every 12 hours; maximum dose 125 mg/dose	Collateral effects reduced at lower doses
Dexamethasone	Steroid	AMS or HACE treatment[2,3]	0.15 mg/kg PO/IM/IV every 6 hours; maximum 4 mg/dose	Hypertension, GI hemorrhage, pancreatitis, growth inhibition
Nifedipine	Calcium-channel blocker	HAPE treatment or prevention[4]	If > 50 kg use adult dosing of 30 mg extended-release PO every 12 hours	Flushing, gastrointestinal distress, hypotension
Amlodipine	Calcium-channel blocker	HAPE treatment or prevention[4,5]	*1-5 years:* 0.1-0.6 mg/kg/dose PO daily; maximum 5 mg/day *6-17 years:* 2.5-5.0 mg PO daily (tablet or liquid suspension)	Flushing, abdominal pain, dizziness, hypotension

*No studies in children for high-altitude indications.

[1]AMS prophylaxis is not routinely recommended in children but indicated when rapid ascent profile is unavoidable or previous altitude illness occurred in a child about to undergo similar ascent profile. AMS and re-entry HAPE prophylaxis should be started 24 hours before ascent and continued for 2 days at altitude.

[2]Oxygen and descent are the treatment of choice for severe AMS. If acetazolamide is not tolerated, dexamethasone may be used. Oxygen, descent and dexamethasone should be used in HACE.

[3]Prophylactic use of dexamethasone for AMS is not warranted because of potential adverse effects. Use slow graded ascent or acetazolamide.

[4]In emergency settings where oxygen and descent are not an option, amlodipine or nifedipine may be used for treatment. Extended-release (ER) nifedipine formulations cannot be broken to obtain smaller doses. If ≥ 50 kg, 30 mg extended-release nifedipine is preferred.

[5]Amlodipine offers advantages over nifedipine for small children because of once daily dosing and availability as liquid or appropriately sized tablet.

Adapted from Luks AM, Beidleman BA, Freer L et al. Wilderness Medical Society Clinical Practice Guidelines for the Prevention, Diagnosis and Treatment of Acute Altitude Illness: 2024 Update. *Wilderness Environ Med.* 2023;Oct 11:S1080-6032(23)00167-9.

delayed. Portable hyperbaric treatment is beneficial, but its use should not delay descent. Dexamethasone should be administered at a dose of 0.15 mg/kg per dose given orally every 6 hours to a maximum of 4 mg per dose (see Table 87.2). The few mild cases of HACE reported in children have recovered with dexamethasone *and* descent.

HIGH-ALTITUDE PULMONARY EDEMA

Epidemiology and Risk Factors

HAPE is a noncardiogenic pulmonary edema caused by intense pulmonary vasoconstriction and subsequent high capillary pressure, secondary to hypoxia, resulting in altered permeability of the alveolocapillary membrane and the extravasation of intravascular fluid into the extravascular space of the lung. The development of HAPE depends on factors affecting pulmonary vasoreactivity, rate of ascent, altitude achieved, and time spent at that altitude. HAPE generally occurs in the setting of recent ascent, most often at altitudes above 3,000 m (~9,800 ft), but in some cases at altitudes as low as 1,740 m (~5,700 ft). Among children HAPE occurs in 2 distinct settings. Most commonly, HAPE occurs in a child who resides at low altitude who travels to high altitude. Reentry HAPE affects children who reside at high altitude but become ill on their return home after descent to lower altitudes (see Special Considerations). HAPE may also occur with or without ascent in children who develop acute respiratory illnesses that exacerbate hypoxia at high altitude. Fatal outcomes of HAPE in children have been reported. Most mild and moderate cases resolve without difficulty; however, if unrecognized and untreated, rapid progression to death can occur, especially when infection or cardiac conditions complicate the illness.

HAPE affects male and female children more equally than adults, among whom the observed male predominance appears due to strenuous sport activities and military assignments. The occurrence, and even the pathophysiology, of HAPE may vary by population and genetic background. Several conditions may predispose a child to HAPE (Table 87.3). Preexisting viral respiratory infections have been linked to HAPE, especially in children. Cardiorespiratory conditions associated with pulmonary hypertension, such as atrial and ventricular septal defects, pulmonary vein stenosis, congenital absence of a pulmonary artery, and obstructive sleep apnea, also predispose to HAPE. Down syndrome is a risk factor for HAPE development, as are previously repaired congenital heart defects and the presence of hypoplastic lungs. Undiagnosed structural cardiopulmonary abnormalities may result in severe hypoxia and/or altitude illness once ascent occurs; for this reason, a new diagnosis of HAPE in a child warrants active investigation of underlying causes.

Table 87.3 Conditions Associated with Increased Risk of HAPE

ENVIRONMENTAL
Ascent above 2,500 m (~8,200 ft)
Rapid rate of ascent (generally >1,000 m [~3,300 ft] per day)
Cold exposure
CARDIAC
Anomalies causing increased pulmonary blood flow or increased pulmonary arterial pressure
• Ventricular septal defect, atrial septal defect, patent foramen ovale, patent ductus arteriosus
• Anomalous pulmonary venous return or pulmonary vein stenosis
• Unilateral absent pulmonary artery or isolated pulmonary artery of ductal origin
Coarctation of the aorta
Congestive heart failure
PULMONARY
Chronic lung disease
Bronchopulmonary dysplasia
Cystic fibrosis (FEV-1 <30% predicted)
Pulmonary hypoplasia
Supplemental oxygen requirement at sea level
Pulmonary hypertension
Perinatal respiratory distress
Persistent pulmonary hypertension of the newborn
Perinatal asphyxia or depression
Sleep apnea
INFECTIOUS
Upper respiratory tract infection
Bronchitis/bronchiolitis
Pneumonitis
Otitis media
PHARMACOLOGIC
Any medication causing central nervous system and respiratory depression
Alcohol
Sympathomimetics
SYSTEMIC
Down syndrome (trisomy 21)
History of premature birth or low birthweight

Physiology

Alveolar hypoxia results in vasoconstriction of the pulmonary arterioles just proximal to the alveolar capillary bed. Hypoxic pulmonary vasoconstriction is a normal physiologic response to optimize ventilation/perfusion ($\dot{V}/\dot{Q}$) matching by redistributing regional pulmonary blood flow to areas of highest ventilation, thereby optimizing arterial oxygenation. However, under conditions that result in widespread alveolar hypoxia, extensive pulmonary vasoconstriction will lead to significant elevations in pulmonary arterial pressure, and uneven pulmonary vasoconstriction can result in localized overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy and heterogeneous edema that is classically observed in HAPE. The combination of pulmonary hypertension and uneven pulmonary vasoconstriction appears to be necessary in the pathogenesis of HAPE. Children and adolescents acutely exposed to high-altitude hypoxia demonstrate pulmonary hypertension, with increases in pulmonary artery pressure inversely related to age. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE.

The conditions that predispose to HAPE are often directly referable to elements in the cascade of pathophysiology. Viral infections result in inflammation that may predispose the pulmonary endothelium to mechanical injury and increase susceptibility to alveolar fluid accumulation and HAPE during ascent. Exercise and cold stress at altitude may increase hypoxemia and exacerbate pulmonary hypertension. Overperfusion of a restricted vascular bed is illustrated by cases of congenital unilateral absence of a pulmonary artery in which the entire cardiac output is delivered to one lung, predisposing to pulmonary hypertension and overperfusion injury. Although data from mechanistic studies of children are lacking, adult HAPE-susceptible subjects have been characterized as having significantly elevated pulmonary artery pressure during altitude exposure and illness, altered vascular permeability, augmented hypoxic pulmonary vasoreactivity during hypoxia and normoxic exercise, blunted hypoxic ventilatory responsiveness, smaller lung volumes, and impaired alveolar fluid clearance.

Diagnosis

The diagnosis of HAPE is based on clinical findings and their evolution in the context of recent ascent from lower elevation. There is no single diagnostic test or constellation of laboratory findings. Symptoms commonly develop within 24-96 hours, and onset of symptoms often occurs during the first or second night at altitude, when hypoxia may be exacerbated during sleep. HAPE is rarely observed beyond 5 days after ascent to altitude (unless additional ascent occurs) because pulmonary vascular remodeling and acclimatization have taken place. The diagnosis of HAPE is made by observing the combination of symptoms, including dyspnea at rest, cough, weakness, or decreased exercise performance, and signs including crackles or wheezing in at least one lung field, central cyanosis, tachypnea, or tachycardia. Determining the onset and timing of the illness relative to ascent and radiographic evidence of alveolar infiltrates may help confirm the diagnosis.

The symptoms of AMS and HAPE show considerable overlap, and AMS may precede the development of HAPE in approximately half of patients. Frequently patients with HAPE first exhibit general malaise, which may progress to more specific signs of cardiopulmonary distress. Young children may show agitation and general debility. Older children may complain of headache, and children of all ages frequently experience nausea and vomiting. Cough is a common pulmonary sign. Dyspnea at rest, orthopnea, cyanosis, tachycardia, and chest pain herald worsening compromise, which may advance within hours to production of pink-tinged sputum.

Findings on physical exam frequently are less severe than a patient's chest radiograph and the hypoxemia on pulse oximetry would predict. Children often appear pale, with or without visible cyanosis. Low-grade fever (<38.5°C) is common, and respiratory rate is generally increased. Auscultation typically reveals rales, usually greater in the right lung than the left, on presentation. The radiographic pattern of pulmonary edema can be highly variable, from patchy and peripheral to more homogeneous in severe cases. Often, the right lung shows more radiographic changes of edema than the left (Fig. 87.2). Cardiomegaly is an uncommon finding, but peribronchial and perivascular cuffing are frequent, as is enlargement of the pulmonary artery silhouette and dilation of more peripheral pulmonary arteries. Portable ultrasound has been shown useful to diagnose HAPE through the finding of "comet tails," artifacts created by microreflections of the ultrasound beam within interlobular septae thickened by interstitial and/or alveolar edema. Significant arterial oxygen desaturation, as measured by pulse oximetry, is a consistent finding, with saturations frequently below 75%. A complete blood count often reveals a leukocytosis with a left shift of the granulocyte series.

The differential diagnosis of HAPE includes viral and bacterial pneumonia, bronchitis/bronchiolitis, asthma, vaping-associated lung disease, and other forms of cardiogenic and noncardiogenic pulmonary edema as well as pulmonary embolism. HAPE is most frequently misdiagnosed as pneumonia or a viral respiratory illness, especially when suspicion of altitude-associated pathology is not appropriately high. The presenting signs of cough, dyspnea, and orthopnea, followed by sputum production, can easily be misinterpreted as pneumonia, an impression that is reinforced by the frequent accompaniment of low-grade fever. Respiratory viral infections increase the risk of developing HAPE, which may lead to further confusion in diagnosis.

Complications of HAPE in children often relate to underlying, sometimes undiagnosed, cardiopulmonary pathology or coexisting viral infections, which potentiate the severity of pulmonary edema and pulmonary hypertension. Acute altitude exposure in such circumstances may lead to severe presentations that progress rapidly to extreme hypoxemia or cardiac failure and death. Children with Down syndrome, with or without structural cardiac anomalies, show increased susceptibility to HAPE and rapid symptom progression. Neonatal respiratory distress with pulmonary hypertension has been linked to exaggerated hypoxic pulmonary vasoreactivity in early adulthood and thereby a theoretical predisposition to HAPE. Other conditions related to pulmonary overcirculation (atrial and ventricular septal defects, patent foramen ovale, patent ductus arteriosus), small cross-sectional area of the pulmonary vascular bed (unilateral absent pulmonary artery, pulmonary hypoplasia), obstruction to pulmonary venous return (total anomalous pulmonary venous return, pulmonary vein stenosis), or left-sided obstruction (coarctation of the aorta) potentiate HAPE. Recent inflammatory processes, such as viral infection, predispose to HAPE and may worsen hypoxemia. Infection with respiratory syncytial virus in particular may trigger severe pulmonary hypertension.

Management

Descent with supplemental oxygen is the treatment of choice for HAPE in children. When feasible, or in the absence of medical care, rapid descent of at least 500-1,000 m (~1,500-3,300 ft) usually results in rapid recovery. As with all altitude illness, the magnitude of the descent is tailored to the resolution of symptoms. Oxygen and bed rest without descent can be safe and effective treatment for mild HAPE in children where careful medical observation is available.

Supplemental oxygen at altitude is administered at 2-6 L/min by nasal cannula for 48-72 hours to maintain an arterial oxygen saturation of at least 90%. Increasing oxygen saturation above 90% does not result in further reduction in pulmonary artery pressure and does not accelerate edema resolution in adults. Oxygen flow can be weaned with improvement in symptoms and saturations; at flow rates below 2-4 L/min, children may be sufficiently stable and comfortable to continue treatment at home under the monitoring of family. Instructions to avoid physical exertion and exposure to cold should be given to reduce exposure to factors known to elevate pulmonary artery pressure. Most children experience complete resolution of mild HAPE within 24-72 hours of oxygen therapy when treated at the altitude of symptom onset.

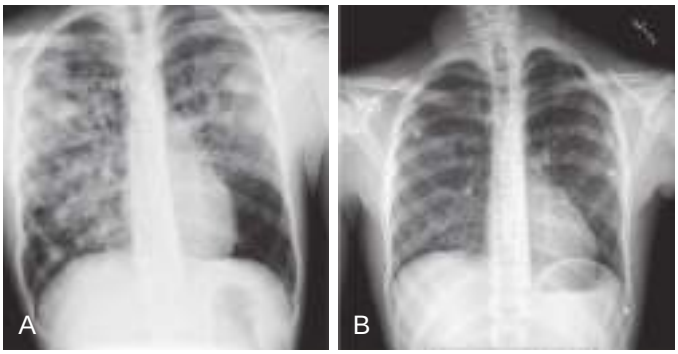

Fig. 87.2 High-altitude pulmonary edema (HAPE). A healthy teenager who resides at low altitude flew to Denver, Colorado, with a school group and immediately drove to a ski resort at 9,300 feet. The following day he felt dizzy and complained of headache. Symptoms progressed over the next 2 days to include emesis, dyspnea, cough, and fatigue. He was taken to an emergency department, where pulse oximetry showed an arterial saturation of 51%. Chest x-ray was obtained. **A,** This diagnostic image of HAPE was obtained at the altitude of presentation. The chest x-ray shows patchy, nodular infiltrates generalized through the right lung and the left upper lobe. The patient was started on supplemental oxygen and transported to Denver. Saturations improved with descent and were 94% on room air at time of arrival. **B,** Repeat radiograph obtained at lower altitude 2 days after presentation with HAPE. This diagnostic image shows substantial resolution of patchy pulmonary edema. *(Courtesy Children's Hospital Colorado, Department of Radiology.)*

Pharmacotherapy for pediatric HAPE is rarely needed because oxygen and descent are so effective. In emergency situations without the options of supplemental oxygen or descent, pharmacotherapy aimed at reducing pulmonary hypertension is indicated (see Table 87.2). Although not systematically studied in children, nifedipine is indicated for the treatment of adult HAPE. Amlodipine offers advantages over nifedipine in children because of daily dosing and availability of a liquid suspension. Patients should be monitored for hypotension during calcium channel blocker administration.

SPECIAL CONSIDERATIONS

Reentry HAPE and HAPE in High-Altitude Residents Without Travel

Children residing at high altitude may experience reentry HAPE upon reascent to the altitude of residence after a sojourn to low altitude. Although stays at low altitude as short as 24 hours may be sufficient to trigger reentry HAPE, most cases occur after several days at lower altitude. Several case series have demonstrated that children between 4 and 18 years of age are much more likely to develop reentry HAPE than adults. Observations from Colorado and Peru suggest that reentry HAPE may occur in 6–17% of children 2-19 years of age compared with <1–3% of adult residents. Various explanations have been proposed for the greater incidence and severity of reentry HAPE among children, including general lack of moderated behavior on ascent, increased likelihood of preexisting inflammatory processes, developmental differences in endothelial cell tight junctions, occult chronic pulmonary artery hypertension, and retained pulmonary arteriolar muscularity with potential for elevated pulmonary arterial pressure and potentially uneven pulmonary arterial vasoconstriction.

Reentry HAPE has a significant probability of recurrence and may justify pharmacologic prophylaxis to prevent the accumulated burden

of morbidity. There are no controlled trials of prophylaxis for reentry HAPE in children; however, acetazolamide has been used empirically (see Table 87.2), based on its blunting of hypoxic pulmonary vasoconstriction in adults and the potential risk of hypotension and reflex tachycardia with calcium channel blockers.

HAPE can also occur in children residing at high altitude without travel, and it should be considered in the differential diagnosis of children who present with hypoxemia at high altitude. The chest radiograph may be consistent with HAPE or viral pneumonia. When rapid improvement with oxygen and little to no response to bronchodilators suggest HAPE, the use of antibiotics and other treatments can be minimized.

Symptomatic High-Altitude Pulmonary Hypertension

Infants and young children residing at high altitude may experience symptomatic high-altitude pulmonary hypertension (SHAPH). All infants, regardless of altitude of gestation and birth, have thickened and muscularized interlobular and intralobular pulmonary arteries and pulmonary artery pressures that are initially near systemic. Although muscular regression and fall in pulmonary artery pressure occur rapidly at sea level, infants permanently residing at high altitude demonstrate slowed regression of these characteristics through infancy and even childhood. Similar changes may occur in infants who experience pulmonary complications at birth (respiratory distress syndrome of prematurity, persistent pulmonary hypertension of the newborn). Infants with SHAPH become symptomatic with exaggerated hypoxemia and signs of subacute pulmonary hypertension; these signs correlate with pathologic findings of right ventricular hypertrophy and dilation, increased muscularization of the pulmonary arterial bed, and eventual right-sided congestive heart failure. Although supplemental oxygen and medications may be used, definitive treatment is relocation to a lower altitude.

Cognitive Dysfunction

It is known that adults may have reversible changes in cognitive function with acute exposure to high altitude. A small study evaluating cognitive function in healthy 10- to 17-year-old children found impairment in verbal short-term memory, episodic memory, and executive functions 24 hours after ascent to 3,450 m (~11,400 ft). These findings were no longer present upon reassessment 3 months after returning to sea level. Similar results were found in children with permanent residence at high altitude; however, additional study is needed to assess the long-term implications of these findings.

Travel with Young Infants

Newborn infants retain some of the circulatory characteristics of recent fetal life, and these can pose a unique risk for altitude exposure. The fetal circulation has high pulmonary resistance, low pulmonary blood flow, and both intracardiac and extracardiac shunts that optimize oxygenation via the placenta instead of the fetal lungs. After birth, a transition begins that closes fetal shunts and establishes normal pulmonary circulation and oxygen transport. Exposure to marked hypoxia can result in reversion to fetal shunting patterns despite the absence of a placenta. Normal infants at sea level complete these changes in 4-6 weeks, though for infants born at moderate or high altitude, changes may last 3 months or longer. Travel to high altitude with young infants is generally safe after 4-6 weeks, when circulatory changes have occurred, breastfeeding is established, and congenital abnormalities may have been detected.

Air travel with young infants frequently raises questions about the effects of exposure to hypobaric hypoxia, as the pressurization of aircraft cabins may vary up to an altitude equivalent of 8,500 ft (~2,600 m). Even transoceanic flights are generally not long enough to trigger AMS or HAPE. However, infants may experience transient desaturation with feedings during flight and likely experience discomfort due to dry air and stress resulting from noise and vibration, much as adults do. Former preterm infants without chronic lung disease who have attained 3 months corrected gestational age do not appear to experience greater hypoxia during air travel than term infants; infants with more significant lung disease merit hypoxic challenge or provision of supplemental oxygen in flight.

Sickle Cell Disease/Trait

Children with sickle cell disease or sickle cell trait should avoid travel to altitude, as hypoxemia may trigger intravascular sickling, leading to acute vasoocclusive pain crises or splenic infarction or sequestration. Up to 20% of pediatric patients with sickle cell disease and sickle-thalassemia disease may experience a vasoocclusive crisis at moderate altitude or in pressurized aircraft. Oxygen is advised for air travelers with known sickle cell disease. Although many children with sickle cell trait remain asymptomatic, children can experience splenic ischemia or infarction with severe left upper quadrant pain.

Recommendations for High-Altitude Travel with Children

A comprehensive approach to travel to high altitude with children should focus on 3 phases: planning the ascent and assessment of risk, recognition and management of altitude-associated illness, and follow-up of any illness relative to future travel or diagnostic testing necessary. Planning for travel to high altitude with children should consider rate of ascent, formulation of an emergency plan for communication and evacuation, and availability of medical care at the high-altitude destination. Slow ascent with time for acclimatization is the best prevention for all forms of altitude illness. Ideally, the first night should not be spent at an altitude higher than 2,800 m (9,000 ft), and then 2-3 nights should be spent at 2,500-3,000 m (~8,200-9,800 ft), with a subsequent increase (to a new sleeping altitude) of not more than 500 m (1,600 ft) each night. One extra night of acclimatization (at the same sleeping altitude) should be taken for every 1,000 m (~3,300 ft) gained. Rapid ascent by air may be avoidable through alternative routes or means of transportation. Difficult descent situations (where further ascent may be necessary before descent is possible) should be avoided with children. Widespread coverage by cellular and satellite phone service may give a false sense of security in remote regions where both terrain and weather can limit the arrival of definitive help.

Prompt recognition of altitude-associated illness requires awareness of the context in which illness occurs and familiarity with the signs and symptoms. Parents are generally adept at recognizing deviation from baseline behavior of their children. Scales such as the Lake Louise Acute Mountain Sickness Score and CLLS may aid parents in modifying activity and/or seeking treatment. Clinicians should emphasize to parents that breathing difficulty, cyanosis, cough productive of pink-tinged sputum, altered mental status, and neurologic abnormalities are *not* part of uncomplicated AMS, but instead are serious signs of potential HAPE or HACE that deserve immediate medical attention.

Descent is the mainstay of therapy for all forms of altitude-associated illness in children. When descent is not feasible or illness is mild, other therapeutic options may be considered. Severe altitude illness or death can be avoided in children by adherence to three general principles:

1. Recognition of the early signs of altitude illness and willingness by adult caregivers to acknowledge them
2. No further ascent, especially to sleep at a higher altitude, when experiencing even minor symptoms/signs of altitude illness
3. Immediate descent if signs/symptoms worsen while resting/receiving treatment at the altitude of onset

Altitude-associated illness in children merits follow-up with the primary care physician. Uncomplicated AMS with full resolution of symptoms upon descent or treatment does not require diagnostic workup, but may prompt discussion of slower ascent, specific plans for treatment, or even prophylaxis for future travel. Signs of HAPE or severe hypoxemia in a child out of proportion to the altitude reached should prompt further diagnostic evaluation, including consideration of echocardiography. Underlying cardiac conditions may not be apparent on physical examination at low altitude; therefore cardiac catheterization or echocardiography under conditions of controlled hypoxia or hypoxic exercise may be necessary. Families of HAPE-susceptible children should be advised to avoid travel during or shortly after viral infections.

Chapter 88

Drowning and Submersion Injury

William Benjamin Prince

Drowning is the second most frequent cause of unintentional injury death among children in the United States after traffic accidents. Prevention is the most important step to reducing the impact of drowning injury, followed by early initiation of cardiopulmonary resuscitation (CPR) at the scene.

ETIOLOGY

Children are at risk of drowning when they are exposed to a water hazard in their environment. The World Congress on Drowning and the World Health Organization (WHO) definition of drowning is "the process of experiencing respiratory impairment from submersion/immersion in liquid." Drowning outcomes are classified as death, no morbidity, or morbidity further divided into moderately or severely disabled, vegetative state/coma, and brain death. Use of confusing descriptive terms such as "near," "wet," "dry," "secondary," "silent," "passive," and "active" should not be used.

EPIDEMIOLOGY

From 2010 to 2020, an average of 4012 people per year were victims of **fatal drowning**, and an estimated 8061 persons per year were treated in U.S. hospital emergency departments (EDs) for **nonfatal drowning**. Compared with other types of injuries, drowning has one of the highest case fatality rates and is in the top 10 causes of death related to unintentional injuries for all pediatric age-groups. In 2019, the highest drowning death rates were seen in children age 1-4 years (crude rate of 2.4 per 100,000); in children age 1-4 years, drowning was the number-one cause of death from *unintentional injury* in the United States in 2019 (Fig. 88.1). Rates of fatal drowning hospitalization declined by ~25% during the same period (Fig. 88.2).

The risk of drowning and the circumstances leading to it vary by age. Drowning risk also relates to other host factors, including male sex, alcohol or drug use, a history of seizures, autism, or cardiac arrhythmia, and swimming lessons. Environmental risk factors include exposure to water and varying supervision. These factors are embedded in the context of geography, climate, socioeconomic status, and culture.

Children <1 Year Old

Most (75%) drowning deaths in children younger than 1 year occur in the **bathtub**, when an infant is left alone or with an older sibling. Infant tub seats or rings may exacerbate the risk by giving caregivers a false sense of security that the child is safe in the tub. The next major risk to children <1 year is the large (5-gallon) household bucket. These buckets are approximately 30 cm (1 ft) tall and designed not to tip over when half-full. The average 9-month-old child tends to be top-heavy and thus can easily fall headfirst into a half-full bucket, become stuck, and quickly drown.

Children 1-4 Years Old

Drowning rates are consistently highest in 1- to 4-year-old children, likely because of their curious but unaware nature, coupled with the rapid progression of their physical capabilities. A common factor in many of these deaths is a lapse in adult supervision, often reportedly <5 minutes. Most U.S. drownings occur in residential **swimming pools**. Usually, the child is in their own home, and the caregiver does not expect the child to be near the pool.

In rural areas, children 1-4 years old often drown in irrigation ditches or nearby ponds and rivers. The circumstances are like those noted previously, in a body of water that is near the house. Drowning is one of the leading causes of *farm injury–related deaths* in children.

Unintentional drowning deaths among children aged 0-17 years: United States, 1999-2019. NCHS Data Brief. 2021;413, Fig. 1.)*

School-Age Children

School-age children are at increased risk of drowning in natural bodies of water such as lakes, ponds, rivers, and canals. Hazards such as unknown depths, undefined areas, and presence of currents and waves increase this risk. Although swimming pools account for most nonfatal drownings across all ages, **natural waterways** account for a higher death rate in children 10-19 years old. Unlike for preschool children,

swimming or boating activities are important factors in drowning injuries in school-age children.

Adolescents

The second peak incidence in drowning death rates occurs in older adolescents, age 15-19 years. Almost 90% drown in open water. In this age-group particularly, striking disparities in drowning deaths exist in gender and ethnicity. Drowning death is roughly twice as common for males when compared with females, but among adolescents, the rate is almost 10 times higher among males. The gender disparity may likely be related to males' greater exposure to aquatic environments, overestimation of swimming ability, underestimation of dangerous situations, increased risk-taking behavior, and greater alcohol use.

Dangerous underwater breath-holding behaviors (DUBBs) are often performed by experienced healthy swimmers or fitness enthusiasts (hypoxic training) or when teenagers hold breath-holding contests during horseplay. DUBBs have been primarily reported in regulated swimming facilities. Behaviors include intentional hyperventilation before submersion, static apnea, and extended periods of underwater distance swimming or breath-hold intervals.

Ethnic Disparities

There is significant ethnic disparity seen across drowning rates and causes. Among children age 0-19 years, the drowning rates from 2014 to 2018 are highest among Black (1.79 per 100,000) and Indigenous Nations people and Alaska Native (1.49 per 100,000) individuals. Rates are lower among White (1.06 per 100,000), Asian American and Pacific Islander (0.85 per 100,000), and Hispanic (0.82 per 100,000) individuals. Age dramatically influences drowning disparities. Black children drown at significantly higher rates than those for White and Hispanic children at every age from 5 to 18 years. Black children are more likely to drown in unguarded public pools, apartment pools, or hotel pools; White children are more likely to drown in private residential pools. Reasons for disparities in drowning rates may include cultural attitudes toward swimming, prohibitive cost and location of swimming lessons, fears about swimming, and lack of lifeguards at pools in many communities.

Underlying Conditions

Several underlying medical conditions are associated with drowning at all ages. **Epilepsy** is a known risk factor in drowning, with a relative risk for fatal and nonfatal drowning 7.5- to 10-fold higher than children without seizures. Drowning is the most common cause of death from unintentional injury for people with epilepsy. **Cardiac etiologies**, including arrhythmias, myocarditis, and prolonged QT or catecholaminergic polymorphic ventricular tachycardia syndromes, have been found in some children who die suddenly in the water, particularly in those with a family history of syncope, cardiac arrest, prior drowning, or QT prolongation. Exertion and fright while swimming can trigger arrhythmia among individuals with long QT and should be considered a possible cause for unexplained submersion injuries, particularly among proficient swimmers in low-risk settings (see Chapter 484.5).

Children with autism spectrum disorder (ASD) are at a significantly higher risk of drowning when compared with the general population; wandering was the most reported behavior leading to drowning in children with ASD. Children with muscle disease or peripheral neuropathies have an increased risk for drowning because of the degree of fatigability.

Drowning may also be an **intentional injury**. A history of the event that changes or is inconsistent with the child's developmental stage is the key to recognition of intentional drowning. Physical examination and other physical injuries rarely provide clues. **Child abuse** is more often recognized in bathtub-related drownings. **Suicide** usually occurs in lone swimmers in open water.

Alcohol Use

The use of alcohol and drugs greatly increases the risk of drowning. A meta-analysis found that 30–70% of swimming and boating fatal drowning victims have a measurable blood alcohol concentration. Alcohol can impair judgment, leading to riskier behavior, decreased balance and coordination, hypothermia, and blunted ability to self-rescue. Alcohol use while boating is also associated with low life jacket use. Furthermore, an intoxicated adult may provide less effective supervision of children around water.

Sports and Recreation

Most U.S. drowning deaths occur during recreational activities. Drowning is the leading cause of *noncardiac sports-related deaths*. Surveys confirm that not using a personal flotation device (PFD) is common during boating activities. In 2021 the U.S. Coast Guard reported that 83% of those who drowned in boating accidents were not wearing a PFD.

Global Impact of Drowning

Drowning injury is the third leading cause of unintentional death worldwide, with the majority (90%) of fatalities occurring in low- and middle-income countries. More than half of the global drowning occurs in the WHO Western Pacific and Southeast Asia regions. Global drowning rates are vastly underestimated, because many drowning deaths in this region go unreported, and many immediate fatalities are unrecognized. In addition, these data exclude any cases of drowning as the result of intentional harm or assault, accidents of watercraft or water transport, and drowning related to forces of nature or cataclysmic storms, which usually claim large numbers of lives per incident; thus true numbers of fatal drowning are likely much higher.

Some patterns of pediatric drowning are similar in all countries. By most accounts, the highest rates are seen in males and in children 1-4 years old. The predominant locations are near or around the home, involving bodies of water used for activities of daily living. These include water-collecting systems, ponds, ditches, creeks, and watering holes. In tropical areas, death rates increase during monsoon season, when ditches and holes rapidly fill with rain, and are highest during daylight hours, when caregivers are busy with daily chores.

Drowning during natural disasters such as **storms** and **floods** is important in all areas of the world. The largest numbers of reported flood-related deaths occur in developing nations; most are drownings that occur during the storm surge. In the United States and much of Europe, advances in weather monitoring and warning systems have reduced such deaths. U.S. flooding incidents, including hurricanes Katrina and Sandy, showed that drowning caused the most deaths, particularly when people became trapped in their vehicles, were unable or refused to evacuate homes, or attempted to rescue others.

PATHOPHYSIOLOGY

Drowning victims drown quickly and quietly and do not signal distress or call for help. Vocalization is precluded by efforts to achieve maximal lung volume to keep the head above the water or by aspiration leading to laryngospasm (Fig. 88.3). Young children can struggle for only 10-20 seconds and adolescents for 30-60 seconds before final submersion. The *instinctive drowning response* is a phenomenon where actual or perceived suffocation in water triggers autonomic nervous system responses resulting in unlearned, instinctive drowning movements. A swimmer in distress is vertical in the water, with arms extended to the side to lift the body up and bring the mouth above water to breathe. This splashing or efforts to breathe are often misconstrued by nearby persons as merely playing in the water, until the victim sinks.

Anoxic-Ischemic Injury

During drowning there is a period of voluntary breath-holding, typically less than 1 minute, before small amounts of water enter the hypopharynx, triggering laryngospasm as a protective reflex. There is a progressive decrease in arterial blood oxyhemoglobin saturation (Sao_2), and the person soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. Laryngospasm resolves, allowing additional fluid (water, stomach contents) into the lungs. At the same time, the cardiovascular response progresses to decreasing cardiac output and oxygen delivery to other organs. By 3-4 minutes, myocardial hypoxia leads to peripheral vasoconstriction, decreased cardiac output, and abrupt circulatory

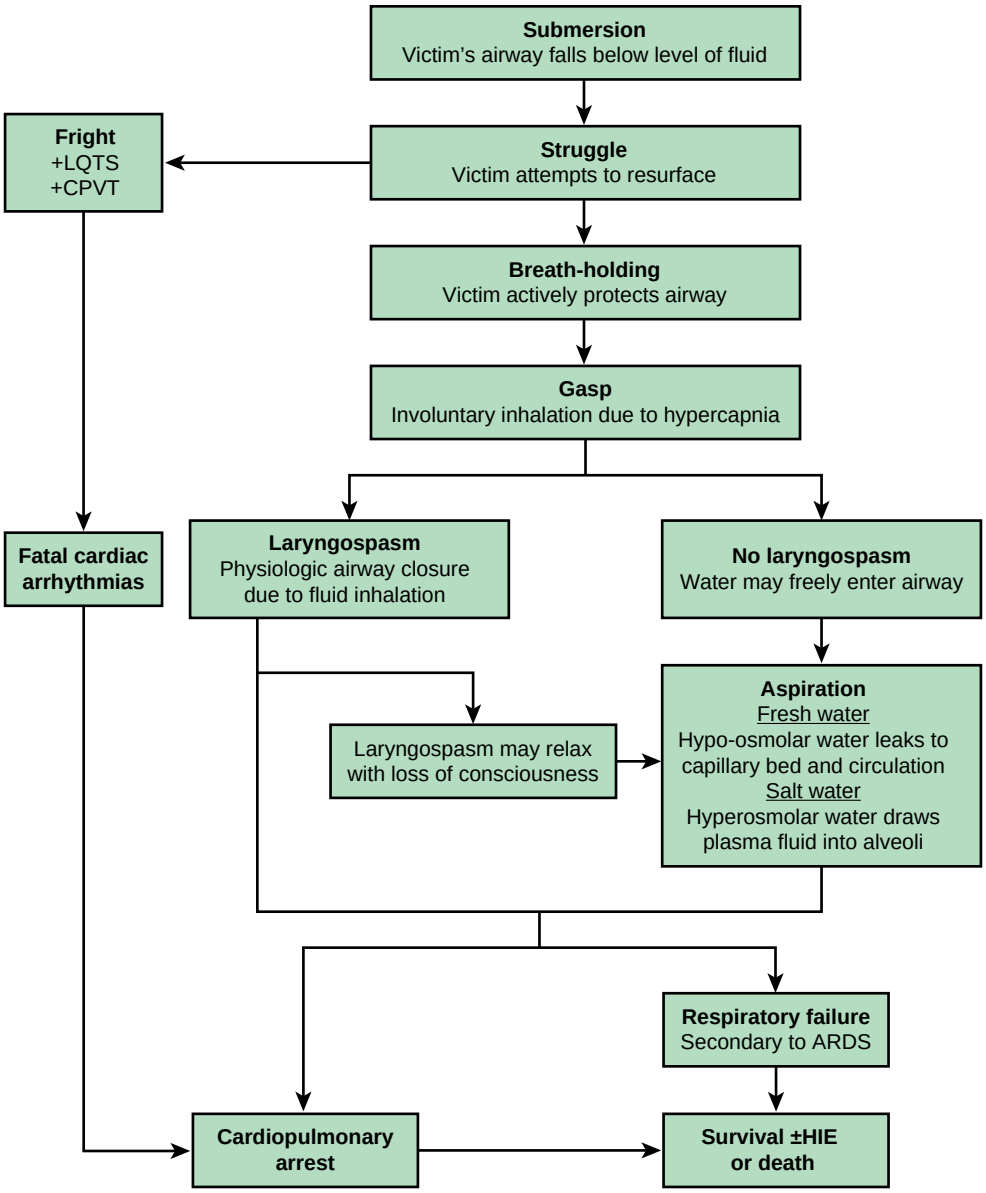

Fig. 88.3 Pathophysiologic events of the drowning process. LQTS, Long QT syndrome; CPVT, catecholaminergic polymorphic ventricular tachycardia; HIE, hypoxic-ischemic encephalopathy; ARDS, acute respiratory distress syndrome. *(Courtesy Andrew Schmidt, DO, MPH.)*

failure. Cardiac arrhythmias progress from tachycardia, to bradycardia, followed by ineffective cardiac contractions with electrical activity (**pulseless electrical activity**). With early initiation of CPR, spontaneous circulation may initially be successfully restored. The extent of the global **hypoxic-ischemic injury** determines the outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic-ischemic central nervous system (CNS) injury (see Chapter 82). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3-5 minutes. Submersion <5 minutes is associated with a favorable prognosis, whereas those >25 minutes are generally fatal.

Several hours after cardiopulmonary arrest, **cerebral edema** may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic-ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to **acute respiratory distress syndrome** (ARDS; see Chapter 86). Aspiration may also compound pulmonary injury. Myocardial dysfunction, arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic-ischemic events (see Chapter 572.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

Pulmonary Injury

Pulmonary aspiration occurs in many drowning victims, but the amount of aspirated fluid is usually small (see Chapter 446). Aspirated water does not obstruct airways and is readily moved into the

pulmonary circulation with positive pressure ventilation. More importantly, it can wash out surfactant and cause alveolar instability, ventilation-perfusion mismatch, and intrapulmonary shunting. The disruption of the alveolar capillary membrane leads to alveolar edema resulting in local ARDS-like syndrome.

In humans, aspiration of small amounts (1-3 mL/kg) can lead to marked hypoxemia and a 10–40% reduction in lung compliance. The composition of aspirated material can also affect the patient's clinical course: gastric contents, oropharyngeal flora, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. Aspiration is typically considered the source of pneumonia in cases of drowning, and antibiotics should be initiated based on radiographic evidence and clinical suspicion; no mortality benefit has been shown in those patients who received empiric or prophylactic antimicrobial therapy. Clinical management is not significantly different in saltwater and freshwater aspirations, because most victims do not aspirate enough fluid volume to make a clinical difference.

Cold Water Injury

Drowning should be differentiated from cold water **immersion** injuries, in which the victim remains afloat, keeping the head above water without respiratory impairment in cold waters. The definition of cold water varies from <15–20°C (<59–68°F).

Heat loss through conduction and convection is more efficient in water than in air. Children are at increased risk for **hypothermia** because of their relatively high ratio of body surface area (BSA) to mass, decreased subcutaneous fat, and limited thermogenic capacity. Body temperature may also continue to fall after removal from the water because of cold air, wet clothes, hypoxia, and hospital transport time. Hypothermia in pediatric drowning victims may be observed even after drowning in relatively warm water and in warm climates (see Chapter 90).

Immersion in cold water has immediate respiratory and cardiovascular effects. Victims experience **cold water shock**, a dynamic series of cardiorespiratory physiologic responses that can cause drowning. In adults, immersion in icy water results in intense involuntary reflex hyperventilation and a decrease in breath-holding ability to <10 seconds, which leads to fluid aspiration. Severe bradycardia, the *diving reflex*, occurs in adults but is transient and rapidly followed by supraventricular and ectopic tachycardia and hypertension. There is *no evidence* that the diving reflex has any protective effect.

Even after surviving the chaotic minutes of cold-water shock, after an additional 5-10 minutes of cold-water immersion, the victim can become incapacitated. Cooling of large and small muscles disables the victim's ability to grab hold, swim, or perform other self-rescue maneuvers. Severe hypothermia with body temperatures below 28°C (82.4°F) can lead to cardiac arrhythmia and asystole.

Depending on water and air temperature, insulation, BSA, thermogenic capacity, physical condition, swimming efforts, or high-water flow rates, heat loss with continued immersion can significantly decrease core temperature to hypothermic levels within 30-60 minutes.

The symptoms and severity of hypothermia are categorized based on body temperature. The victim with mild hypothermia has a core body temperature of 32–35°C (90–95°F) with intact thermogenic mechanisms (shivering and nonshivering thermogenesis, vasoconstriction) and active movements. Compensatory mechanisms usually attempt to restore normothermia at body temperatures >32°C (89.6°F). Lower core temperatures lead to impaired cognition, coordination, and muscle strength and, with it, less ability to self-rescue. Thermoregulation may fail, and spontaneous rewarming will not occur. With moderate hypothermia (28 to <32°C [82 to <90°F]), loss of consciousness leads to water aspiration. Progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. At body temperatures <28°C (82.4°F), extreme bradycardia is usually present with decreases in cardiac output, and the propensity for spontaneous ventricular fibrillation or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. A deep coma, with fixed and dilated pupils and absence of reflexes at very low body temperatures (<25–29°C [77–84.2°F]), may give the false appearance of death.

If the cooling process is quick—and cardiac output lasts long enough for sufficient heat loss to occur before the onset of severe hypoxia—the brain can cool to a level that may be considered in the *neuroprotective* range, approximately 33°C (91.4°F) in controlled, experimental conditions. However, if submersion leading to drowning occurs before development of a neuroprotective level of hypothermia, severe anoxia devastates tissue organs. The theoretical benefits, implications, and consequences of hypothermia in drowning victims are areas of controversy. Known adverse effects are associated with hypothermia, and these must be balanced against the potential benefits observed in experimental data. One should clearly differentiate among **controlled hypothermia**, such as that used in the operating room before the onset of hypoxia or ischemia; **accidental hypothermia**, such as occurs in drowning, which is uncontrolled and variable, with onset during or shortly after hypoxia-ischemia; and **therapeutic hypothermia**, involving the purposeful and controlled lowering and maintenance of body (or brain) temperature after a hypoxic-ischemic event.

In drowning victims with uncontrolled accidental hypothermia associated with icy water submersion, there are isolated and rare reports of good neurologic recovery after prolonged (10-150 minutes) cardiopulmonary arrest. Almost all these rare survivors have been in freezing water (<5°C [41°F]) and had core body temperatures <30°C (86°F), often much lower. Presumably, very rapid and sufficiently deep hypothermia developed in these fortunate survivors before irreversible hypoxic-ischemic injury occurred. Intact neurologic functioning after sustaining a severe hypothermic submersion is likely associated with a combination of variables, including submersion times (most important), water temperature, immediate resuscitation, quality and duration of resuscitation, idioventricular bradycardia, and rewarming speed.

Most often, hypothermia is a poor prognostic sign, and a neuroprotective effect has not universally been demonstrated. A 2014 study from Washington State found that submersion duration <6 minutes is most strongly related to good outcome, not water temperature. In another study of comatose drowning patients admitted to the pediatric intensive care unit (PICU), 65% of hypothermic patients (body temperature <35°C [95°F]) died, compared with a 27% observed mortality rate in nonhypothermic victims. Thus a beneficial effect of drowning-associated hypothermia has not been seen in most pediatric submersion victims.

MANAGEMENT

Duration of submersion, speed of the rescue, effectiveness of resuscitative efforts, and clinical course determine the outcome in submersion victims (Fig. 88.4). Two groups may be identified based on responsiveness at the scene. The first group consists of children who require minimal resuscitation at the scene and quickly regain spontaneous respiration and consciousness. They have good outcomes and minimal complications. In awake, alert victims with hypoxemia, the first line of therapy is supplemental oxygen. These victims should be transported from the scene to the ED for further evaluation and observation. The second group comprises children in cardiac arrest who require aggressive or prolonged resuscitation and have a high risk of multiple organ system complications, major neurologic morbidity, or death. Compared with cardiac arrest from other causes, cardiac arrest from drowning has a higher survival rate.

Initial management of drowning victims requires coordinated and experienced prehospital care following the ABCs (airway, breathing, circulation) of emergency resuscitation. CPR of drowning victims must include providing adequate ventilation as the initial phase of respiratory arrest, as these children may still have intact circulation. However, this phase will progress to cardiac arrest if hypoxia persists. Children with severe hypoxic injury and symptoms often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involve advanced life support (ALS) strategies and management of multiorgan dysfunction with discussions about end-of-life care.

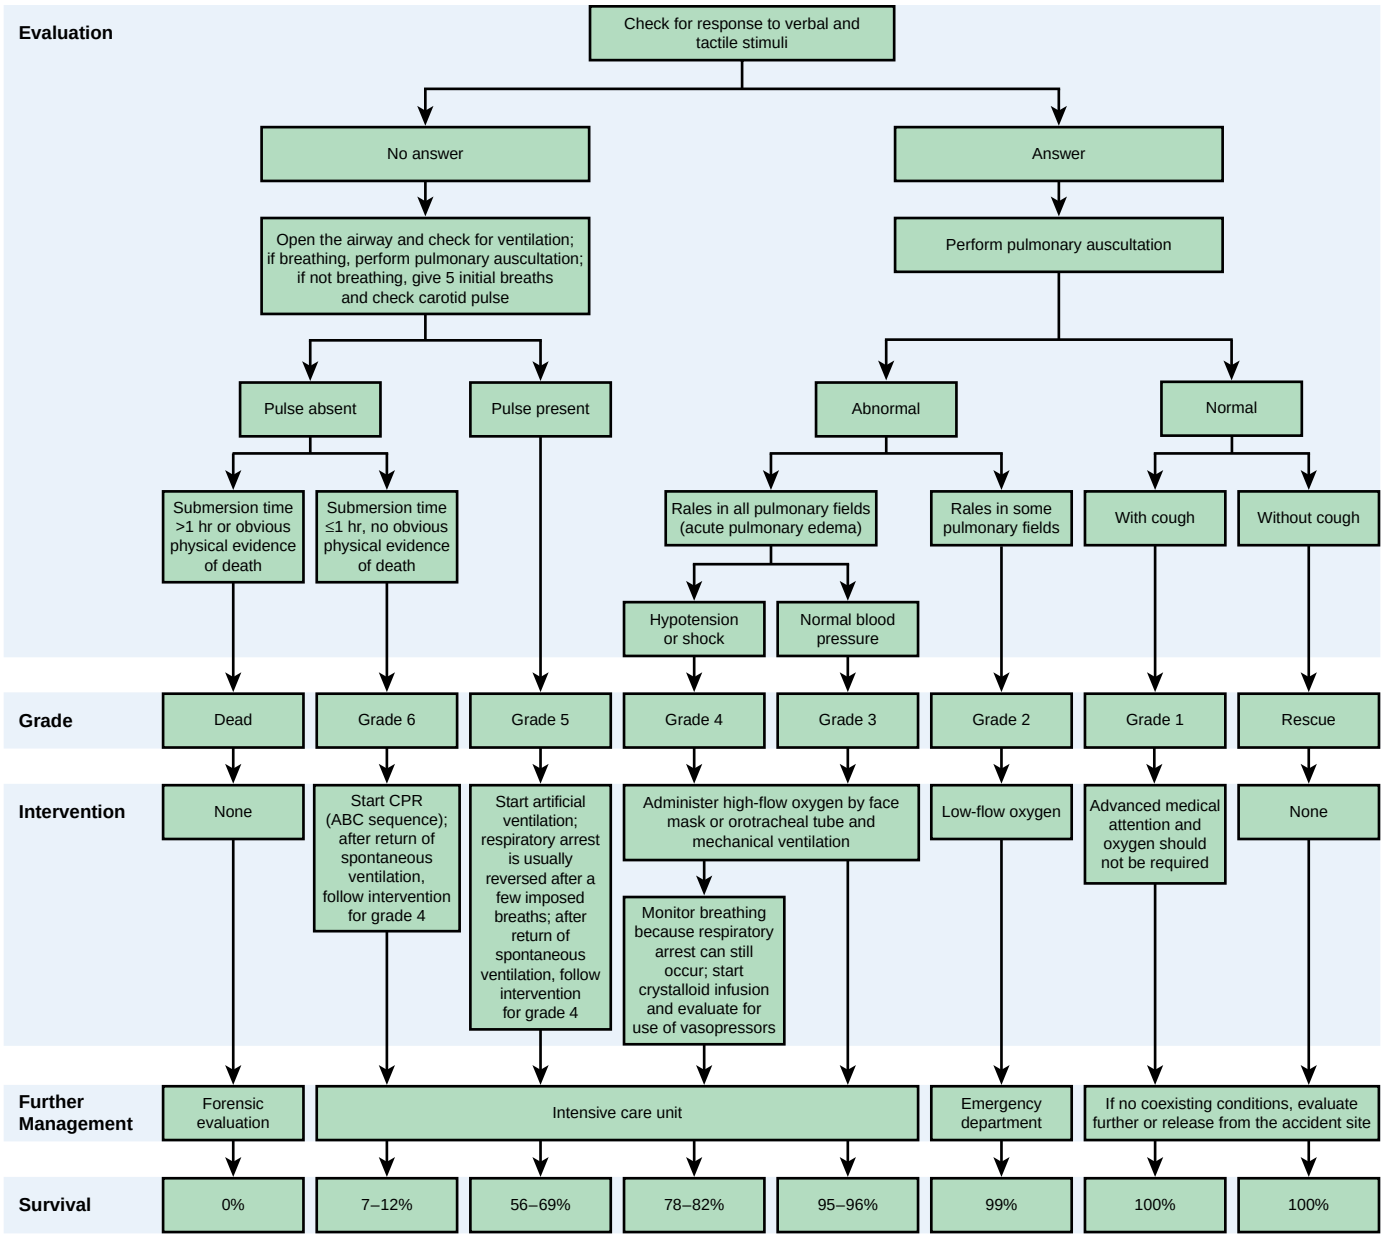

Fig. 88.4 Treatment of persons who have drowned, with classification system. *(From Szpilman D, Bierens J, Handley A, Orloweski J. Drowning. N Engl J Med 2012;366:2102–2110. Fig. 1.)*

Initial Evaluation and Resuscitation

See Chapter 79.

Immediate resuscitation at the submersion site, even before arrival of emergency medical services (EMS) personnel, is the most effective method to improve outcomes after drowning. Neurologic prognosis is significantly improved by prompt bystander CPR and activation of prehospital ALS. The goal is to reverse the anoxia from submersion and limit secondary hypoxic injury after submersion. Every minute that passes without the reestablishment of adequate breathing and circulation dramatically decreases the possibility of a good outcome. When safe for the victim and the rescuer, institution of in-water resuscitation for nonbreathing victims by trained personnel may improve the likelihood of survival. In-water resuscitation protocols recommend performing up to 1 minute of ventilation before attempting to bring the unconscious and apneic patient to shore. For patients in deep water, in-water resuscitation requires rescue flotation equipment or at least 2 rescuers. Practically, victims usually need to be extricated from the water as quickly as possible so that effective CPR can be provided.

Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation. The airway should be clear of vomitus and foreign material, which may cause obstruction or aspiration. Abdominal thrusts *should not* be used for fluid removal, because many victims have a distended abdomen from swallowed water; abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine (C-spine) should be protected in anyone with potential traumatic neck injury (see Chapters 80 and 81). Cervical spine injury is a rare concomitant injury in drowning; approximately 0.5% of submersion victims have C-spine injuries, and history of the event and victim's age should guide suspicion of C-spine injury. Drowning victims with C-spine injury are usually preteens or teenagers whose drowning event involved diving, a motor vehicle crash, a fall from a height, a water sport accident, child abuse, or other clinical signs of serious traumatic injury. In such cases, the neck should be maintained in a neutral position and protected with a well-fitting cervical collar. Patients

rescued from unknown circumstances may also warrant C-spine precautions. In low-impact submersions, spinal injuries are exceedingly rare, and routine spinal immobilization is not warranted.

If the victim has ineffective respirations or apnea, ventilatory support must be initiated immediately. Mouth-to-mouth or mouth-to-nose breathing by trained bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive pressure bag-mask ventilation with 100% inspired oxygen should be instituted in patients with respiratory insufficiency. If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected rapidly to optimize the chance of recovery.

Concurrent with securing of airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated and treated according to the usual resuscitation guidelines and protocols. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims, as studies have shown receiving bystander CPR is associated with neurologically favorable survival in all age groups. Continuous monitoring of the electrocardiogram (ECG) allows appropriate diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, and altered mental status are potential indicators of shock (see Chapter 85).

Recognition and treatment of hypothermia are unique aspects of cardiac resuscitation in the drowning victim. Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias. Wet clothing should be removed to prevent ongoing heat losses, although in the hemodynamically stable patient, rewarming should be initiated in the controlled environment of the receiving ED or PICU. Unstable patients (i.e., arrhythmias) should be warmed to 34°C (93.2°F), taking care not to overheat (see Chapter 90, Fig. 90.2).

Often, intravenous (IV) fluids and vasoactive medications are required to improve circulation and perfusion. Vascular access should be established as quickly as possible for the administration of fluids or pressors. Intraosseous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish IV access in critically ill children. Epinephrine is the initial drug of choice in victims with brady-asystolic cardiopulmonary arrest (IV dose is 0.01 mg/kg using the 1:10,000 [0.1 mg/mL] solution given every 3-5 minutes, as needed). Epinephrine can be given intratracheally (endotracheal tube dose is 0.1-0.2 mg/kg of 1:1,000 [1 mg/mL] solution) if no IV access is available. An intravascular bolus of lactated Ringer solution or 0.9% normal saline (10-20 mL/kg) is often used to augment preload; repeated doses may be necessary.

Hospital-Based Evaluation and Treatment

Most pediatric drowning victims should be observed for at least 4-6 hours, even if they are asymptomatic on presentation to the ED. Serial monitoring of vital signs and oxygenation by pulse oximetry, repeated pulmonary examination, and neurologic assessment should be performed in all drowning victims. Additional studies may also be warranted, depending on the specific circumstances (possible abuse or neglect, traumatic injuries, or suspected intoxication). Almost half of asymptomatic or minimally symptomatic alert children (who did not require ALS in the prehospital setting or who have an initial ED Glasgow Coma Scale [GCS] score of ≥13) experience some level of respiratory distress or hypoxemia progressing to pulmonary edema during the initial 4-6 hours after submersion. Most alert children with early respiratory symptoms respond to oxygen and, despite abnormal initial radiographs, become asymptomatic with a return of normal room-air pulse oximetry oxyhemoglobin saturation (Spo_2) and pulmonary examination by 4-6 hours. Subsequent delayed respiratory deterioration is extremely unlikely in such children. Low-risk patients who present with normal mental status and normal respiratory function may be considered for discharge after 4-6 hours of observation if there is no deterioration of respiratory symptoms and appropriate follow-up can be ensured.

Initial ED management of symptomatic patients with respiratory distress or lethargy may require further testing depending on clinical severity. Initial studies may include blood gas monitoring, a complete metabolic panel, a complete blood count, and chest radiography. Toxicology tests, including drug and alcohol levels, should be considered when appropriate.

There has been much misinformation about **dry drowning** and **secondary drowning**. These are misnomers and not accepted medical terms. Dry drowning has been described historically as cases in which no water was found in the lungs at autopsy. Secondary drowning has been used interchangeably to describe patients who clinically worsen due to pulmonary edema after aspiration of water. These terms cause harm by misdiagnosing cases of sudden death as drowning when there is an alternative diagnosis. They also cause confusion when describing and monitoring drowning events. Drowning victims with no or minimal clinical signs of distress will either improve or worsen within 4–6 hours, and patients will not unexpectedly die of drowning days or weeks later without preceding signs.

Cardiorespiratory Management

For children who are not in cardiac arrest, the level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. Frequent assessments are required to ensure that adequate oxygenation, ventilation, and airway control are maintained (see Chapter 86). Hypercapnia should generally be avoided in potentially brain-injured children. Patients with altered mental status, actual or potential hypoventilation, or markedly elevated work of breathing should receive mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration. Noninvasive ventilation (NIV) strategies such as bilevel positive airway pressure (BiPAP) and high-flow nasal canula (HFNC) have been associated with rapid improvement in the early phase of oxygenation in patients without altered mental status to reduce mortality.

Measures to stabilize cardiovascular status should also continue. Conditions contributing to myocardial insufficiency include hypoxic-ischemic injury, hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory for recognition and treatment of arrhythmias (see Chapter 484).

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Patients should be given 100% inspired oxygen until oxygen saturation can be reasonably measured. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion (see Chapter 79). Increasing preload with IV fluids may be beneficial through improvements in stroke volume and cardiac output. Overzealous fluid administration, however, especially in the presence of poor myocardial function, can worsen pulmonary edema.

For patients with persistent cardiopulmonary arrest on arrival in the ED after *non–icy water* drowning, the decision to withhold or stop resuscitative efforts can be addressed by review of the history and the response to treatment. Because there are reports of good outcome after ongoing CPR in the ED, most drowning victims should be treated aggressively on presentation. However, for children who do not show ready response to aggressive resuscitative efforts, the need for prolonged ongoing CPR after non–icy water submersion almost invariably predicts death or persistent vegetative state. Consequently, in most cases, discontinuation of CPR in the ED is probably warranted for victims of non–icy water submersion who do not respond to resuscitation within 25-30 minutes. Final decisions regarding whether and when to discontinue resuscitative efforts must be individualized, with the understanding that the possibility of good outcome is generally very low with protracted resuscitation efforts. In circumstances of severe ARDS or cardiac insufficiency, extracorporeal life support has been successfully employed.

Neurologic Management

Drowning victims who present to the hospital awake and alert usually have normal neurologic outcomes. In comatose victims, irreversible

CNS injury is highly likely. The most critical and effective neurologic intensive care measures after drowning are rapid restoration and maintenance of adequate oxygenation, ventilation, and perfusion. Core body temperature and glucose management are important modulators of neurologic injury after hypoxia-ischemia.

Comatose drowning patients are at risk for intracranial hypertension. There is little evidence that ICP monitoring and therapy to reduce intracranial hypertension improve outcomes for drowning victims. Patients with elevated ICP usually have poor outcomes—either death or persistent vegetative state. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurologic intensive care therapies, such as fluid restriction; hyperventilation; and administration of muscle relaxants, osmotic agents, diuretics, barbiturates, and corticosteroids, have not been shown to benefit the drowning victim, either individually or in combination. There is some evidence that these therapies may reduce overall mortality but increase the number of survivors with severe neurologic morbidity.

Seizures after hypoxic brain injury are common, although detection is often difficult in the ICU because these patients are frequently sedated. Continuous electroencephalographic (EEG) monitoring in critically ill patients revealed a 13% incidence of seizures, 92% of which were exclusively nonconvulsive. However, EEG monitoring has only limited value in the management of drowning victims, except to detect seizures or as an adjunct in the clinical evaluation of brain death (see Chapter 83). Seizures should be treated, if possible, to stabilize cerebral oxygen use, although benefits are inconclusive. Fosphenytoin or phenytoin (loading dose of 10-20 mg of phenytoin equivalents/kg, followed by maintenance dosing with 5-8 mg of phenytoin equivalents/kg/day in two or three divided doses; levels should be monitored) may be considered as an anticonvulsant; it may have some neuroprotective effects and may mitigate neurogenic pulmonary edema. Benzodiazepines, barbiturates, and other anticonvulsants may also have some role in seizure therapy, although no conclusive studies have shown improved neurologic outcome.

With optimal management, many initially comatose children can have impressive neurologic improvement, but usually do so within the first 24-72 hours. Unfortunately, half of deeply comatose drowning victims admitted to the PICU die of their hypoxic brain injury or survive with severe neurologic damage. Deeply comatose drowning victims who do not show substantial improvement on neurologic examination after 24-72 hours and whose coma cannot be otherwise explained should be seriously considered for limitation or withdrawal of support.

Additional Management Issues

Many drowning victims may have traumatic injury (see Chapter 80), especially if their drowning event involved participation in high-energy water sports such as personal watercraft, boating, diving, or surfing. A high index of suspicion for such injury is required. *Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury.*

Hypoxic-ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Hyperglycemia is associated with a poor outcome in critically ill pediatric drowning victims. Glucose control in patients after drowning should be focused on avoiding hypoglycemia, hyperglycemia, and wide or rapid fluctuations in serum glucose to prevent further harm.

Manifestations of acute kidney injury may be seen after hypoxic-ischemic injury (see Chapter 572). Diuretics, fluid restriction, and dialysis are occasionally needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. Rhabdomyolysis after drowning has been reported.

Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH neutralization. Nutritional support for most drowning victims is usually not difficult, because most children either die or recover quickly and resume a normal diet within a few days. Enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not recover quickly.

Hyperthermia after drowning or other types of brain injury may increase the risk of mortality and exacerbate hypoxic-ischemic CNS damage. Almost half of drowning victims have a fever during the first 48 hours after submersion. Hyperthermia is usually not caused by infection and resolves without antibiotics in approximately 80% of patients. Generally, prophylactic antibiotics are not recommended. However, there is general consensus that fever or hyperthermia (core body temperature >37.5°C [99.5°F]) in comatose drowning victims resuscitated from cardiac arrest should be prevented at all times in the acute recovery period (at least the first 24-48 hours).

Psychiatric and psychosocial sequelae in the family of a pediatric drowning victim are common. Grief, guilt, and anger are typical among family members, including siblings. Divorce rates increase within a few years of the injury, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling, pastoral care, or social work referral should be initiated for drowning victims and their families.

Hypothermia Management

Attention to core body temperature starts in the field and continues during transport and in the hospital. The goal is to prevent or treat moderate or severe hypothermia. Damp clothing should be removed from all drowning victims. Rewarming measures are generally categorized as passive, active external, or active internal (see Chapter 90). **Passive rewarming measures** can be applied in the prehospital or hospital setting and include the provision of dry blankets, a warm environment, and protection from further heat loss. These should be instituted as soon as possible for hypothermic drowning victims who have not had a cardiac arrest.

Full CPR with chest compressions is indicated for hypothermic victims if no pulse can be found or if narrow complex QRS activity is absent on ECG (see Chapters 79 and 90). When core body temperature is <30°C (86°F), resuscitative efforts should proceed according to the American Heart Association guidelines for CPR, but IV medications may be given at a lower frequency in moderate hypothermia because of decreased drug clearance. When ventricular fibrillation is present in severely hypothermic victims (core temperature <30°C [86°F]), defibrillation should be initiated, but may not be effective until the core temperature is ≥30°C (86°F), at which time successful defibrillation may be more likely.

Significant controversy surrounds the discontinuation of prolonged resuscitative efforts in hypothermic drowning victims. Body temperature should be considered before resuscitative efforts are terminated. Other considerations include whether the victim may have been immersed before submerged, whether water was icy, or the cooling was very rapid with fast-flowing cold water. Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld based on initial clinical presentation unless the victim is obviously dead (dependent lividity or rigor mortis). Rewarming efforts should usually be continued until the temperature is 32–34°C (89.6–93.2°F); if the victim continues to have no effective cardiac rhythm and remains unresponsive to aggressive CPR, resuscitative efforts can be discontinued.

Complete rewarming is not indicated for all arrest victims before resuscitative efforts are abandoned. Discontinuing resuscitation in victims of non–icy water submersion who remain asystolic despite 30 minutes of CPR is probably warranted. Physicians must use their individual clinical judgment about deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

Once a drowning victim has undergone successful CPR after a cardiac arrest, temperature management should be carefully considered and body temperature continuously monitored. In victims in whom resuscitation duration was brief and who are awake soon after resuscitation, attempts to restore and maintain normothermia are warranted. Careful monitoring is necessary to prevent unrecognized worsening hypothermia, which can have untoward consequences.

For drowning victims who remain comatose after successful CPR, more contentious issues include rewarming of hypothermic patients and controlled application of therapeutic hypothermia. Although there is no evidence basis or opinion consensus, many investigators

cautiously recommend that hypothermic drowning victims who remain unresponsive because of hypoxic-ischemic encephalopathy after restoration of adequate spontaneous circulation should not be actively rewarmed to normal body temperatures. Active rewarming should be limited to victims with core body temperatures <32°C (89.6°F), but temperatures 32–37.5°C (89.6–99.5°F) should be allowed without further rewarming efforts.

More controversial is the **induction of therapeutic hypothermia** in drowning victims who remain comatose because of hypoxic-ischemic encephalopathy after CPR for cardiac arrest. *A specific recommendation for therapeutic hypothermia, especially in children, is not yet generally accepted.* The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (2002) did not recommend therapeutic hypothermia in drowned children resuscitated after cardiopulmonary arrest, citing insufficient evidence and older studies demonstrating a potential deleterious effect in pediatric drowning victims. Several subsequent studies evaluating extracorporeal membrane circulation, rewarming, and therapeutic hypothermia in pediatric and adult drowning patients have shown no significant improvement in neurologic outcome or mortality.

The Therapeutic Hypothermia After Out-of-Hospital Pediatric Cardiac Arrest (THAPCA) randomized controlled trial (RCT) investigators analyzed post hoc the findings of *targeted temperature management* (TTM) in pediatric comatose survivors of out-of-hospital cardiac arrest caused by drowning. Drowning comprised 28% of the landmark pediatric TTM (33°C vs 36.8°C) RCT, and the authors' principal observation is that targeting hypothermia, compared with targeting normothermia, did not result in better survival.

PROGNOSIS

The outcomes for drowning victims are remarkably bimodal: The great majority of victims either have a good outcome (intact or mild neurologic sequelae) or a poor outcome (severe neurologic sequelae, persistent vegetative state, or death), with very few exhibiting intermediate neurologic injury at hospital discharge. Subsequent evaluation of good-outcome survivors may identify significant persistent cognitive deficits. Of hospitalized pediatric drowning victims, 15% die and as many as 20% survive with severe permanent neurologic damage.

Strong predictors of outcome are based on the incident and response to treatment at the scene. Intact survival or mild neurologic impairment has been seen in 91% of children with submersion duration <5 minutes and in 87% with resuscitation duration <10 minutes. Children with normal sinus rhythm, reactive pupils, or neurologic responsiveness at the scene virtually always had good outcomes (99%). Poor outcome is highly likely in patients with deep coma, apnea, absence of pupil responses (fixed dilated pupils), and hyperglycemia in the ED; with submersion durations >10 minutes; and with failure of response to CPR given for 25 minutes. In one comprehensive case series, all children with resuscitation durations >25 minutes either died or had severe neurologic morbidity, and all victims with submersion durations >25 minutes died. Long-term health-related quality of life and school performance in those who had received either bystander- or emergency medical service personnel–initiated CPR were high if their submersion duration was <5 minutes. Higher morbidity, higher mortality, and lower quality of life were reported in patients with >10 minutes submersion duration. In several studies of pediatric drowning, submersion duration was the best predictor of outcome and water temperature was not. However, there are rare case reports of intact recovery after non–icy water drowning with longer submersion or resuscitation duration.

The GCS score has some limited utility in predicting recovery. Children with a score ≥6 on hospital admission generally have a good outcome, whereas those with a score ≤5 have a much higher probability of poor neurologic outcome. Improvement in the GCS score during the first several hours of hospitalization may indicate a better prognosis. Overall, early GCS assessments fail to adequately distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the first 24-72 hours are the best prognosticators of long-term CNS outcome. Children who regain consciousness within 48-72 hours, even after prolonged resuscitation, are unlikely to have serious neurologic sequelae. Laboratory and technologic methods to improve prognostication have not yet proved superior to neurologic examination. Serial neurologic evaluations after CPR should be performed over the ensuing 48-72 hours, with consideration given to limitation or withdrawal of support in patients who do not have significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved. Patients with minimal improvement during this initial period rarely show significant subsequent neurologic recovery despite aggressive resuscitation efforts and remain in a persistent vegetative state or die. Survivors with severe neurologic limitations necessitate neurorehabilitation to restore function and facilitate psychomotor development and prevent long-term damage caused by contractures, deformities, or scoliosis.

PREVENTION

The most effective way to decrease the injury burden of drowning is prevention. Drowning is a multifaceted problem, but several evidence-based preventive strategies are effective. The pediatrician has a prime opportunity to identify and inform families at risk of these strategies through anticipatory guidance. Advocacy should focus on anticipatory guidance regarding the appropriate supervision of children, access to swim lessons, presence of lifeguards, barriers to swimming pools, and use of PFDs. A family-centered approach to anticipatory guidance for water safety helps explore and identify the water hazards that each family is exposed to in their environment. The practitioner can then discuss the best tools and strategies for prevention that are relevant for the family. It is important to identify the risk both in and around the home and in other locations they may frequent, often when vacationing, such as vacation or relatives' homes. If the family recreates near or on open water, they also need to learn about safety around boats and open water. In a rural environment, water collection systems and natural bodies of water may pose great risk.

Parents must build layers of water protection around their children. Table 88.1 provides an approach to the hazards and preventive strategies relevant to the most common sources of water involved in childhood drowning. A common preventive strategy for exposure to all water types and all ages is ensuring **appropriate supervision**. Pediatricians should define for parents what constitutes appropriate supervision at the various developmental levels of childhood. Many parents either underestimate the importance of adequate supervision or are simply unaware of the risks associated with water. Even parents who say that constant supervision is necessary will often admit to brief lapses while their child is alone near water. Parents also overestimate the supervisory abilities of older siblings; many bathtub drownings occur when an infant or toddler is left with a child <5 years old.

Drowning most often occurs quickly and quietly during periods of inadequate supervision. Supervisory behavior is composed of three components: proximity, attention, and continuity. The caregiver must be alert, must not be consuming alcohol or other drugs or socializing, and must be attentive and focused entirely on watching the child. If the child cannot swim independently, *touch supervision* is required, meaning that the caregiver should always be within arm's reach. Adolescents require active adult supervision and avoidance of alcohol or drug use during water activities.

Learning to swim offers another layer of protection. Children may start swim lessons at an early age that are developmentally appropriate and aimed at the individual child's readiness and skill level. Swim lessons are beneficial and provide some level of protection to young children. A study from Bangladesh, where drowning accounts for 20% of all deaths in children age 1-4 years, showed that swim lessons and water safety curricula are cost-effective and led to a decrease in mortality from drowning. As with any other water safety intervention, parents need to know that swimming lessons and acquisition of swim skills cannot be solely relied on to prevent drowning. *No child can be drown-proof.* A supervising caretaker should be aware of where and how to get help and know how to safely rescue a child in trouble. Because only those trained in water rescue can safely attempt it, families should be encouraged to swim in designated areas only when and where a lifeguard is on duty.

Table 88.1 Approach to Prevention Strategies for Drowning

	HOME	RECREATION	NEIGHBORHOOD
Water hazards	• Swimming pools • Ponds • Bathtubs • Large buckets • Drain entrapment	• Playing in water (swimming, wading) • Playing near water • Being on water (boating)	• Irrigation ditches • Watering holes • Water drainage

Common risks	• Lapse in supervision
	• Unexpected toddler exposure
	• Delayed discovery of child
	• Reliance on water wings or pool toys
	• Reliance on sibling or bath seat for bathing supervision
	• Epilepsy
	• Autism
	• ADHD
	• LQTS
		• Lapse in supervision
		• Change in weather
		• Unfamiliarity with or change(s) in water conditions:
		  • Steep drop-off
		  • Current/tide
		  • Low temperature
		• Alcohol and other drug use
		• Peer pressure
			• Lapse in supervision, particularly when caregiver is socializing
			• Risky behavior when with peers

Prevention strategies	• Recognize hazards and risks • Provide constant adult supervision around water • Install 4-sided, isolation locked fencing of pools • Install rescue equipment and phone at poolside • Learn swimming and water survival skills • Avoid unsupervised baths in older child/teen with seizure disorder; instead, shower • Learn first aid and CPR	• Provide constant adult supervision • Swim in lifeguarded areas • Know when and how to wear US Coast Guard–approved PFDs • Avoid alcohol and other drugs • Learn swimming and water survival skills • Teach children about water safety • Be aware of current weather and water conditions • Buddy system • Learn first aid and CPR	• Identify hazardous bodies of water • Prevent access to water with barriers • Provide fenced-in "safe area" for water recreation • Provide lifeguarded swim sites • Provide access to low-cost swim/water survival lessons

ADHD, attention deficit hyperactivity disorder; CPR, cardiopulmonary resuscitation; LQTS, long QT syndrome; PFDs, personal floatation devices.

Children and adolescents should never swim alone regardless of their swimming abilities. Even as they become more independent and participate in recreational activities without their parents, they should be encouraged to seek areas that are watched by **lifeguards**. The United States Lifesaving Association (USLA) reports that more than 75% of drownings at USLA sites occurred at times when the beaches were unguarded. It is important to emphasize that even if the child is considered a strong swimmer, the ability to swim in a pool does not translate to being safe in open water, where water temperature, currents, and underwater obstacles can present additional and unfamiliar challenges. For swimmers, supervision by lifeguards reduces drowning risk, because lifeguards monitor risk behaviors and are trained in the difficult and potentially dangerous task of rescuing drowning victims.

Two of the preventive strategies listed in Table 88.1 deserve special mention. The most vigorously evaluated and effective drowning intervention applies to swimming pools. Compared with no fencing, installation of four-sided **isolation fencing** surrounding in-ground and aboveground pools with a secure, self-locking gate decreases the number of pool immersion injuries among young children by more than 50%. Guidelines for appropriate fencing, provided by the U.S. Consumer Product Safety Commission (CPSC), are very specific; they were developed through testing of active toddlers in a gymnastics program on their ability to climb barriers of different materials and heights, and recent studies show them to be effective in preventing drowning in young children. In families who have a pool on their property, caregivers often erroneously believe that if a child falls into the water, there will be a loud noise or splash to alert them. Unfortunately, these events are usually silent, delaying timely rescue. This finding highlights the need for a fence that separates the pool from the house, not just surrounds the entire property. The CPSC recommends power safety covers be installed on pools, as well as door alarms if the pool is not completely separated from the house and the yard by a fence. Entrapment and hair entanglement in open drains or pipes are other risks commonly associated with drowning in the pediatric population; special drain covers, safety vacuum release systems, and filter pumps with multiple drains can help prevent this.

The use of U.S. Coast Guard–approved **lifejackets or PFDs** should be advised with all families spending time around open water, not just those who consider themselves boaters. A PFD should be chosen with respect to the weight of the child and the proposed activity. Young children should wear PFDs that will float their head up. Parents should be urged to wear PFDs as well, because their use of PFDs is associated with greater use by their children. Toys such as water wings and "floaties" should not be relied on as drowning prevention measures. The use of life jackets decreases boat-related drowning morbidity and mortality by 50%; unfortunately, their use remains low.

Effective preventive efforts must also consider **cultural practices**. Different ethnic groups may have certain attitudes, beliefs, dress, or other customs that may affect their water safety. The higher drowning risk of minority children needs to be addressed by community-based prevention programs.

In addition to anticipatory guidance, pediatricians can play an active role in drowning prevention by participating in advocacy efforts to improve legislation for pool fencing, PFD use, and alcohol consumption in various water activities. Several counties in the United States, Australia, and New Zealand have laws requiring isolation fencing for pools. Their effectiveness has been limited by a lack of enforcement. Similarly, all states have boating-under-the-influence laws but, similarly, rarely enforce them. Furthermore, efforts at the community level may be needed to ensure the availability of swimming lessons for underserved populations and lifeguarded swim areas.

The Drowning Chain of Survival refers to a series of steps that, when followed, attempt to reduce mortality associated with drowning. The steps of the chain include prevent drowning, recognize distress, provide flotation, remove from water, and provide care as needed. These interventions may be used by the drowning victim for self-rescue or via bystanders who recognize child distress, initiate rescue, and provide resuscitation. The timeline shows that rescue and resuscitation must occur within minutes to save lives, and care should be taken by rescuers to not become victims themselves.

Chapter 89

Burn Injuries

Tina L. Palmieri

Burns are among the top five leading causes of *unintentional injury* in children, after motor vehicle crashes, suffocation, drowning, and poisoning. There has been a decline in the incidence of burn injury requiring medical care that has coincided with a stronger focus on burn treatment and prevention, increased fire and burn prevention education, greater availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reductions in smoking and alcohol abuse.

EPIDEMIOLOGY

Approximately 1.1 million people in the United States require medical care for burn injuries each year, with over 100,000 children admitted to a hospital or treated in the emergency department (ED). **Fires** remain a major cause of mortality in children, but children <14 years old have a lower relative risk of dying in a fire than the general population.

Thermal burns are caused when an external heat source comes in contact with the skin and tissues causing injury; thermal burns may occur from contact with hot surfaces, hot liquids, steam, or flame. **Scald burns** are most prevalent in children ≤4 years old and account for 65% of burn-related admissions in this age-group. Although the incidence of hot water scalding has been reduced by legislation requiring water heaters to be preset at 48.9°C (120°F), scald injury remains the leading cause of hospitalization for burns in this age-group. **Steam** inhalation used as a home remedy to treat respiratory infections is a rare potential cause of burns. **Flame burns** are the most common cause of burn injury in all age-groups ≥5 years old. Electrical and chemical burns are also more common in older children and adults than in young children. **Clothing ignition** events have declined since passage of the Federal Flammable Fabric Act requiring sleepwear to be flame-retardant. Polyester is the fabric most resistant to ignition by a small flame source. Polyester burns deeply as it melts, but it self-extinguishes when the flame source is removed. Cotton, on the other hand, continues to burn after the flame source has been removed, resulting in large, deep burns. Polyester melts downward, sparing the face and respiratory tract; cotton burns upward toward the face. Pellet stoves, glass front stoves, and flat top stoves are frequent sources of hand burns in children, as is contact with hot hair appliances, such as curling irons and hair straighteners. Approximately 18% of burns are the result of **child abuse** (usually scalds), making it important to assess the pattern and site of injury and their consistency with the patient's history (see Chapter 17). **Friction burns** from treadmills are also a problem. Hands are the most commonly injured sites, with burns ranging from deep second-degree to fourth-degree with tendon disruption and fractures from the friction injury. *Anoxia,* not the actual burn, is a major cause of morbidity and mortality in house fires.

Review of the history usually shows a common pattern: a v-shaped distribution of the scald burns to the chest and abdomen if liquid is pulled from a table or stove, burns in the pant leg area if clothing ignites, burns in a splash pattern from a hot liquid spill, and burns on the palm of the hand from contact with a hot stove or curling iron. However, **glove or stocking burns** of the hands and feet; single-area deep burns on the trunk, buttocks, or back; and small, full-thickness burns (e.g., cigarette burns) in young children should raise the suspicion of child abuse.

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychologic and social support as well as resuscitation. Surgical debridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal outcomes. To maximize survival, the clinical approach includes aggressive surgical removal of devitalized tissue with timely skin closure via grafting, infection control, and judicious use of antibiotics; life support with endotracheal intubation and mechanical ventilation; and use of early enteral nutrition. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for reentry to school and social and sporting activities.

PREVENTION

The aim of burn prevention is a continuing reduction in the number of serious burn injuries (Table 89.1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. The use of flame-retardant clothing and smoke detectors, control of hot water temperature (thermostat settings) to 48.9°C (120°F) within buildings, and prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Treatment of children with significant burn injuries in dedicated burn centers facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with burns of 90% of the total body surface area (TBSA) is possible for children and young adults. Death is more likely in children with irreversible anoxic brain injury sustained at the time of the burn. Some burns occur on a seasonal basis, including:

Winter:
- Glass-front fireplaces/pellet stoves and radiators increase hand burns
- Treadmill injuries as more people exercise inside—child imitates adults or young child touches belt
- Soup scald burns from spilling liquid while removing bowl from microwave

Summer:
- Fireworks, sparklers—temperatures reach 537.8°C (1,000°F)
- Burn contact with hot grill; hand/feet burn from hot embers
- Burns from children walking or falling into a campfire
- Lawnmowers

Spring/Fall:
- Burning leaves
- Gasoline burns
- Tap water scalds
- House fires from propane heater explosion

Pediatricians can play a major role in preventing the most common burns by educating parents and healthcare providers. Simple, effective, efficient, and cost-effective preventive measures include the use of appropriate clothing and smoke detectors and the planning of routes for emergency exit from the home. The National Fire Protection Association (NFPA) recommends replacing smoke detector batteries

Table 89.1 Burn Prophylaxis

PREVENT FIRES
Install and use smoke detectors.
Control the hot water thermostat; maximum water temperature should be 48.9°C (120°F).
Keep fire, matches, and lighters out of the reach of children.
Avoid cigarette smoking, especially in bed.
Do not leave lit candles unattended.
Keep hair appliances such as curling irons and straighteners out of the reach of children.
Use caution when cooking, especially with oil.
Keep cloth items off heaters.
PREVENT INJURY
Stop, drop, and roll (do not run) if clothing catches fire; wrap in a blanket.
Practice escape procedures.
Crawl beneath smoke if a fire occurs indoors.
Use educational materials.*

*National Fire Protection Association pamphlets and videos.

Table 89.2 Indications for Referral to a Burn Center

Partial-thickness burns affecting >10% TBSA
Full-thickness burn affecting >5% TBSA
Third-degree burns
Electrical burns caused by high-tension wires or lightning
Chemical burns
Inhalation injury, regardless of the amount of TBSA burned
Inadequate home or social environment
Suspected child abuse or neglect
Burns to the face, hands, feet, perineum, genitals, or major joints
Burns in patients with preexisting medical conditions that may complicate the acute recovery phase
Associated injuries (fractures)

TBSA, Total body surface area.
Adapted from American Burn Association/American College of Surgeons. Guidelines for the operation of burn centers. *J Burn Care Res.* 2007;28(1):134–141 and Bettencourt AP, Romanowski KS, Joe V, et al. Updating the Burn Center Referral Criteria: Results from the 2018 eDelphi Consensus Study. *J Burn Care Res.* 2020;41(5):1052–1062.

Table 89.3 Acute Treatment of Burns

First aid, including washing of wounds and removal of devitalized tissue
Fluid resuscitation
Provision of energy requirements
Control of pain
Prevention of infection
Early excision and grafting
Prevention of excessive metabolic expenditures
Control of bacterial wound flora
Early mobility, range of motion, and strength exercises

annually and the smoke detector alarm every 10 years (or earlier, if indicated on the device).

ACUTE CARE, RESUSCITATION, AND ASSESSMENT

Indications for Admission

Burns covering >10% TBSA, burns associated with smoke inhalation, burns resulting from high-tension (voltage) electrical injuries, and burns associated with suspected child abuse or neglect should be treated emergently and referred to a burn center for definitive care (Table 89.2). Small first- and second-degree burns of the hands, feet, face, perineum, and joint surfaces may require admission if close follow-up care is difficult to provide. Children who have been in enclosed-space fires and those who have significant face and neck burns should be evaluated carefully for airway or neurologic compromise, including monitoring for 24 hours in the hospital for potential central nervous system (CNS) effects of anoxia from carbon monoxide (CO) poisoning or pulmonary effects from smoke inhalation.

First Aid Measures

Acute care should include the following measures:

1. Extinguish flames by rolling the child on the ground; cover the child with a blanket, coat, or carpet.
2. Remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the first 24-72 hours after burn injury.
3. In cases of **chemical injury**, brush off any remaining chemical, if powdered or solid; then use copious irrigation or wash the affected area with water. Call the local poison control center for the neutralizing agent to treat a chemical ingestion.
4. Wash the burned area with soap and cool running water. For burns on less than 10% of the body, irrigate with cool tap water for 10-20 minutes. Significant large-burn injury (>15% TBSA) decreases body temperature control so the use of cold water is contraindicated.
5. Cover the burned area with clean, dry sheeting or dressing. Avoid using tape.
6. If the burn is caused by *hot tar,* cool the burn and then use mineral oil to remove the tar.
7. Administer analgesic medications.

Emergency Care

Supportive measures are as follows (Table 89.3 and Table 89.4):

1. Rapidly review the cardiovascular and pulmonary status and document preexisting or physiologic lesions (asthma, congenital heart disease, renal or hepatic disease).
2. Ensure and maintain an adequate airway (Fig. 89.1). For any child with a facial burn or suspected inhalation of smoke, the following actions are indicated:
   a. Start 100% oxygen and measure carboxyhemoglobin (CO) levels as well as a blood gas, because cutaneous oxygen saturations are not accurate in CO poisoning (see Chapters 79 and 86).
   b. Assess for laryngeal edema (examine mouth; assess for stridor, retractions) and intubate for evidence of significant airway compromise.
   c. Assess oxygenation to evaluate for lung damage from smoke inhalation. Bronchoscopy may be helpful in the intubated child to further delineate the extent of smoke inhalation injury. Use a humidified ventilator circuit to prevent dry secretions that can obstruct an airway.
3. Children with burns >15% TBSA require intravenous (IV) fluid resuscitation to maintain adequate perfusion. IV access is preferably obtained in a nonburned area, but if none is readily available, placing the initial line through a burn may be necessary. Monitor peripheral IV sites closely for infiltration, as extremities will become edematous after burn injury. In an emergency situation in which IV access is unattainable, an intraosseous (IO) line may be placed. The IO line should be replaced in a timely fashion with a central line, as IO needles may be unable to sustain the large fluid volume needed for major burn resuscitation. Patients with inhalation injury, regardless of the extent of TBSA burn, require large volumes of fluid for resuscitation due to insensible losses from the injured airway epithelium. Significant high-tension and electrical injuries require venous access to ensure sufficient fluid resuscitation volumes, as forced alkaline diuresis may be needed in fluid-refractory myoglobinuria to avoid renal damage. Lactated Ringer solution, 10-20 mL/kg/hr (normal saline may be used if lactated Ringer solution is not available), is initially infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, including the type of fluid, the preferred formula for calculation, and preferences for the use of colloid agents, particularly if transfer to a burn center is anticipated.
4. For patients with circumferential burns of the extremities, elevate the extremities and monitor perfusion (capillary refill, pulses), as compartment syndrome (see Chapter 80) may develop and require escharotomy.
5. Evaluate the child for associated injuries. Children with burns may have associated accidental traumatic injuries (fall) or nonaccidental injuries (child abuse). In cases of high-voltage electrical burn (>1,000 volts), especially if there has also been a fall from a height, injuries to the spine, bones, and thoracic or intraabdominal organs may occur (see Chapter 80). Cervical spine precautions should be observed until this injury is ruled out. If ventricular fibrillation occurs at the scene of an electrocution, cardiopulmonary resuscitation (CPR) should be instituted promptly, and cardiac monitoring started on the patient's arrival at the ED (see Chapter 79).
6. Children with burns of >15% TBSA should not initially receive oral fluids because gastric distention may develop. These children may require insertion of a nasogastric tube in the ED to prevent aspiration.
7. A Foley catheter should be inserted into the bladder to monitor urine output in children who require IV fluid resuscitation.

Table 89.4 Phases of Burn Care

PHASE AND TIMING	PHYSIOLOGIC CHANGES	OBJECTIVES
1: Resuscitation, 0-72 hours	Massive capillary leak, edema, and burn shock	Airway, breathing, and circulation optimization via accurate fluid resuscitation and thorough evaluation
2: Acute treatment phase, day 3 through discharge	Hyperdynamic and catabolic state, immunosuppression, risk of infection	Enteral nutrition to optimize wound healing; excision and biologic wound closure of full-thickness wounds with excision and grafting within 7 days of injury
3: Rehabilitation, day 1 through discharge	Gradual waning of initial catabolic state, wounds heal, scars form, and strength recovers	Maintain and restore range of motion; reduce edema; strengthen muscles; facilitate return to home, work, and school

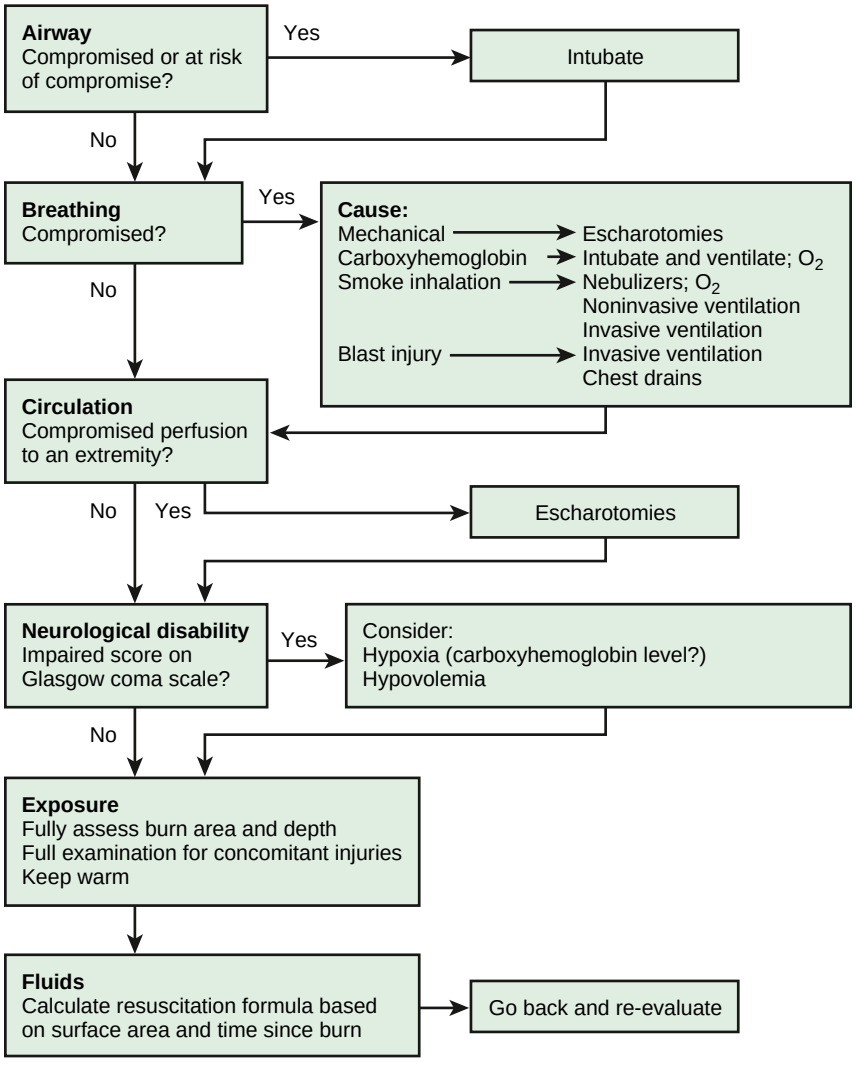

Fig. 89.1 Algorithm for primary survey of a major burn injury. (*From Hettiaratchy S, Papini R. Initial management of a major burn. I. Overview. BMJ. 2004;328:1555–1557.*)

8. In general, wounds should be wrapped with a clean sheet or dressing until it is decided whether to treat the patient on an outpatient basis or refer to an appropriate facility.
9. For children trapped in a fire, a CO measurement (carboxyhemoglobin [HbCO]) should be obtained and 100% oxygen administered until the result is known. Pulse oximetry is unreliable in CO poisoning.
10. Review child immunizations, including tetanus immunization. Use diphtheria, tetanus toxoids, and acellular pertussis (DTaP) for tetanus prophylaxis for children <7 years old, and use tetanus, diphtheria, and pertussis (TdaP) for children ≥7 years old (see Chapter 257).

Classification of Burns

Proper triage and treatment of burn injury require assessment of the extent and depth of the injury (Table 89.5 and Fig. 89.2). **First-degree burns** involve only the epidermis and are characterized by swelling, erythema, and pain (similar to mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48-72 hours; in a small percentage of patients, the damaged epithelium peels off, leaving no residual scars.

A **second-degree burn** involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic). A *superficial* second-degree burn is extremely painful because many remaining viable nerve endings are exposed. Superficial

Table 89.5 Categories of Burn Depth

	FIRST-DEGREE BURN	SECOND-DEGREE BURN (PARTIAL THICKNESS)	THIRD-DEGREE BURN (FULL-THICKNESS)
Surface appearance	Dry, no blisters Minimal or no edema Erythematous Blanches, bleeds	Moist blebs, blisters Underlying tissue is mottled pink and white, with fair capillary refill Bleeds	Dry, leathery eschar Mixed white, waxy, khaki, mahogany, soot-stained No blanching or bleeding
Pain	Very painful	Very painful	Insensate centrally, edges (usually less deep) may still have sensation
Histologic depth	Epidermal layers only	Epidermis, papillary, and reticular layers of dermis May include domes of subcutaneous layers	Through all layers of the skin to subcutaneous tissue (loss of muscle, bone is fourth-degree burn)
Healing time	2-5 days with no scarring	Superficial: 5-21 days with no grafting Deep partial: 21-35 days with no infection, but scar is expected; if infected, converts to full-thickness burn	Large areas require grafting, but small areas may heal from the edges after weeks

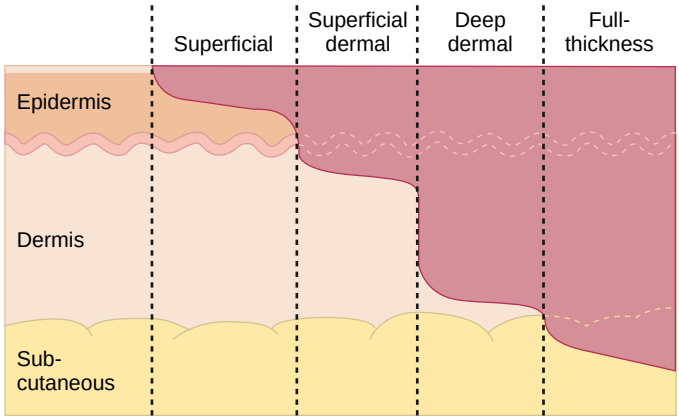

Fig. 89.2 Diagram of different burn depths. (*From Hettiaratchy S, Papini R. Initial management of a major burn. II. Assessment and resuscitation. BMJ. 2004;329:101–103.*)

second-degree burns heal in 7-14 days as the epithelium regenerates in the absence of infection. *Mid-level to deep* second-degree burns will generally heal in 14-21 days, but often result in significant scarring. Deep second-degree burns tend to be dry, pale, and white (flame) or red (scald); they are often grafted to mitigate scarring (Fig. 89.3). Pain may be less with these burns than in more superficial burns because fewer nerve endings remain viable; however, the edge of the burn, which will be less deep, will still cause pain. Fluid losses and metabolic effects of deep dermal (second-degree) burns are essentially the same as those of third-degree burns. If a blister is intact in a burned area, the burn is at least second-degree but may be deeper. Definitive diagnosis of burn depth is not possible because the blister blocks visualization of the burned tissue under the blister.

Full-thickness, or **third-degree burns**, involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the damaged area. The wound heals by wound contraction or skin grafting. Wounds are either white or leathery (flame burn) or mottled, nonblanching, and cherry red (scald) (Fig. 89.4). The absence of painful sensation and capillary filling demonstrates the loss of nerve and capillary elements. Pain exists at the edges of the burn. Hence, using pain to determine burn depth is not accurate.

Technologies can help accurately determine the depth of burns. Laser *Doppler imaging* can be used from 25 days after the burn. It produces a color map of the affected tissue; *yellow* indicates second-degree burns, reflecting the presence of capillaries, arterioles, and venules, and *blue* reflects very low or absence of blood flow, which indicates third-degree burns. Although early reports are promising, the clinical utility of laser Doppler imaging for burn depth determination is not clearly established.

Estimation of Total Body Surface Area for a Burn

Appropriate burn charts for different childhood age-groups should be used to accurately estimate the extent of TBSA burned. The extent and depth of the burn are the largest determinants of fluid resuscitation requirements. Mortality and morbidity also depend on the extent and depth of the burn. Children have a larger surface area to mass ratio than adults, and the variable growth rate of the child's head and extremities makes it necessary to use body surface area (BSA) charts, such as that modified by Lund and Brower, to accurately calculate burn size (Fig. 89.5). Another method of estimating burn size is to employ the palm rule. The palm of the child's hand (from base of palm to fingertip) is 1% of the child's TBSA. A quick method of estimating burn size is to hold your hand up to the child's hand to gauge the area and use that to determine burn size. The **rule of nines** used in adults should only be used in children >14 years old or >20 kg as a rough estimate to institute therapy before transfer to a burn center. The rule of nines divides body regions by 9% BSA: head and neck, chest and upper back, each arm, abdomen, lower back, upper leg, and lower leg; hand or genitals (1%).

TREATMENT

Outpatient Management of Minor Burns

A patient with first- and second-degree burns <10% TBSA may be treated on an outpatient basis unless pain is uncontrolled on oral agents, the family cannot successfully complete wound care, or there are issues of child neglect or abuse. These outpatients do not require prophylactic antibiotics. Blisters should be left intact and dressed with a nonstick dressing such as Telfa or Xeroform. Topical creams do not penetrate the blister and are not indicated unless the blister ruptures. Dressings should be changed once daily, after the wound is washed with lukewarm water. Very small wounds, especially those on the face, may be treated with bacitracin ointment and left open. **Debridement** (i.e., removal) of the devitalized skin is indicated when the blisters rupture. A variety of wound dressings are available for application to second-degree burns; the affected area should be subsequently wrapped with a dry, clean dressing. Silver dressings are popular because they provide pain relief, prevent wound desiccation, reduce wound colonization, and can be left in place for 5-7 days (Table 89.6). Although silver dressings are antimicrobial, wound infections can occur beneath these dressings. Patients should be instructed to seek immediate medical care for signs and symptoms of infection (elevated temperature, malaise, pain) and should be reevaluated at least weekly by the medical team. The great majority of superficial burns heal in 7-10 days, with deep second-degree burns taking longer to heal. Burns that have not healed within 2 weeks (or clearly will not be healed in 2 weeks) have a >97% chance of developing a significant scar and should be referred to a burn center.

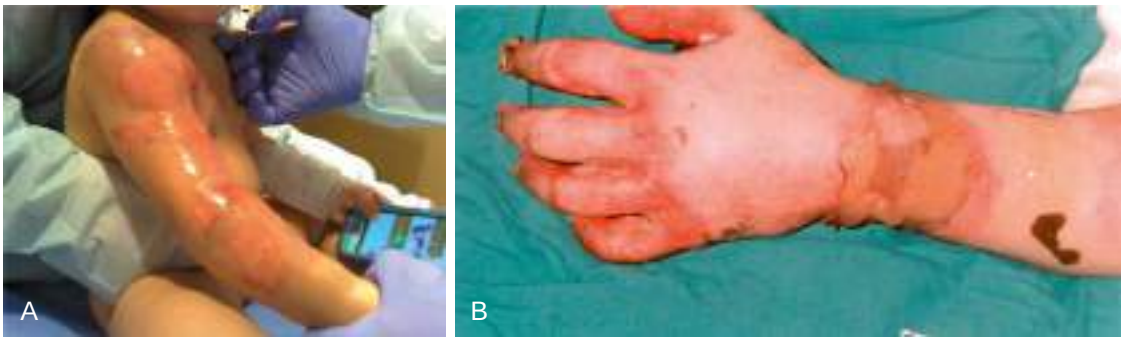

Fig. 89.3 Second-degree burns. **A**, Superficial partial-thickness (second-degree) burn, which is pink and glistening. **B**, Deep partial-thickness (second-degree) burn. The white-appearing area over the dorsum of the hand is a deep partial-thickness burn. (*From Singer AJ, Lee CC. Thermal burns. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. Rosen's Emergency Medicine, 9th ed. Philadelphia: Elsevier; 2018: Figs. 56.1 and 56.2, p. 717.*)

Fig. 89.4 Full-thickness (third-degree) burn over both feet. The central area is depressed and has a yellowish color indicating it is full thickness. (*Modified from Singer AJ, Lee CC. Thermal burns. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. Rosen's Emergency Medicine, 9th ed. Philadelphia: Elsevier; 2018: Fig. 56.3, p. 717.*)

Table 89.6 Select Silver Antimicrobial Dressings for Burns

DRESSING	CHARACTERISTIC(S)
Mepitel Ag	Silicone mesh dressing
Mepilex Ag	Foam dressing
ACTICOAT	Polyethylene nonadherent net dressing
AQUACEL Ag	Absorptive Hydrofiber
Silverlon	Knitted nylon nonadherent dressing

The palm of the hand is one of the most frequently burned areas in children, particularly toddlers. Because the skin on the palm of the hand is thicker than other parts of the body, burns to the palm often heal. Generally, blisters of the palm can be left intact unless they are already open, or they are so large that they will likely rupture (usually about 1-2 cm in height), or purulence is draining from the blister. If leaving a blister intact, inform the family to either return to the office if the blister ruptures or instruct them on how to remove the blister and apply bacitracin to the wound. If a palm burn has not healed in 2 weeks (or it is clear that it will not be healed), referral to a burn center is needed.

The depth of scald injuries is difficult to assess early, as the wounds are often reddish in color. Nonoperative treatment is appropriate initially. Generally, third-degree scald burns will become increasingly pale and white by 4-5 days post injury, whereas those that heal will be a lighter pink color. A wound that has not healed in 2 weeks will likely need grafting (Fig. 89.6). This conservative approach obviates the risk of anesthesia and unnecessary grafting.

Fluid Resuscitation

Fluid resuscitation, if required, should begin as soon as possible (at the scene, in the ED, or before transfer) after the injury has occurred because delays of as little as 30 minutes affect outcomes. Numerous formulas exist to help guide practitioners in calculating fluid resuscitation needs in patients with burns. For most children, the *Parkland formula* is an appropriate *guideline* to determine starting IV fluid resuscitation rate; however, fluids should be adjusted hourly based on the patient's response. The steps in calculating the starting rate are as follows:

1. Calculate the 24-hour fluid requirement: 4 mL lactated Ringer solution per (times) weight in kg per (times) % TBSA burned. The TBSA burned is a whole number, NOT a percentage.
2. Determine the volume of fluid to be given in the first 8 hours: for the Parkland formula, that is half of the 24-hour requirement.
3. Calculate the starting hourly infusion rate: divide the volume to be given in the first 8 hours by 8 to determine the starting rate. The

Fig. 89.6 Tea scald over the chest and shoulder of a child showing heterogeneity of burn depth. D, Deep; I, intermediate; S, superficial. (*From Enoch S, Roshan A, Shah M. Emergency and early management of burns and scalds. BMJ. 2009;338:937–941.*)

infusion rate is adjusted hourly based on urine output goals of 0.8-1 mL/hour in children <20 kg or <12 years of age and 0.4-0.5 mL/kg/hr (maximum of 30 mL/hr) in children >12 years or >20 kg.

Providers should increase the fluid rate by 10% if urine output is below the hourly target and decrease the fluids by 10% if over the target. Because major burns have a hypermetabolic response, tachycardia is NOT an accurate measure of resuscitation in a child with a major burn. Acid-base balance, mental status, serum lactate, and noninvasive monitoring are useful adjuncts to evaluate the adequacy of resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline (preburn) body weight. Patients with burns of >20% TBSA often require a large venous access (central venous line) to deliver the fluid required over the critical first 24 hours; these patients are best cared for in a specialized pediatric burn unit. In addition to fluid resuscitation, children <20 kg should receive standard maintenance fluids (see Chapter 74).

During the second 24 hours after the burn, patients begin to reabsorb edema fluid and to experience diuresis. IV fluid requirements after resuscitation will consist of isotonic crystalloid infusion for insensible losses (see Chapter 73) plus the fluid losses from the burn wound. Controversy surrounds whether *colloid* should be provided in the early period of burn resuscitation. One preference is to administer albumin if a patient is not responding to crystalloid resuscitation. In children <12 months old, sodium tolerance is limited; the volume and sodium concentration of the resuscitation solution should be decreased if the urinary sodium level is rising. The adequacy of resuscitation should be constantly reassessed by integrating vital signs with urine output, blood gas, serum lactate, base deficit, hematocrit, and serum protein measurements. Some patients require arterial and central venous lines, particularly those undergoing multiple excision and grafting procedures, for monitoring and fluid replacement purposes. Central venous pressure monitoring may be indicated to assess circulation in patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation, especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as soon as enteral access is obtained. Early nutrition helps to minimize effects of the hypermetabolic response. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. These feedings are not part of the initial 24-hour fluid resuscitation, as absorption may be variable. When oral fluids are tolerated after several days, IV fluids are decreased proportionately to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

Colloids such as albumin are lost through the burn wound. To maintain oncotic pressure and protein binding, a **5% or 25% albumin infusion** may be used to maintain the serum albumin levels at a desired 2 g/dL. Infusion of **packed red blood cells** is recommended if the hematocrit falls to <20% (hemoglobin = 7 g/dL). Most patients are hemoconcentrated during resuscitation; thus transfusion in the first 24-48 hours is rare unless there is accompanying trauma. **Fresh-frozen plasma** (FFP) is indicated if clinical and laboratory assessment shows a deficiency of clotting factors, a prothrombin level >1.5 times control, or a partial thromboplastin time >1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of more than half of blood volume. Although FFP use for volume resuscitation during the first 24 hours of injury is advocated by some, this strategy has not yet undergone rigorous evaluation through randomized prospective trials.

Sodium supplementation may be required for children with burns of >20% TBSA, particularly if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350 mEq/m^2 burn surface area. The aim is to maintain serum sodium levels >130 mEq/L and urinary sodium concentration >30 mEq/L. Young children <5 years are especially susceptible to hyponatremia and cerebral edema. IV **potassium supplementation** is supplied to maintain a serum potassium level >3 mEq/dL. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when aminoglycoside, diuretic, or amphotericin therapy is required. Magnesium and ionized calcium can also become rapidly depleted and should be assessed at least daily for the first week and weekly thereafter in major burns.

Prevention of Infection and Surgical Management of the Burn Wound

In general, prophylactic antibiotic administration is not indicated for burn injuries because it predisposes patients to development of resistant pathogens. Topical antimicrobial creams or silver agents reduce wound colonization; systemic antibiotics do not reach the nonviable tissue in the burn wound. There is conflicting evidence as to whether relocation of the IV catheter every 48-72 hours decreases or increases the incidence of catheter-related sepsis in burn injury. Central venous catheters should be monitored closely for infection. Many burn units replace or relocate central lines every 5-7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis, particularly if the line is near a burn wound. The incidence of central line–associated bloodstream infection is directly related to the distance between the catheter and the burn wound. The fragile tissue and frequency of patient turning and movement, combined with the moisture of the burn wound, make it imperative to securely attach central venous catheters with sutures placed securely in at least three locations to prevent catheter movement, kinking, or accidental removal.

Mortality related to burn injury is associated not with the toxic effect of thermally injured skin, but with the metabolic and bacterial consequences of a large open wound, reduction of the patient's immune response, and malnutrition. These abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Thorough early wound cleaning, application of topical antimicrobial creams, and early wound excision and grafting promote wound healing and improve aesthetic and functional outcomes. Topical antimicrobial agents for burn wound treatment include bacitracin (second-degree burns or burns that will heal in a week), silver sulfadiazine cream (third-degree burns), mafenide acetate (Sulfamylon) cream (third-degree burns on ears, cartilage), or 0.5% silver nitrate solution (third-degree burns with sulfa allergy) (Table 89.7). Regardless of the choice of topical antimicrobial agent, it is essential that all third-degree burn tissue be fully excised and grafted before bacterial colonization progresses to systemic infection. Children with a burn of >20% TBSA should be housed in reverse isolation with all personnel required to wear gown, gloves, mask, and hat to prevent cross-contamination and to provide a temperature- and humidity-controlled environment that minimizes hypermetabolism.

Deep third-degree burns of >10% TBSA benefit from early excision and grafting. To improve outcome, sequential excision and grafting of

Table 89.7 Topical Agents Used for Burns

AGENT	EFFECTIVENESS	SIDE EFFECTS	EASE OF USE
Bacitracin	Gram-positive organisms; good for wounds that will heal in 7-10 days	May cause yeast overgrowth rash or pustules if on intact skin; resolves with discontinuation	Clear ointment, 1-2 times daily, easy to clean off
Silver sulfadiazine cream (Silvadene)	Broad spectrum including gram-positive and -negative organisms, some fungus; may cause leukopenia	Leukopenia, self-limited; may be painful Leaves adherent residue	Changed twice daily Residue *must* be washed off with each dressing change
Mafenide acetate cream* (Sulfamylon)	Targets resistant gram-negative organisms, particularly *Pseudomonas*, some gram-positive coverage Rapid and deep wound penetration; used on cartilage (ears) and deep wound infection	Carbonic anhydrase inhibitor, may cause metabolic acidosis	Changed twice daily; application may be painful Residue *must* be washed off with each dressing change
0.5% Silver nitrate solution	Bacteriostatic Broad spectrum, including some fungi Superficial penetration	Permanent staining of surfaces from silver oxidation; electrolyte disturbances from hypotonic solution, potential methemoglobinemia	Closed bulky dressing soaked every 2 hr and changed 1-2 times daily

*Mafenide acetate solution at concentrations of 2.5% or 5% for use on heavily colonized, multidrug-resistant organisms to be used for 5 days only.

third-degree and deep second-degree burns may be required in children with large burns. Prompt excision with immediate wound closure is achieved with **autografts**, skin obtained from another part of the patient's body, which may be meshed to increase the efficiency of coverings. Alternatives for wound closure, such as allografts, dermal substitutes, and other biologic dressings, may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Cultured epidermal cells (autologous keratinocytes), grown from a skin biopsy from the patient, are a costly alternative and are not always successful. Another approach employs an autologous cell spray (theoretically containing stem cells) as an adjunct to meshed skin for wound closure. An experienced burn team can safely perform early stage or total excision while burn fluid resuscitation continues. Important keys to success are (1) accurate preoperative and intraoperative determination of burn depth, (2) the choice of excision area and appropriate timing, (3) control of intraoperative blood loss, (4) specific instrumentation, and (5) the type of wound coverage chosen.

Nutritional Support

Supporting the increased energy requirements of a patient with a burn is a high priority. The burn injury produces a hypermetabolic response characterized by both protein and fat catabolism. Depending on the time lapse since the burn, children with a burn of 40% TBSA require basal energy expenditure (oxygen consumption) approximately 50–100% higher than predicted for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the large BSA:mass ratio allows proportionately greater heat loss than in adolescents and adults. Providing environmental temperatures of 28–33°C (82.4–91.4°F), adequate covering during transport, and liberal use of analgesics and anxiolytics can decrease caloric demands. Appropriate sleep intervals are necessary and should be part of the regimen. Early enteral nutrition, initially with high-carbohydrate, high-protein caloric content (1,800 kcal/m^2/24-hr maintenance plus 2,200 kcal/m^2 of burn/24 hr) reduces metabolic stress.

The objective of nutrition supplementation programs is to maintain body weight and minimize weight loss by meeting metabolic demands. This reduces the loss of lean body mass. Calories are provided at approximately 1.5 times the basal metabolic rate, with 3-4 g/kg of protein/day. The focus of nutritional therapy is to support and compensate for the metabolic needs. Multivitamins, particularly the B vitamin group, vitamin C, vitamin A, vitamin D, vitamin E, copper, selenium, and zinc, are also necessary.

Alimentation should be started as soon as is practical, preferably enterally, to meet all caloric needs and maintain gastrointestinal (GI) tract function throughout treatment. Patients with burns of >40% of TBSA need a flexible nasogastric or small bowel feeding tube to facilitate continuous delivery of calories without the risk of aspiration at the time of admission. To decrease the risk of infectious complications, parenteral nutrition should be avoided or discontinued as soon as is practical after delivery of sufficient enteral calories is established. Continuous GI feeding is essential, even if feeding is interrupted for frequent visits to the operating room, until full grafting takes place. In third-degree burns >20% the use of anabolic agents such as *oxandrolone* to improve wound healing and promote protein synthesis or anticatabolic agents (propranolol) to reduce metabolic stress is common practice. It is vital to continue enteral feeding while using these agents to obtain maximal response. Liver function studies should be monitored weekly when giving oxandrolone, and oxandrolone should be discontinued if liver function deteriorates.

Topical Therapy

Topical therapy is widely used to decrease wound colonization from a wide variety of wound pathogens (see Table 89.7). Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. However, all agents impair wound healing. The type of organism on a wound varies with the age of the wound. In the first week, gram-positive organisms predominate. During weeks 2-4, gram-negative organisms are frequently found in burn wounds. Prolonged open burn wounds eventually tend to develop resistant gram-negative organisms, fungus, or mold. The choice of topical antimicrobial depends on wound age and depth. *Bacitracin* is a clear ointment effective against gram-positive organisms and is often used in wounds that will heal within a week. If placed on nonburned skin, it may cause a yeast rash or pimples that resolve with discontinuation. *Silver sulfadiazine* is a white cream containing silver with a broad spectrum of coverage, including

gram-positive and gram-negative organisms and some fungi. It is used commonly in deep third-degree burns that require grafting and may cause transient self-limiting leukopenia if applied over large areas. *Mafenide acetate* is a white cream with the ability to diffuse through the burn eschar; it is the treatment of choice for injury to cartilaginous surfaces, such as the ear. Mafenide acetate solution at a concentration of 5% is useful for the treatment of burn wounds that are heavily colonized with multidrug-resistant gram-negative bacteria and is often used postoperatively to keep grafts moist. The carbonic anhydrase inhibition activity of mafenide acetate may cause metabolic acidosis if large surface areas are treated in a small child. No sulfa-containing agent should be used if the child has a history of sulfa allergies. Silver nitrate solution may be used in children with sulfa allergy because of its broad spectrum of coverage. However, it causes gray staining of the environment and wound from silver oxidation as well as electrolyte disturbances because of the hypotonic nature of the solution.

Inhalation Injury

Inhalation injury is serious in the infant and child, particularly if preexisting pulmonary conditions are present (see Chapter 86). Inhalation injury should be suspected based on history of sustained exposure to smoke in association with the burn injury, such as being confined in a closed space or from an indoor explosion, with decreased level of consciousness or with evidence of carbon deposits in the oropharynx or nose, singed facial hair, or carbonaceous sputum. Mortality estimates vary, depending on the type of inhalation injury and the extent of exposure. Each of the three types of inhalation injury (toxic gases, upper airway edema, and lower airway injury) has a different treatment.

Toxic Gases

Carbon monoxide poisoning from the burning of organic materials is caused by displacement of oxygen from the hemoglobin molecule by CO, leading to tissue hypoxia (see Chapter 94). CO poisoning should be treated with 100% oxygen until carboxyhemoglobin levels drop below 10%. Toxic fumes, including cyanides from combustible plastics as well as sulfur and nitrogen oxides and alkalis formed during the combustion of synthetic fabrics, produce corrosive chemicals that may erode the mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

Injury from gases generally manifests early in the course of treatment. Acute asphyxia is the leading cause of death at the fire scene and can cause anoxic brain injury, particularly in children. Signs of CNS injury from hypoxemia caused by asphyxia or CO poisoning vary from irritability to depression. CO poisoning may be *mild,* with slight dyspnea, headache, nausea, and decreased visual acuity and higher cerebral functions; *moderate,* with irritability, agitation, nausea, dimness of vision, impaired judgment, and rapid fatigue; or *severe,* producing confusion, hallucination, ataxia, cardiovascular collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. Pulse oximetry is NOT a reliable marker of oxygenation in CO poisoning. If significant CO exposure is suspected, a blood gas with co-oximetry and a HbCO level should be obtained to determine Pao_2 and CO toxicity extent. CO poisoning and hypoxia are assumed to be present until the tests are performed, and patients should receive 100% oxygen until the HbCO level is <10% and adequate oxygenation is confirmed. Significant CO poisoning (level >25%) may require hyperbaric oxygen therapy; the risk of transporting a burn patient to the hyperbaric chamber needs to be carefully considered. **Cyanide poisoning** should be suspected if a metabolic acidosis persists despite adequate fluid resuscitation and in environments containing synthetic polymers (see Chapter 94). Unless specifically suspected, most burn centers do not routinely screen for cyanide poisoning.

Upper Airway Edema

The treatment priority for edema of the upper airway caused by inhalation injury focuses on establishing and maintaining a patent airway. If airway obstruction is apparent, prompt and early nasotracheal or orotracheal intubation is indicated to maintain airway patency and assure adequate ventilation and oxygenation. The most experienced provider should perform the intubation, as edema may allow only one attempt. The endotracheal tube size should be chosen carefully, as replacement during the first 1-3 days is often not possible. Endotracheal tubes should *not be secured* with tape if a facial burn is present, as the tape will not adhere to the moist surface. The endotracheal tube can be secured to a tooth, to the maxilla, or tied in two planes. Monitoring the security of the endotracheal tube and assuring it remains in the same location at the level of the teeth is essential, as edema may alter tube position.

Parenchymal Injury

Intubation and mechanical ventilation may be required in patients who have significant hypoxia, hypercarbia, or mental status changes caused by smoke inhalation. Wheezing and bronchospasm are common, and use of inhaled bronchodilators is often helpful. Smoke inhalation injury is gauged via clinical progression and bronchoscopy. Aggressive pulmonary toilet and chest physiotherapy are necessary, as casts and airway obstruction from debris are common. Extubation should be delayed until the patient has adequate oxygenation and ventilation, is able to sustain the increased minute ventilation and work of breathing that accompanies burn injury, and edema has resolved. A spontaneous breathing trial and a cuff leak test are often used to gauge readiness for extubation. Children with an anticipated need for mechanical ventilation >2 weeks may benefit from tracheostomy, as it provides a secure, comfortable airway with decreased sedation requirements. Tracheostomy should only be performed under general anesthesia by experienced surgeons using optimal positioning, proper tracheostomy tube size, and hemostatic conditions. In children with deep burns of the face, tracheostomy provides a secure airway that facilitates excision and grafting yet allows for oral movement, including a pacifier.

Patients with severe inhalation injury or with other causes of respiratory deterioration that lead to pediatric acute respiratory distress syndrome who do not improve with conventional pressure-controlled ventilation (progressive oxygenation failure, as manifested by oxygen saturation <90% while receiving Fio_2 of 0.9-1.0 and positive end-expiratory pressure of at least 12 cm H_2O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per million (ppm) and increased to 30 ppm. This method of therapy reduces the need for extracorporeal membrane oxygenation (ECMO; see Chapter 86). ECMO may be indicated for failure of these conventional techniques.

Pain Relief and Psychologic Adjustment

See Chapter 93.

It is important to provide adequate analgesia, anxiolysis, sedation, and psychologic support to reduce early metabolic stress, decrease the potential for posttraumatic stress disorder (PTSD), and allow future stabilization as well as physical and psychologic rehabilitation. Patients and family members require team support to work through the grieving process and accept long-term changes in appearance.

Children with burn injury have frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn; the stage of healing; the patient's age, stage of emotional development, and cognition; the experience and efficiency of the treating team; the use of analgesics and other drugs; the patient's pain threshold; and interpersonal and cultural factors. From the onset of treatment, **preemptive pain control** during dressing changes is crucial. The use of a variety of nonpharmacologic interventions and pharmacologic agents must be reviewed throughout the treatment period. Opioid analgesia, prescribed in an adequate dose and timed to cover dressing changes, is essential to comfort management. A supportive person who is consistently present and knows the patient profile can integrate and encourage patient participation in burn care. The problem of *undermedication* is most prevalent in adolescents, in whom fear of drug dependence may inappropriately influence treatment. A related problem is that the child's specific pain experience may be misinterpreted;

for anxious patients, those who are confused and alone, or those with preexisting emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief **(relaxation techniques)** can decrease the physiologic stress response.

A multimodal pain strategy is recommended for burns, as burn pain is a combination of background, acute, procedural, neuropathic, and inflammatory pain. The specific agents used will vary by institution and provider training. *Background pain,* which exists primarily in burns >20%, should be addressed with long-acting oral agents administered twice daily, such as methadone or long-acting morphine. This helps to maintain a steady state of pain relief. *Acute pain* from the injury (all burn sizes) is generally treated initially with oral acetaminophen, escalating to a short-acting opioid such as morphine, hydromorphone, oxycodone, or similar agents orally. If oral administration is not sufficient (a common scenario in major burn injury), intermittent IV opioids are used. The use of *codeine* is not recommended because of the possibility of ultrarapid metabolism of codeine. *Procedural pain,* such as for dressing changes, is short-lived but severe. Potent IV opioids such as fentanyl, morphine, or hydromorphone are effective but require appropriate monitoring. Naloxone is rarely needed but should be immediately available to reverse the effect of IV narcotics. Ketamine 1-4 mg/kg IV can be employed for children with high opioid requirements; however, continuous cardiovascular monitoring is mandatory, and ketamine should be administered by a provider trained in advanced airway techniques. *Neuropathic pain* (pins and needles sensation) should be addressed with scheduled oral gabapentin given 4 times daily. *Inflammatory pain* can be effectively treated with nonsteroidal antiinflammatory agents unless the patient has upcoming surgery, as this may increase surgical complications. *Midazolam* is very useful for conscious sedation at a dose of 0.01-0.02 mg/kg for nonintubated patients and 0.05-0.1 mg/kg for intubated patients as an IV bolus and may be repeated in 10 minutes; if used with an opioid, continuous cardiovascular monitoring is warranted. Oral midazolam for premedication before a dressing change at 0.5 mg/kg can be highly effective in reducing anxiety surrounding dressings. Dexmedetomidine infusion may be required for children with high levels of anxiety or who are refractory to benzodiazepine therapy, but this requires monitoring in an intensive care unit (ICU) setting. Postoperative pain after burn surgery, which is severe because of the combination of donor sites and the wound itself, is often treated with a multimodal continuous infusion of an opioid (hydromorphone or morphine) and sedative (dexmedetomidine and/or ketamine). This combination decreases opioid requirements and improves pain but requires monitoring in an ICU. Regional blocks by a trained anesthesiologist can mitigate donor site pain.

During the process of weaning from IV analgesics, the dose of opiates is reduced by 25% over 1-3 days, sometimes with the addition of oral opioids and then acetaminophen as opioids are tapered. When weaning off antianxiety medications, the approach involves reducing the dose of benzodiazepines, at 25–50% per dose, daily over 1-3 days.

Regular evaluation of burned children during hospitalization by a trained psychologist or psychiatrist is necessary, as PTSD, anxiety, depression, acute stress disorder, and other psychiatric issues are common after burn injury. Early recognition and treatment of the patient and family improve psychosocial outcomes. As a result, there is a growing use of *psychotropic medication* in the care of children with burns, including prescription of selective serotonin reuptake inhibitors as antidepressants, the use of neuroleptic agents in the critical care setting, and the treatment of PTSD with prazosin.

Reconstruction and Rehabilitation

To ensure maximum cosmetic and functional outcome, occupational and physical therapy must begin on the day of admission, continue throughout hospitalization, and for many patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. **Pressure therapy** is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas. These custom-made garments deliver consistent pressure on scarred areas; shorten the time of scar maturation; and decrease scar thickness, redness, and associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and improve appearance. Replacement of areas of alopecia and scarring has been achieved with the use of tissue-expander techniques. The use of ultrapulse laser for reduction of scarring is an adjunct in scar management. Pruritis can be a severe issue in the rehabilitative phase. Commonly used oral agents include antihistamines such as loratadine, hydroxyzine, and diphenhydramine, as well as gabapentin or H2 blockers. Topical agents include moisturizers, topical steroid creams, or colloidal oatmeal baths. Refractory itching may be treated with desensitization therapy or laser treatment, although literature supporting these therapies is scarce.

School Reentry and Long-Term Outcome

Optimally the child will return to school immediately after discharge. Occasionally, a child may need to attend on an altered schedule because of rehabilitation needs. It is important for the child to return to the normal routine of attending school and being with peers to begin the resocialization process. Planning for a return to home and school often requires a **school reentry program** that is individualized to each child's needs. For a school-age child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with the school faculty, nurses, social workers, recreational/child-life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school reentry program designed based on the child's developmental and educational needs can alleviate these fears and facilitate the child's reintegration into the school environment.

Major medical advances have made it possible to save the lives of children with massive burns. Although some children have lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in recovery. Table 89.8 lists the long-term disabilities and complications of burns.

ELECTRICAL BURNS

Three types of burns are caused by electricity: electrical burns, caused by electricity passing through the body; arc burns, caused by the heat released from high-amperage currents discharging through the air; and thermal contact burns, from touching a hot electrical device. Electrical burns are divided into high voltage (>1,000 volts) and low voltage (<1,000 volts). Electricity is delivered via alternating current (AC), which is generally used in households, or direct current (DC), often used in industry or car batteries. The majority of pediatric electrical burns involve 110 volts AC electricity and occur in the household. **Minor electrical burns** in children usually occur as a result of biting on an extension cord or inserting an object in an electrical outlet. These injuries produce localized burns to the mouth or finger. Children who chew electrical cords usually sustain burns to portions of the upper and lower lips that come in contact with the extension cord, particularly the corners of the mouth. Because these are *nonconductive* injuries (do not extend beyond the site of injury), hospital admission is not necessary. Care is focused on the area of the injury visible in the mouth, ensuring it is low voltage and does not cause entry or exit wounds or cardiac issues. Treatment with topical antibiotic creams is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon for potential reconstruction or excision of the burn site.

A more serious category of electrical burn is the **high-voltage electrical burn**, for which children must be admitted for observation,

Table 89.8 Common Long-Term Complications and Disabilities in Patients with Burn Injuries

COMPLICATIONS AFFECTING THE SKIN AND SOFT TISSUE	**PSYCHIATRIC AND NEUROLOGIC DISABILITIES**
Hypertrophic scars	Sleep disorders
Susceptibility to minor trauma	Adjustment disorders
Dry skin	Posttraumatic stress disorder
Contractures	Depression
Itching and neuropathic pain	Body image issues
Alopecia	Neuropathy and neuropathic pain
Chronic open wounds	Long-term neurologic effects of carbon monoxide poisoning
Skin cancers	Anoxic brain injury
Epidermal inclusion cysts	
Cutaneous abscesses	**LONG-TERM COMPLICATIONS OF CRITICAL CARE**
	Deep vein thrombosis, venous insufficiency, or varicose veins
ORTHOPEDIC DISABILITIES	Tracheal stenosis, vocal cord disorders, or swallowing disorders
Amputations	Renal or adrenal dysfunction
Contractures	Hepatobiliary or pancreatic disease
Heterotopic ossification	Cardiovascular disease
Temporary reduction in bone density	Reactive airway disease or bronchial polyposis
Decreased endurance and weakness	
	PREEXISTING DISABILITIES THAT CONTRIBUTED TO THE INJURIES
METABOLIC DISABILITIES	Risk-taking behavior
Heat sensitivity	Untreated or poorly treated psychiatric disorder
Obesity	
Glucose intolerance	
Hypertension	

Modified from Sheridan RL, Schultz JT, Ryan CM, et al. Case records of the Massachusetts General Hospital. Weekly clinicopathological exercises. Case 6-2004: A 35-year-old woman with extensive, deep burns from a nightclub fire. *N Engl J Med.* 2004;350:810–821.

regardless of the extent of the surface area burn. Deep muscle injury is typical and cannot be readily assessed initially. These injuries occur in high-voltage installations, such as electric power stations or railroads; children climb an electric pole and touch an electric box out of curiosity or accidentally touch a high-tension electrical wire. Such injuries have a mortality rate of 3–15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity, including major limb amputations. Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The current is conducted throughout the body, regardless of entry and exit points. Virtually any structure in the body is at risk (Table 89.9). Damage to the abdominal viscera, thoracic structures, and nervous system (confusion, coma, paralysis) in areas remote from obvious extremity injury occurs and must be sought, particularly in injuries with multiple current pathways or those in which the victim falls from a high pole. *Cardiac abnormalities,* manifested as ventricular fibrillation or cardiac arrest, are common; patients with high-tension electrical injury need an initial electrocardiogram (ECG) and cardiac monitoring until they are stable and have been fully assessed. Higher-risk patients have abnormal ECG findings and a history of loss of consciousness. Renal damage from *deep muscle necrosis* and subsequent myoglobinuria is another complication; such patients need forced alkaline diuresis to minimize renal damage. Soft tissue (muscle) injury of an extremity may produce a **compartment syndrome** (see Chapter 80). Aggressive removal of all dead and devitalized tissue, even with the risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early debridement facilitates early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on immediate intensive care; functional result depends on long-term care and delayed reconstructive surgery. The incidence of cataract formation is also increased in patients who have sustained electrical injuries; patients should be referred to an ophthalmologist for regular examinations.

Arc burns generally are caused by clothing *ignition* from the superheated arc that can be emitted from high-amperage current discharge. The hallmark of this injury is a large cutaneous burn following clothing lines and covered in thick soot. Discreet entrance and exit points are not generally seen. Muscle injury is rare, as current does not actually traverse the skin. Treatment should follow the principles for major flame burn injury treatment.

Contact burns, in which tissue destruction is localized to a small area of contact with an electrical box with no evidence of electricity conducted through the body, are generally treated as any other burn injury. Careful history and physical examination should be performed to assure that there was no transmission of electricity.

89.1 Lightning Burns

Tina L. Palmieri

Worldwide, lightning occurs approximately 50 times per second, primarily via ground strikes involving 30,000-100,000 amperes at 30,000 Kelvin temperature. Fortunately, the incidence of lightning burns is low, with 400 injuries and 40 deaths per year attributed to lightning. Lightning injury occurs via (1) direct strike (electrical current), (2) thermal burns from conversion of electrical energy to heat, or (3) mechanical trauma from the acoustic shock wave, flying debris, fall, or muscle contraction. The most common form of lightning burn, accounting for approximately half of lightning injuries, is **ground current**, in which lightning strikes the ground or an object near an individual and travels through the ground to the individual. **Side splash** injuries constitute ~30% of lightning injuries and occurs when current jumps from a nearby object, then follows the path of least resistance to an individual. Direct strikes account for 5% of lightning injuries. Sudden death after a direct strike is due to simultaneous cardiac and respiratory arrest from depolarization of cardiac muscle cells and paralysis of the medullary respiratory center.

Lightning cutaneous burns depend on the current path, the type of clothing worn, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common

Table 89.9 Electrical Injury: Clinical Considerations

SYSTEM	CLINICAL MANIFESTATIONS	MANAGEMENT
General	—	• Extricate the patient • Perform ABCs of resuscitation; immobilize the spine • Obtain history: voltage, type of current • Obtain complete blood count with platelets, electrolytes, BUN, creatinine, and glucose
Cardiac	Dysrhythmias: asystole, ventricular fibrillation, sinus tachycardia, sinus bradycardia, premature atrial contractions, premature ventricular contractions, conduction defects, atrial fibrillation, ST- and T-wave changes	• Treat dysrhythmias • Provide cardiac monitor, electrocardiogram, and radiographs with suspected thoracic injury • Perform creatinine phosphokinase with isoenzyme measurements if indicated
Pulmonary	Respiratory arrest, acute respiratory distress, aspiration syndrome	• Protect and maintain the airway • Provide mechanical ventilation if indicated, chest radiograph, and arterial blood gas levels
Renal	Acute kidney injury, myoglobinuria	• Provide aggressive fluid management unless central nervous system injury is present • Maintain adequate urine output, >1 mL/kg/hr if myoglobinuria; addition of HCO_3^-, mannitol may be needed to alkalinize urine and stimulate diuresis, respectively • Consider central venous or pulmonary artery pressure monitoring • Measure urine myoglobin; perform urinalysis; measure BUN, creatinine
Neurologic	Immediate: loss of consciousness, motor paralysis, visual disturbances, amnesia, agitation; intracranial hematoma	• Treat seizures • Provide fluid restriction if indicated
	Secondary: pain, paraplegia, brachial plexus injury, syndrome of inappropriate antidiuretic hormone secretion, autonomic disturbances, cerebral edema	• Consider spine radiographs and MRI, especially cervical
	Delayed: paralysis, seizures, headache, peripheral neuropathy	• Perform CT or MRI scan of the brain if indicated
Cutaneous/oral	Oral commissure burns, tongue and dental injuries; skin burns resulting from ignition of clothes, entrance and exit burns, and arc burns	• Document entrance and exit wounds • Treat cutaneous burns; determine patient's tetanus status • Obtain consultation for plastic surgery of ear, nose, and throat, if indicated
	Electrical burns to mouth could include oral commissures and lips; low-voltage electrical burns secondary to high conductivity of saliva	• Ensure no entry or exit wounds and no cardiac involvement • Confirm all injuries are localized • Management is observation until eschar sloughs off and granulation tissue fills in • If bleeding at corner of mouth from labial artery, pinch lower lip to stop bleeding and consult surgeon • High risk for scarring; refer to burn center for long-term management
Abdominal	Viscus perforation and solid-organ damage; ileus; abdominal injury rare without visible abdominal burns	• Place nasogastric tube if patient has airway compromise or ileus • Obtain serum ALT, AST, amylase, BUN, and creatinine measurements and CT scans as indicated
Musculoskeletal	Compartment syndrome from subcutaneous necrosis limb edema and deep burns	• Monitor patient for possible compartment syndrome
	Long-bone fractures, spine injuries	• Obtain radiographs and orthopedic/general surgery consultations as indicated
Ocular	Visual changes, optic neuritis, cataracts, extraocular muscle paresis	• Obtain an ophthalmology consultation to document and follow for cataract formation

AST, Aspartate transaminase; ALT, alanine transaminase; BUN, blood urea nitrogen.
Adapted from Hall ML, Sills RM. Electrical and lightning injuries. In: Barkin RM, ed. *Pediatric Emergency Medicine*. St Louis: Mosby; 1997: p. 484.

and *does not* relate to the severity of the cutaneous burn. Linear burns, usually first- or second-degree, are in the locations where sweat is present. **Feathering**, also called *Lichtenberg figures,* is an arborescent pattern appearing on the skin and is pathognomonic for lightning injury (Fig. 89.7). The feathering skin appearance, thought to be caused by changes in cutaneous blood flow, is transient and disappears within several hours. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with CPR (see Chapter 79). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and paralysis of the lower extremities. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur but are rare. Ocular manifestations include vitreous hemorrhage, iridocyclitis, retinal tearing, or retinal detachment. Rupture of the tympanic membrane occurs in 50–80% of those sustaining a direct strike.

Treatment of lightning injury generally follows traditional trauma management with one exception: In the event of multiple lighting injuries (mass casualty), a "reverse triage" system is employed, in which initial treatment is focused on those who appear to be in cardiac arrest,

Fig. 89.7 Lightning burn: Lichtenberg feathering. (*Courtesy Dr. Mary Ann Cooper.*)

which is often reversible. Early attention to ventilation after restoration of cardiac rhythm in lightning-injured patients is crucial to prevent recurrent cardiovascular collapse and hypoxic brain injury. This triage algorithm is employed because those who have cardiorespiratory function immediately after the strike rarely succumb to their injury before hospital arrival. Ultimate outcomes depend on injury severity, mental status, organ involvement, cardiac arrest presence, and arrhythmias. Lightning survivors who have a normal ECG and normal vital signs and no obvious injury can be discharged home if they *do not* have history of a direct strike, loss of consciousness, focal neurologic complaint, major trauma, significant burns, or chest pain or dyspnea. However, they should be referred for ophthalmologic evaluation and audio-vestibular evaluation should there be ocular or otic injury. Neurologic effects of lightning injury may be significant. CNS dysfunction can be immediate or delayed and includes spinal cord injury, ischemic stroke, or *keraunoparalysis* (temporary condition that mimics spinal cord injury) as well as trauma-related injuries such as skull fractures or spinal cord injury. Personality alterations and sleep disorders may develop over time post injury.

Chapter 90

Cold Injuries

Jennifer Dow

Children and youth are exposed to cold environments through outdoor recreation, occupational activities, or housing crises. Although cold injuries are commonly attributed to subfreezing temperatures, it is a misnomer that it must be below 0°C (32°F) for systemic injury or local tissue damage to occur. Injury from cold occurs when the body's ability to generate heat is overwhelmed by environmental loss.

MECHANISMS OF HEAT TRANSFER

Environmental heat or cold injury occurs when the metabolic capacity for thermoregulation cannot maintain core body temperature in the setting of extreme environmental temperatures. The hypothalamus controls the production and conservation of heat, responding to central and peripheral receptors. Local skin temperature is partially responsible for the regulation of peripheral blood flow. Heat production is a product of cellular metabolism and by both voluntary (exercise) and involuntary (shivering) muscle use, while vasoconstriction and behavioral action influence conservation. Heat is transferred to the environment by five mechanisms: radiation, conduction, convection, respiration, and evaporation.

Radiation is the transfer of heat from one object to another without physical contact. This type of heat loss is moderated by vasoconstriction, diminishing warm blood flow to the periphery, and behavioral adaptation of wearing insulating layers. Medications or conditions that prohibit the vasoconstrictive response contribute to heat loss by radiation. Children may not have the knowledge or experience to recognize when additional clothing is necessary; adults are obliged to ensure that appropriate clothing is available. In a dry environment, radiation is the predominant method of heat transfer. **Conduction** is the direct transfer of heat to another object and is the primary mechanism of heat loss when a body is immersed, as water has up to 30 times more thermal conductivity than air. Heat is also conducted when an individual touches a cold object (e.g., a cold rock, snow, metal chair). Behavioral adaptations include avoidance and placement of insulation between the individual and the surface. **Convective** loss of body heat to cooler circulating air or water can be mitigated by clothing and vasoconstriction. Convection is a method of rewarming, using hot air as a delivery method. **Evaporative** heat loss results from the conversion of water (sweat) to vapor; like *respiratory* loss, it is a small but obligate contribution to thermal balance.

HYPOTHERMIA

Accidental hypothermia is the unintentional drop in core temperature below 35°C (95°F), occurring when the combination of physiologic and behavioral mechanisms to maintain core temperature are overwhelmed by environmental losses. Although cold and wet environments pose the most significant risk, accidental hypothermia can occur in any season and in most climates. The predominant clinical manifestations are reflective of disruptions of the cardiopulmonary and central nervous systems (Table 90.1). Cerebral function begins to diminish at a core temperature of 33–34°C (91.4–93.2°F), with early manifestations being irritability, confusion, and poor decision-making, progressing to lethargy, somnolence, and coma. Cerebral oxygen requirements are decreased by cooling, affording transient protection in cardiac standstill or cold-water drowning events. The initial cardiopulmonary response to cold is an increase in cardiac output and ventilation to support the metabolic demand of shivering. Further cardiac cooling manifests as bradycardia and abnormalities of cardiac conduction (atrial and ventricular dysrhythmias, including fibrillation) (Fig. 90.1). The crucial factors for reducing morbidity and mortality due to hypothermia are prevention, prompt recognition, and rapid treatment.

Risk Factors and Prevention of Hypothermia

The risk factors associated with hypothermia are extensive. Illnesses, medications, and substance use can disrupt the normal physiologic responses to cold. Vasoconstriction is disrupted by ethanol, vasodilatory medications, and infections. Central nervous system (CNS) trauma, stroke, medications (antidepressants, mood stabilizers, anxiolytics), and endocrine disorders (hypothyroid, adrenal insufficiency, diabetes, hypoglycemia, hypopituitarism) disrupt the hypothalamic response to cold. Mental illness, intoxication (opiates, organophosphates, barbiturates, carbon monoxide), and lack of awareness, as seen in the extremes of age, may impair the ability to recognize cold. General conditions of malnutrition and inability to move make it such that the patient does not have the caloric reserves to shiver or cannot move safely out of the cold. Autonomic dysfunction may produce hypothermia. Knowledge of these conditions ideally results in a heightened attentiveness to the potential for hypothermia. Active prevention includes awareness of the weather conditions and the utilization of appropriate clothing. Insulation

Table 90.1 Physiologic Characteristics of the Four Zones of Hypothermia

STATE	CORE TEMPERATURE °C (°F)	CHARACTERISTICS
Mild	35 (95)	Urine temperature, 34.8°C (94.6°F); increased shivering thermogenesis; increase in metabolic rate
	34 (93.2)	Amnesia and dysarthria develop; normal blood pressure; maximum respiratory stimulation
	33 (91.4)	Ataxia, apathy develop
Moderate	32 (89.6)	Stupor; 25% decrease in oxygen consumption
	31 (87.8)	Decreased shivering thermogenesis
	30 (86)	Atrial fibrillation and other dysrhythmias; poikilothermia; pulse and cardiac output two-thirds normal; insulin ineffective
	29 (85.2)	Progressive decrease in level of consciousness, pulse, and respiration; pupils dilated
Severe	28 (82.4)	Ventricular fibrillation susceptibility; 50% decrease in oxygen consumption and pulse
	27 (80.6)	Losing reflexes and voluntary motion
	26 (78.8)	Major acid-base disturbances; no reflexes or response to pain
	25 (77)	Cerebral blood flow one-third normal; cardiac output 45% normal; pulmonary edema may develop
	24 (75.2)	Significant hypotension
	23 (73.4)	No corneal or oculocephalic reflexes
	22 (71.6)	Maximum risk of ventricular fibrillation; 75% decrease in oxygen consumption
Profound	20 (68)	Lowest resumption of cardiac electromechanical activity; pulse 20% of normal
	19 (66.2)	Flat electroencephalogram
	18 (64.4)	Asystole develops
	14.2 (57.6)	Lowest accidental hypothermia survival in an infant
	13.7 (56.7)	Lowest accidental hypothermia survival in an adult
	9 (48.2)	Lowest therapeutic hypothermia survival

From Zafren K, Danzl DF. Accidental hypothermia. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. *Rosen's Emergency Medicine*, 9th ed. Philadelphia: Elsevier; 2018, Table 132.1, p. 1744.

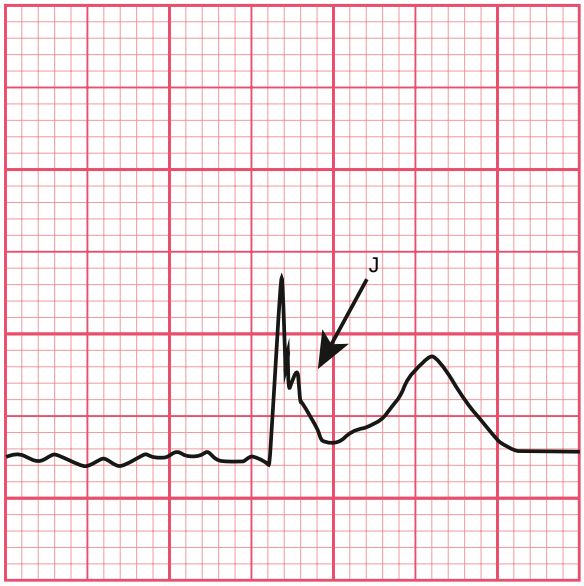

Fig. 90.1 Characteristic J or Osborne wave of hypothermia (temp <32°C) closely follows QRS. It may be mistaken for a T wave with narrow QT interval if the true T wave is not appreciated. The slightly rounded peak distinguishes it from R′ of bundle branch block. (*From Gunnarsson B, Heard CMB. Accidental hypothermia. In: Zimmerman JJ, Clark RSB, Fuhrman BP, et al., eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Elsevier: Philadelphia; 2022: Fig. 114.1, p. 1333.*)

and ease of layering are factors to be considered when choosing clothing. Removing a layer while engaging in aerobic activity helps prevent sweating and subsequent evaporative heat loss; replacing it when activity slows prevents loss by radiation through the inadequate insulation. Socks and gloves should fit properly, without circulatory impingement, and be constructed of materials other than cotton. Covering the head and face prevents losses through these exposed areas. Infants and young children will lose more heat by radiation through the head than adults because of its relatively increased surface area. The utilization of wind-blocking materials mitigates loss due to convection, and waterproofing keeps clothing dry and minimizes losses resulting from convection and radiation. Additional preventative measures are ensuring adequate nutrition for the activity, recognizing an increased metabolic demand in the cold, and having access to shelter for warmth.

Clinical Presentation of Hypothermia

Hypothermia is a cold injury syndrome with progressive signs and symptoms (see Table 90.1 and Fig. 90.2). The differential diagnosis is broad, and the clinician must be aware of the environment from which the patient presents. It is also essential that the clinician recognize that each patient is unique and presents with subtle differences. A patient may continue to shiver below the 30°C (86°F) "cut-off" but manifest all other signs of moderate to severe hypothermia. Standard classification is based on measured core temperature, whereas field classification is based on signs and symptoms (see Fig. 90.2). Treatment of all stages includes preventing further heat loss and initiating rewarming (Fig. 90.3).

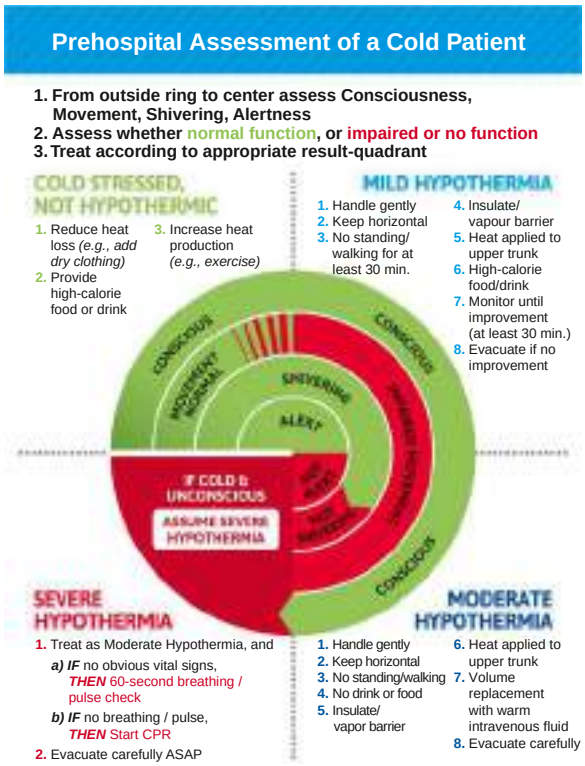

Fig. 90.2 Algorithm for field assessment and treatment of a cold patient. (*Sources: BICOrescue.com; Zafren K, Giesbrecht GG, Danzl DF, et al. Wilderness Medical Society practice guidelines for the out-of-hospital evaluation and treatment of accidental hypothermia: 2014 update. Wilderness Environ Med. 2014;25(4 Suppl):S66-S85.*)

Cold Stress

Cold stress is marked by shivering and a core temperature >35°C (95°F). Measures to prevent further heat loss and increase heat production are all that are necessary for reversal. This may entail increasing physical activity to generate warmth, relocating to a warm environment, or adding clothing layers.

Mild Hypothermia

Patients with mild hypothermia are conscious and alert with measured core temperatures of 32–35°C (89.6–95°F). Most will shiver, even violently, if there are enough energy reserves. As the core temperature drops, the patient may begin to demonstrate discoordination or loss of fine motor control. Hemodynamic parameters are generally stable, with tachycardia and tachypnea observed due, in part, to the increased catecholamine response and support of the metabolic demands of shivering. Protection from further heat loss, removal and replacement of wet clothing, and calorie replacement should be initiated simultaneously. Application of insulation (e.g., sleeping bag) and a vapor barrier will optimize passive rewarming. Active external rewarming can be initiated using hot water bottles or rewarming heat packs applied to the neck, chest, upper torso, axilla, and groin. Try to avoid burns to exposed skin. Patients with mild hypothermia retain consciousness but may demonstrate diminished alertness. Transport for further evaluation and observation is recommended if they do not return to full alertness and function in the field.

Moderate Hypothermia

Moderate hypothermia, with core temperatures of 28–32°C (82.4–89.6°F), is the slowing phase of symptom progression. Patients present with bradycardia, respiratory depression, and altered mental status, manifesting as depressed level of consciousness, often stuporous, and hyporeflexia. Shivering generally stops at 30°C (86°F), but there is variation among patients. Active external rewarming should be initiated with heat applied to the upper torso, chest, axilla, and back. Fluid replacement is initiated with intravenous fluids, ideally containing glucose, warmed to 40–42°C (104–107.6°F). Cardiac monitoring is indicated, as a cold heart and hypothermia-associated acidosis increases the risk of unstable arrhythmias. Hemodynamically stable patients may be transported to any hospital; however, if unstable, a hospital with extracorporeal membrane oxygenation (ECMO) is recommended.

Severe/Profound Hypothermia

Core temperatures <28°C (82.4°F) are characterized by stupor, leading to coma with loss of cerebrovascular autoregulation. Further cardiovascular instability manifests as bradycardia, hypotension, and a significant risk for unstable tachycardias, often beginning as atrial fibrillation with progression to ventricular dysrhythmias. There is no coordinated musculoskeletal activity. Patients with severe hypothermia may appear dead. Cardiopulmonary resuscitation (CPR) should be initiated if there is no cardiac activity, as determined by a pulse check of at least 1 minute duration or the absence of organized electrical activity on a monitor. Bedside echocardiography may also be used to identify cardiac activity. Vasoactive medications should be held until the core temperature is >30°C (86°F) and then administered at twice the dosing interval until 35°C (95°F). Defibrillation or cardioversion, if indicated, is attempted once, at maximum power, then held until the core temperature is above 30°C (86°F).

In hypothermic cardiac arrest, rescuers should initiate CPR regardless of the patient's temperature. Contraindications to initiation of CPR include if there is obvious fatal injury, ice or snow is visualized in the airway, chest wall compression is impossible, or rescuers are at risk. The usual signs of death—rigor, pupillary dilation, and lividity—are unreliable in the hypothermic patient.

Complications of hypothermia include compartment syndrome, rhabdomyolysis, hyperkalemia or hypokalemia, hemoconcentration, hypercoagulability, disseminated intravascular coagulation (DIC), confusion (paradoxical undressing), Takotsubo cardiomyopathy, and mydriasis. Core temperature **afterdrop** is a decrease in core temperature after removal from the cold and/or when external rewarming begins; external rewarming extremities with frostbite is another risk factor.

Hypothermia is fatal if not treated. Prevention and risk mitigation through awareness of weather conditions, appropriate clothing and layering systems, and breaks for rewarming during outdoor activities will limit its incidence. Adults supervising children and adolescents participating in outdoor activities must be aware that behavior changes and apparent clumsiness might signal the onset of hypothermia.

SOFT TISSUE COLD INJURY

Soft tissue injuries caused by cold are divided into freezing and nonfreezing injuries. Frostbite is a freezing injury, whereas frostnip, chilblains (pernio), cold immersion, and cold-induced fat necrosis are nonfreezing injuries.

FROSTBITE

Frostbite is an injury occurring at or below freezing temperatures. It can have devastating effects with tissue loss leading to functional debility. It is preventable. Frostbite, like hypothermia, is a condition occurring when tissue heat loss is greater than the warmth delivered by peripheral perfusion. Minimizing exposure to cold, either by avoidance, use of appropriate clothing, and responding to changing conditions appropriately, are keys to frostbite prevention. Clothing, especially hand and footwear, should insulate well and not be constricting. Vasoconstriction inhibits peripheral cutaneous warming. Inhibitors of peripheral perfusion, such as vasoconstricting medications, circulatory disorders (e.g., Raynaud syndrome), and chronic skin conditions (e.g., psoriasis), increase frostbite risk. Emollients applied to the skin do not protect from the cold. Any complaints of numbness are to be taken seriously, and the child should be assessed for signs of cold injury in a protected environment. Frostnip, although not a freezing injury, does indicate that the temperature and exposure conditions may promote frostbite.

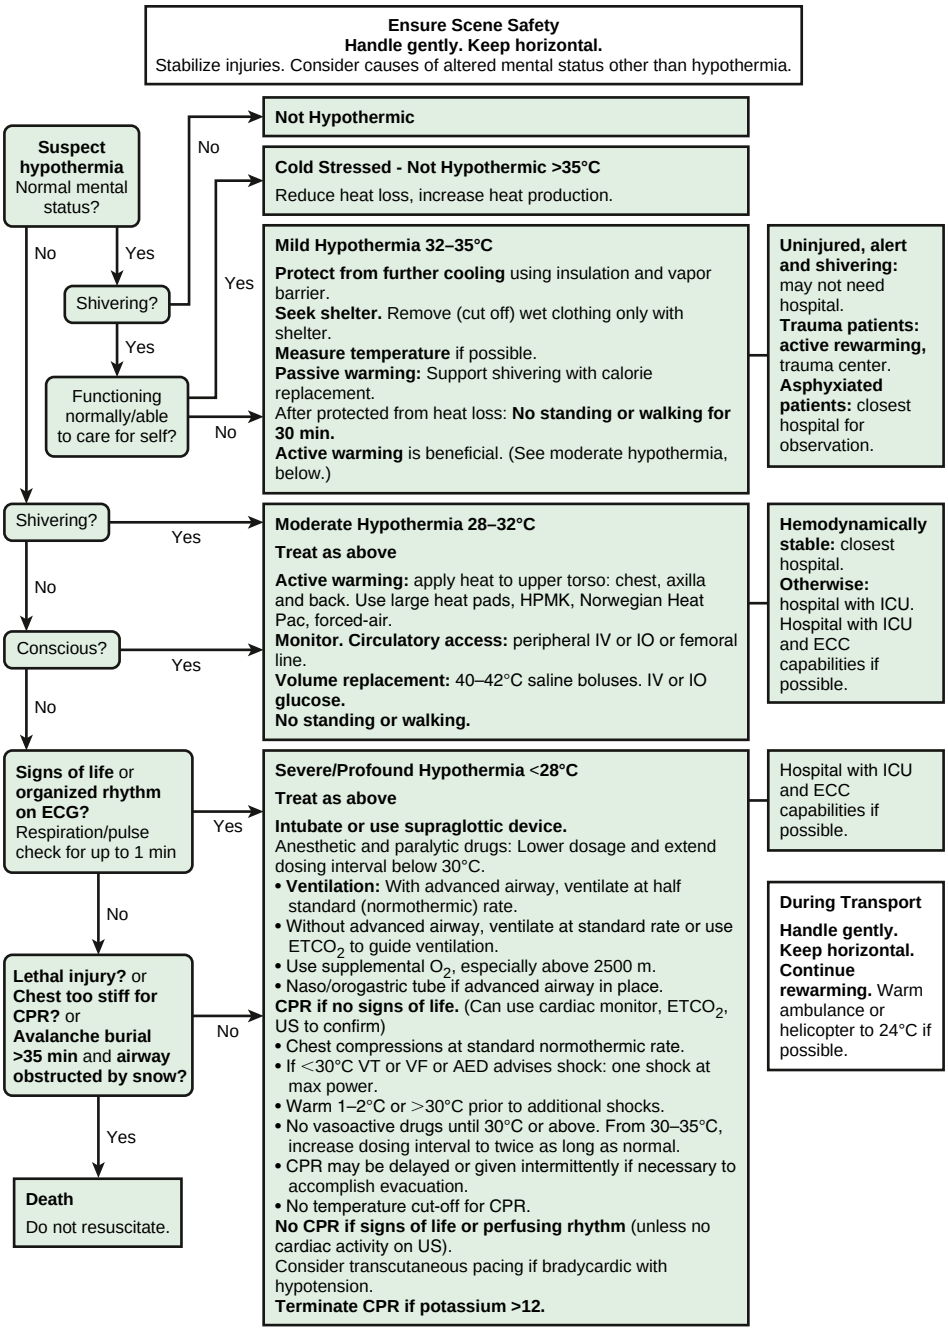

Fig. 90.3 Recommendations for out-of-hospital evaluation and treatment of accidental hypothermia. AED, Automatic external defibrillator; CPR, cardiopulmonary resuscitation; ECC, extracorporeal circulation; ECG, electrocardiogram; $ETCO_2$, end-tidal carbon dioxide; HPMK, Hypothermia Prevention Management Kit; ICU, intensive care unit; IO, intraosseous; IV, intravenous; US, ultrasound; VF, ventricular fibrillation; VT, ventricular tachycardia. (*From Zafren K, Giesbrecht GG, Danzl DF, et al. Wilderness Medical Society practice guidelines for the out-of-hospital evaluation and treatment of accidental hypothermia: 2014 update. Wilderness Environ Med. 2014;25:S66–S85, Fig. 2.*)

Table 90.2 Different Degrees of Frostbite and Their Physiologic Characteristics

GRADE I INJURY	GRADE II INJURY	GRADE III INJURY	GRADE IV INJURY
• Superficial • Edema and redness without tissue necrosis in the affected area • Numbness, firm white-yellow plaque • No blisters or necrosis • Occasional skin desquamation (5-10 days later)	• Blister formation • Erythema, substantial edema • Vesicles with clear or milky fluid • Blisters • Desquamation and black eschar formed	• Tissue necrosis • Hemorrhagic deeper blisters • Skin necrosis • Blue-gray discoloration	• Development of gangrene, requiring amputation • Full-thickness skin, subcutaneous tissue, muscle, tendon, and bone freezing • Little edema • Initially mottled, deep red or eventually dry, black, and mummified

Modified from Joshi K, Goyary D, Mazumder B, et al. Frostbite: Current status and advancements in therapeutics. *J Therm Biol*. 2020;93:102716, Table 1.

Pathophysiology of Frostbite

Frostbite is a freezing injury with four phases: prefreeze, freeze-thaw, vascular stasis, and late ischemic. The degree of cold, duration of exposure, and physiologic compromise caused by medications and underlying illness determine how severe the injury will be. The tissue cooling of **prefreeze** is marked by local vasoconstriction and ischemia without the formation of ice crystals. Intracellular and extracellular ice crystal development causes cellular damage during the **freeze-thaw phase**. Reperfusion leads to ischemic-reperfusion injury and initiation of the inflammatory cascade. **Vascular stasis** is characterized by both blood leaking from vessels and the formation of thrombi. Progressive tissue ischemia from micro-emboli, local thrombosis, and persistent

Fig. 90.5 Early appearance of severe frostbite of the hand after thawing. A purple color and absence of blisters are very unfavorable prognostic signs. (*Courtesy Dr. Ken Zafren.*)

Fig. 90.7 A, Perniosis (chilblains). Edematous, red, painful nodules appeared on the fingers after exposure to cold. B, Perniosis (chilblains). Note the inflamed nodules on the toes of this adolescent girl. Although nodules resolved, painful nodules continued to develop on an annual basis beginning in January and lasting until April. She was otherwise healthy. (*From Paller AS, Mancini AJ. Hurwitz Clinical Pediatric Dermatology, 6th ed. Elsevier: Philadelphia; 2022, Figs. 20.48 and 20.49, p. 566.*)

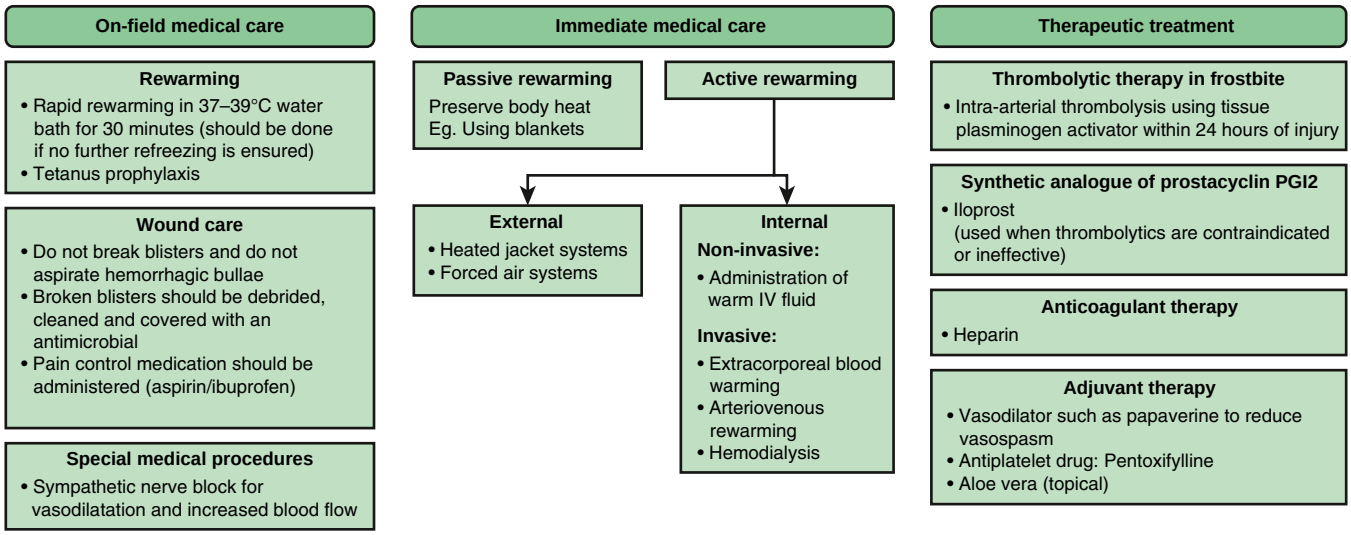

Fig. 90.6 Treatment protocol for the management of frostbite. (*Modified from Joshi K, Goyary D, Mazumder B, et al. Frostbite: Current status and advancements in therapeutics. J Therm Biol. 2020;93:102716, Fig. 2.*)

reperfusion injury marks the **late-ischemic phase**. Compromise of microcirculation and cellular destruction from crystal formation are the main factors contributing to cellular death.

Clinical Presentation of Frostbite

The depth of injury is the basis for the classification of frostbite injury. In the field, frostbite is classified as superficial or deep. Upon arrival to a healthcare facility, a degree or grade of injury is assigned after the tissue has thawed and any advanced imaging is performed (Table 90.2).

First-degree frostbite is marked by numbness and local erythema with a pale raised plaque in the area of injury. Only mild tissue sloughing occurs, and there is no infarction. **Second-degree** injury presents with clear, fluid-filled blisters and surrounding erythema (Fig. 90.4). Local edema may be present. First- and second-degree frostbite injury results in minimal tissue loss and is considered superficial in the field. **Third-degree** frostbite extends into the dermis and dermal vascular plexus. The resulting blisters are hemorrhagic. **Fourth-degree** injury involves the dermis and underlying tissues, extending into muscle and bone (Fig. 90.5). Third- and fourth-degree frostbite has anticipated tissue loss and is field classified as deep.

Treatment of Frostbite

Prevention is preferred for any environmental injury, but rapid recognition and treatment will mitigate the long-term impact. Once frostbite is suspected, the patient should be assessed for concomitant hypothermia. The injury must be protected from the cold and prevented from refreezing if spontaneous thawing has begun. Any constricting items, such as jewelry, are removed. Thawing should be initiated with a circulating water bath at 37–39°C (98.6–102.2°F). Pain medication should be administered. There are numerous combined therapies for frostbite, including anticoagulants, thrombolytics, and vasodilators (Fig. 90.6). The indications for each therapy depend on the extent of injury, length of time since tissue thaw, local availability, and individual national regulatory decisions. It is recommended that the clinician be aware of their local resources and protocols. Regardless, treatment with these agents must be initiated within 12-72 hours of tissue thaw.

NONFREEZING COLD INJURY

Nonfreezing cold injuries include but are not limited to frostnip, chilblains (pernio), cold-immersion foot, and cold-induced fat necrosis.

Frostnip is associated with vasoconstriction of skin exposed to the cold with ice crystals, or frost, forming on the skin surface. The tissue may be numb, and local pallor is present. There is no cellular damage, and the condition resolves rapidly upon warming. Frostnip does indicate that conditions are appropriate for frostbite, and preventative measures should be taken.

Chilblains, also called **pernio**, is an idiopathic condition suspected to be a vasculopathy. Typically occurring in cold, damp conditions, vasculitic-appearing lesions develop on the fingers and toes, ears, and exposed areas of the legs after environmental exposure (Fig. 90.7). It is suspected that vasoconstriction and inflammatory reaction are responsible for the lesions. Recognition and prevention of further cold exposure is key to treatment. The lesions are self-limiting, and symptoms may be addressed with nonsteroidal antiinflammatory drugs (NSAIDs) and topical soothing creams. Continued exposure to cold can cause persistent lesions. Lesions similar to chilblains have been noted in children with COVID-19 infection. **Familial chilblain lupus**, an autosomal dominant variant of lupus, is caused by variants in the *TREX1* and *SAMHD1* genes (see Chapter 90.1). Patients develop cold-induced erythematous peripheral skin lesions and manifest systemic disease typical of lupus. In addition, fever and arthralgias may be present.

Immersion foot or **trench foot** occurs with continuous immersion in warm or cold water. The injury occurs more rapidly in cold water. Continuous exposure to the wet environment, whether through actual immersion in water or saturated footwear, causes hyperemia, edema, and ultimately blister formation with skin sloughing. The condition can progress to ischemia and gangrene. Awareness of wet footwear and subsequent changing, or drying, of shoes and socks is the method of prevention. Vapor barrier socks or boots do not prevent sweat from accumulating and creating a wet environment. Like other cold injuries, treatment consists of thoroughly drying and warming the tissue. Antibiotics are not necessary unless signs of infection are present.

Cold-induced fat necrosis is secondary to local cold injury to the superficial adipose tissue. It presents with raised, erythematous nodules or plaques, evolving over 12-72 hours after exposure to cold. Distribution in children is predominantly on the face, specifically the cheeks and forehead. Obese children and adolescents may have lesions on areas poorly protected from the cold, including the buttocks, thighs, abdominal pannus, and under the chin. Lesions are self-limiting and typically resolve in 10-20 days. Treatment consists of rewarming, avoidance of the cold, and NSAIDs as necessary for discomfort.

90.1 Cold-Induced Autoinflammatory and Other Genetic Disorders

James J. Nocton and James W. Verbsky

A number of **autoinflammatory** and other genetic disorders have been identified that are characterized by an *exacerbation of symptoms upon exposure to cold temperatures*. These disorders differ from **cold injury**, **cold urticaria**, and problems related primarily to vasoconstriction because they typically manifest very early in life and are associated with a wider spectrum of signs and symptoms, reflecting either underlying systemic inflammation or the protean effects of specific genetic variants. A relatively lower ambient temperature or rapid cooling and evaporation from the skin are often sufficient to produce the signs and symptoms of these disorders; therefore the relationship to cold temperature is not always obvious. The genetic variants associated with most of these disorders impact cellular signaling pathways that lead to the expression of proinflammatory cytokines in the absence of an extrinsic trigger; therefore most of these diseases are classified as autoinflammatory.

These conditions should be suspected primarily in infants or very young children who develop persistent, recurrent, or periodic fevers associated with rashes or arthralgias that cannot be explained by an infectious disease or another chronic inflammatory or rheumatic disease. Signs and symptoms associated with these diseases may begin as early as the first week of life. The very early onset distinguishes these genetic diseases from acquired conditions such as Raynaud phenomenon, pernio, cryoglobulinemia, cold urticaria, and other cold-induced problems potentially related to acquired autoimmunity. The rashes are most often evanescent and appear similar to urticaria; however, they are usually not pruritic and are histologically different from urticaria. Laboratory evidence of chronic inflammation is often present, including elevations of the erythrocyte sedimentation rate and C-reactive protein. The association with cold exposure may be subtle and not initially apparent.

The diagnostic algorithm for these disorders should begin with a thorough history and a careful examination, paying particular attention to potential additional signs of conjunctivitis, a frequent accompanying feature, decreased limb movement that might indicate arthralgia or arthritis, the morphology of any cutaneous lesions, and the association of symptoms and signs with cooling or colder temperatures. Unlike cold urticaria, the hivelike lesions often associated with these disorders cannot be precipitated by a cold stimulation test using the application of an ice cube to the skin. Measurement of serum inflammatory markers may help distinguish autoinflammatory disease from more benign conditions; infectious diseases may need to be excluded with appropriate testing. A skin biopsy may provide information that will help narrow the differential diagnosis by identifying either a neutrophilic dermatosis, granulomatous inflammation, or vasculitis characteristic of one of these diseases. Ultimately, focused genetic sequencing can

be performed, searching for specific genetic variants that will confirm a diagnosis.

Familial cold autoinflammatory syndrome (FCAS), along with neonatal-onset multisystem inflammatory disorder (NOMID) and Muckle-Wells syndrome (MWS), constitute the **cryopyrin-associated periodic syndromes (CAPS)** (see Chapter 204). These diseases are all the result of pathogenic variants in *NLRP3* which encodes the protein **cryopyrin**, a component of the inflammasome complex, which is critical in the production of the proinflammatory cytokines interleukin (IL)-1β and IL-18. Although each of these diseases may be exacerbated by cold exposure or cooling, the association with cold is most consistent in those with **FCAS**. **FCAS** should be considered in infants who develop episodes of a hivelike rash, often beginning in the neonatal period, accompanied by fever, conjunctivitis, joint pain, neutrophilia, thrombocytosis, and elevated inflammatory markers, and triggered by exposure to cold or low ambient temperatures. The rash is typically not pruritic and histologically consists of a neutrophilic perivascular and perieccrine inflammatory infiltrate. Episodes are short and generally last less than 24 hours. **MWS** is more severe than FCAS, causing more frequent hivelike rashes and fevers, along with arthralgias, conjunctivitis, and aseptic meningitis, and with potential eventual progression to hearing loss. Like FCAS, the onset of symptoms is most often in infancy, and the histology of skin lesions in these two disorders is similar. **NOMID** is the most severe form of CAPS and is associated with a nonpruritic urticarial rash often present at birth and more profound neurologic and bone disease. CAPS are inherited in an autosomal dominant manner, and the diagnosis is made based on clinical features and the identification of a variant in the NLRP3 gene. Variants in *NLRP12* and in *NLRC4* have also been associated with similar clinical syndromes sometimes referred to as **FCAS2** and **FCAS4**, respectively. Treatment with the IL-1 inhibitors anakinra and canakinumab has been effective in most individuals with CAPS.

PLCG2-associated antibody deficiency and immune dysregulation (PLAID) (sometimes referred to as **FCAS3**) is an autosomal dominant disease resulting from a pathogenic variant of *PLCG2*, which encodes a transmembrane enzyme expressed primarily in myeloid and lymphoid cells that regulates inflammasome activity and proinflammatory cytokine production. PLAID causes pruritic urticaria from birth induced by ambient cold temperatures or cooling and lasting for minutes to hours. In some individuals, acral blistering lesions resembling a burn may also be present during infancy on the ears, nose, and fingers. Histology of urticarial lesions reveals increased mast cells. Because PLCG2 is expressed in mast cells and affects mast cell degranulation, these subjects can have more classic hives as compared with other FCAS syndromes. Other lesions reveal noncaseating granulomas. Older individuals may develop syncope induced by cold exposure and a burning sensation in the throat when eating cold foods. Hypogammaglobulinemia may lead to frequent sinopulmonary and other infections. The diagnosis is made based on clinical features and the identification of variants in the PLCG2 gene. Treatment of PLAID includes avoiding evaporative cooling and minimizing cold exposure, antihistamines, and for those with evidence of immunodeficiency, intravenous immunoglobulin infusions to prevent frequent infections.

STING-associated vasculopathy with onset in infancy (SAVI) is an autosomal dominant disease resulting from a pathogenic variant in *TMEM173*, which encodes **stimulator of interferon genes (STING)**, an activator of interferon gene transcription (see Chapter 205). Signs and symptoms usually appear in infancy but may also appear later and include fever and a variety of cutaneous lesions. Violaceous nodules and plaques on the cheeks, ears, and nose and telangiectasias, pustules, or blisters, often most noticeable on the extremities, may occur. The skin lesions are exacerbated by cold temperatures, and some develop ulcerative or gangrenous lesions. In time, interstitial lung disease progressing to fibrosis has been described. Histology reveals vasculitis of medium and small vessels. The diagnosis is made based on clinical features and the identification of the variant in the TMEM173 gene. Responses to treatment with corticosteroids and immunomodulators, including cyclophosphamide and mycophenolate mofetil, have been variable and inconsistent. Janus kinase inhibitors, which inhibit interferon receptor signaling, have shown promise in treatment of these disorders.

Familial chilblain lupus is a rare condition triggered by cold exposure that presents with painful, bluish-red, papular or nodular lesions of the skin in acral locations. Ulceration can occur, but deep ulceration and necrosis are infrequent, and the lesions tend to heal without scarring. This is an autosomal dominant disorder caused by heterozygous variants in *TREX1* or *SAMHD1*, the same genes containing variants associated with Aicardi-Goutières syndrome (AGS). AGS is a syndrome characterized by developmental delay, abnormal neurologic signs, microcephaly with brain calcifications, and CNS pleocytosis, as well as skin lesions resembling chilblains. Both *TREX1* and *SAMHD1* are involved in DNA degradation, and their deficiencies result in intracellular nucleic acid that stimulates interferon production. AGS and familial chilblain lupus can be considered a spectrum of severity of the same genetic defect.

Factor XII–associated cold autoinflammatory syndrome is an autosomal dominant disease resulting from a pathogenic variant in *F12* encoding the coagulation factor XII. The variant leads to spontaneous activation of factor XII, which in turn increases bradykinin and IL-1 levels. Individuals with this mutation develop an urticarial-like rash that begins in the first few weeks of life precipitated by cold. The rash is nonpruritic and evanescent, and as individuals age it is accompanied by more severe systemic symptoms of chills, headaches, arthralgias, and fatigue. Serum inflammatory markers are elevated, and skin histology reveals perivascular macrophage and neutrophilic infiltrates. The diagnosis is made by identifying a variant in *F12*. Treatment with the IL-1 receptor antagonist anakinra or the bradykinin B2 receptor antagonist icatibant has shown promise in a small number of individuals.

Crisponi syndrome/cold-induced sweating syndrome (CS/CISS) is an autosomal recessive disease resulting from variants in *CRLF1* or *CLCF1*. These genes encode proteins involved in neurologic development, including facial motor neurons and the sympathetic nervous system; therefore this syndrome is not classified as an autoinflammatory syndrome. Symptoms and signs are typically apparent in the neonatal period and include fever, camptodactyly, and involuntary episodic contractions of facial and pharyngeal muscles resulting in breathing and feeding difficulties. There is high neonatal mortality, and those that survive develop cold-induced profuse sweating in childhood. Scoliosis and other dysmorphic features (depressed nasal bridge, high arched palate) are also common. The diagnosis is made by identifying a variant most commonly in *CRLF1*. Treatment of the neonatal symptoms is supportive. The cold-induced sweating is managed with clonidine, amitriptyline, or moxonidine.

Chapter 91

Anesthesia and Perioperative Care

John P. Scott

The continuum of anesthesia includes varying degrees of sedation (i.e., mild, moderate, or deep) and general anesthesia. All forms of **sedation** are characterized by some preservation of purposeful movement (see Chapter 92), whereas **general anesthesia** is defined by the complete loss of consciousness. Potent pharmacologic agents are required to suppress the perception and physiologic response to noxious stimuli. Perioperatively, the anesthesiologist is responsible for providing hypnosis and analgesia while preserving physiologic homeostasis (Table 91.1). This begins with the performance of a comprehensive preanesthesia history (Table 91.2). Although anesthetic risk has greatly decreased with advancements in pharmacology and monitoring technology, the persistent risk of perioperative morbidity and mortality demands vigilance. The risk is elevated in certain disease states (Table 91.3).

PREANESTHETIC EVALUATION

All children presenting for surgery should undergo a preanesthetic history and multiorgan system assessment with assignment of **American Society of Anesthesiologists Physical Status (ASA-PS)** (Table 91.4). Children of ASA-PS I-II generally require a brief focused history and physical examination with no additional testing. Patients with a complex medical history of ASA-PS ≥III require a more comprehensive preanesthetic assessment, often with ancillary preoperative testing. Every patient should be screened for anesthetic risks, including drug allergies, previous reactions to anesthetics, and family history of problems with anesthesia (e.g., sudden perioperative death, hyperthermia after surgery), which may indicate risk of malignant hyperthermia.

Respiratory System

Recent respiratory tract infections should be noted. *Clear rhinorrhea without fever or evidence of lower respiratory disease is not associated with increased anesthetic risk.* Respiratory illnesses associated with fever, mucopurulent nasal discharge, productive cough, or lower respiratory symptoms (wheezing, rales) are associated with increased airway reactivity and anesthetic complications (laryngospasm, bronchospasm, reduced mucociliary clearance, atelectasis, and hypoxemia) for up to 6 weeks thereafter. Thus elective procedures requiring general anesthesia should be postponed 4-6 weeks in this setting.

Children with reactive airway disease require a thorough preanesthetic assessment. Acute, potentially fatal bronchospasm can occur during induction of anesthesia and endotracheal intubation for routine, minor surgery in children with asthma. Risk factors for anesthetic complications include previous asthma exacerbations requiring (1) hospital admission within the previous year, (2) emergency department (ED) care within the last 6 months, (3) previous intensive care unit (ICU) admission, or (4) previous parenteral systemic corticosteroids. Ideally, children should be free of wheezing for least several days before surgery, even if this necessitates increased controller medication administration (β-adrenergic agonist and corticosteroids). Active wheezing may be an indication to delay elective surgery. Chronic respiratory conditions such as bronchopulmonary dysplasia and cystic fibrosis are also associated with significant intraoperative risks. Every effort should be made to ensure that children with such disorders achieve optimal respiratory status before surgery.

Analgesia
Amnesia
Hypnosis
Akinesia
Maintenance of physiologic homeostasis
Vigilance

Airway Evaluation

Induction of general anesthesia is associated with reduced spontaneous ventilation and airway reflexes. Prediction of difficult bag-mask ventilation and/or intubation before anesthesia is critical. Congenital anomalies associated with airway compromise include micrognathia, macroglossia, and thoracic anomalies (Table 91.5). Conditions that impair mouth opening (e.g., temporomandibular joint disease) should be noted. A history of wheezing or stridor may indicate postoperative airway complications and difficult intraoperative airway management. It is imperative to ask about a history of sleep-disordered breathing, including obstructive and central sleep apnea, as this may lead to increased risk of perianesthetic respiratory complications in children. Polysomnography is the gold standard for diagnosis and grading of sleep disordered breathing. The **STBUR** (snoring, trouble breathing, unrefreshed) questionnaire is used to identify patients with sleep-disordered breathing who may be at risk for perioperative respiratory complications. Postoperative admission for monitoring may be indicated for patients with moderate and severe forms of sleep-disordered breathing.

Cardiovascular System

Most anesthetic agents possess myocardial depressant properties. All patients should be screened for the presence of heart disease. Important cardiovascular considerations include history of congenital heart disease (CHD), cyanosis, arrhythmias, or cardiomyopathy. Room-air pulse oximetry should be performed as part of the preanesthetic evaluation. Accurate diagnosis of cardiac murmurs in neonates is essential. A history of cardiac dysrhythmias should be investigated because inhalational anesthetics may be arrhythmogenic. A pediatric cardiologist should evaluate children with known CHD undergoing surgery. Preoperative ancillary studies may include chest x-ray, electrocardiogram (ECG), echocardiogram, or cardiac catheterization. Lesions associated with increased anesthetic risk include single-ventricle heart disease, fixed obstructive outflow tract lesions (aortic valve and pulmonary valve stenosis), and cardiomyopathy. Children with these conditions should be cared for by a **cardiac anesthesia service**. Antibiotic prophylaxis for the prevention of bacterial endocarditis should be administered when appropriate in accordance with the American Heart Association (AHA) guidelines.

Hematologic System

Evidence of coagulopathy should be sought. Easy bruising, familial bleeding disorders, and anticoagulant (e.g., aspirin, heparin, direct oral anticoagulant [DOAC], warfarin) use should be discussed. Preoperative adequacy of hemostatic function (e.g., platelet count, fibrinogen, prothrombin time, partial thromboplastin time) and correction of coagulopathic disorders may be indicated for complex procedures associated with significant risk of perioperative hemorrhage. In neonates, assurance of vitamin K prophylaxis and adequate coagulation status is critical before any major surgery. Although anemia may be well tolerated in healthy children, anesthesia and surgery increase oxygen consumption. Preoperative anemia should be corrected when oxygen delivery is limited or blood loss is expected. In the patient with life-threatening hemorrhage (trauma), massive transfusion protocols of 1:1:1 replacement of packed red blood cells:fresh-frozen plasma:platelets should be used. Initiation of early antifibrinolytic therapy in the setting of life-threatening hemorrhage has been linked to reduced early morality.

Neurologic System

A history of neurologic and neuromuscular disorders should be sought. Preoperative developmental assessments may be helpful in interpreting age-dependent variation in the response to pain. Maintenance of appropriate perioperative anticonvulsant therapy is essential

Table 91.2 The Preanesthetic History

Child's Previous Anesthetic and Surgical Procedures
- Review previous anesthetic records:
  - Ease of mask ventilation
  - Grade of laryngoscopy; type and size of laryngoscope; endotracheal tube size
  - Issues during emergence (awakening) from anesthesia (postoperative vomiting, emergence delirium)
  - History of hyperthermia or acidosis in the child or family members

Perinatal Problems (Especially for Infants)
- Prematurity
- Need for supplemental oxygen or intubation and ventilation
- History of apnea and bradycardia
- History of cardiovascular compromise
- Other major illnesses and hospitalizations
- Family history of anesthetic complications, malignant hyperthermia, or pseudocholinesterase deficiency

Respiratory Problems
- Long-term exposure to environmental tobacco smoke
- Obstructive breathing score
- STBUR (snoring, trouble breathing, unrefreshed)
- Cyanosis (especially in infants <6 mo of age)
- Recurrent respiratory infections
- Recent lower respiratory tract infection
- Previous laryngotracheitis (croup) or laryngomalacia
- Reactive airway disease
- Airway abnormalities, facial anomalies, mucopolysaccharidosis

Cardiac Problems
- Murmur or history of congenital heart disease
- Dysrhythmia
- Exercise intolerance
- Syncope
- Cyanosis

Gastrointestinal Problems
- Reflux and vomiting
- Feeding difficulties
- Failure to thrive
- Liver disease
- Exposure to infectious pathogens

Neuromuscular Problems
- Neuromuscular diseases
- Developmental delay
- Myopathy
- Seizure disorder

Hematologic Problems
- Anemia
- Bleeding diathesis
- Tumor
- Immunocompromise
- Prior blood transfusions and reactions

Renal Problems
- Renal insufficiency, oliguria, anuria
- Fluid and electrolyte abnormalities

Psychosocial Considerations
- Drug abuse, use of cigarettes or alcohol
- Physical or sexual abuse
- Family dysfunction
- Previous traumatic medical or surgical experience
- Psychosis, anxiety, depression

Gynecologic Considerations
- Sexual history (sexually transmitted infections)
- Possibility of pregnancy

Current Medications
- Prior administration of corticosteroids

Allergies
- Drugs
- Iodine
- Latex products
- Surgical tape
- Food (especially soy and egg albumin)

Other
- Dental condition (loose or cracked teeth)
- When and what the child last ate (especially in emergency procedures)

in children with seizure disorders because the seizure threshold may be lowered perioperatively. Children with obstructive hydrocephalus typically require ventriculoperitoneal (VP) shunt insertion to divert cerebrospinal fluid (CSF) and to prevent intracranial hypertension (ICH). Repeated shunt malfunction is common, and these children may present for shunt revision with signs of ICH (vomiting, altered mentation, sundowning). Similarly, shunt patency and function should be ensured preoperatively in children with VP shunts presenting for non-neurosurgical procedures.

Psychologic Assessment

Surgery and painful medical procedures are psychologically traumatic events for children and families. Children who require anesthesia may experience fear and anxiety. They may also sense stressful signals from parents and caregivers. Children undergoing surgery may exhibit negative behavioral changes postoperatively. These maladaptive behavioral responses may include enuresis, separation anxiety, temper tantrums, and nighttime crying, as well as fear of strangers, medical providers, and hospitals. Sleep quality may be altered postoperatively, resulting in further behavioral compromise. Preoperative psychologic preparation programs have been developed to reduce the incidence of perioperative behavioral changes. **Parental presence during induction (PPI)** has not been shown to improve postoperative behavior. Oral preoperative midazolam (0.5 mg/kg) produces rapid-onset anxiolysis and amnesia and may decrease negative behavioral changes.

Genetic Evaluation

Children with genetic conditions may have syndrome-specific anesthetic considerations. For example, children with trisomy 21 may have cardiac anomalies, macroglossia, upper airway obstruction, and hypothyroidism (see Chapter 99.2). Atlantoaxial instability, common in trisomy 21, has been linked to cervical dislocation and spinal cord trauma with neck extension during intubation. Some anesthesiologists recommend extension and flexion lateral neck films to detect instability before surgery. For children with other known genetic disorders, it is essential to review specific anesthetic considerations.

PREOPERATIVE PREPARATION

Preoperative Fasting

Preoperative fasting guidelines have been developed to reduce the incidence of aspiration of gastric contents during anesthesia. Aspiration may lead to laryngospasm, bronchospasm, and postoperative pneumonitis. Aspiration of gastric contents may be a potentially lethal complication in children with chronic lung disease or critical illness. Table 91.6 lists preoperative fasting guidelines (e.g., nothing by mouth, or nil per os [NPO] status). Clear, sweet liquids (e.g., Pedialyte, 5% dextrose

Table 91.3 Specific Pediatric Diseases and Their Anesthetic Implications

DISEASE	IMPLICATIONS
RESPIRATORY SYSTEM	
Asthma	Intraoperative bronchospasm that may be life threatening
	Pneumothorax or atelectasis
	Optimal preoperative medical management is essential
Difficult airway	Special equipment and personnel may be required
	Should be anticipated with dysmorphic features or storage diseases
	Patients with trisomy 21 may require atlantooccipital joint evaluation
	Increased risk with acute airway obstruction, epiglottitis, laryngotracheobronchitis, or airway foreign body
Bronchopulmonary dysplasia	Barotrauma with positive pressure ventilation
	Oxygen toxicity, pneumothorax a risk
Cystic fibrosis	Airway reactivity, bronchorrhea, increased intraoperative pulmonary shunt and hypoxia
	Risk of pneumothorax, pulmonary hemorrhage
	Atelectasis, risk of prolonged postoperative ventilation
	Patient should be assessed for cor pulmonale
Sleep apnea	Pulmonary hypertension and cor pulmonale must be excluded
	Careful postoperative observation for obstruction required
CARDIAC	
	Bacterial endocarditis prophylaxis as indicated
	Use of air filters; careful purging of air from the intravenous equipment
	Physician must understand the effects of various anesthetics on the hemodynamics of specific lesions
	Possible need for preoperative evaluation of myocardial function and pulmonary vascular resistance
	Provide information about pacemaker function and ventricular device function
HEMATOLOGIC	
Sickle cell disease	Possible need for simple or exchange transfusion based on preoperative hemoglobin concentration and percentage of hemoglobin S
	Avoid hypoxemia, hypothermia, dehydration, and hyperviscosity states
Oncology	Pulmonary evaluation of patients who have received bleomycin, *bis*-chloroethyl-nitrosourea, chloroethyl-cyclohexyl-nitrosourea, methotrexate, or radiation to the chest
	Avoidance of high oxygen concentration
	Cardiac evaluation of patients who have received anthracyclines; risk of severe myocardial depression with volatile agents
	Potential for coagulopathy
RHEUMATOLOGIC	
	Limited mobility of the temporomandibular joint, cervical spine, arytenoid cartilages
	Careful preoperative evaluation required
	Possible difficult airway

DISEASE	IMPLICATIONS
GASTROINTESTINAL	
Esophageal, gastric	Potential for reflux and aspiration
Liver	Altered metabolism of many anesthetic drugs
	Potential for coagulopathy and uncontrollable intraoperative bleeding
RENAL	
	Altered electrolyte and acid-base status
	Altered clearance of many anesthetic drugs
	Need for preoperative dialysis in selected cases
	Succinylcholine to be used with extreme caution and only when the serum potassium level has recently been shown to be normal
NEUROLOGIC	
Seizure disorder	Avoidance of anesthetics that may lower the seizure threshold
	Optimal control ascertained preoperatively
	Preoperative serum anticonvulsant measurements
Increased intracranial pressure	Avoidance of agents that increase cerebral blood flow
	Maintain cerebral perfusion pressure.
Neuromuscular disease	Avoidance of depolarizing relaxants; at risk for hyperkalemia
	Patient may be at risk for malignant hyperthermia; avoid volatile anesthetics in myopathies
Developmental delay	Patient may be uncooperative during induction and emergence
Psychiatric	Monoamine oxidase inhibitor (or cocaine) may interact with meperidine, resulting in hyperthermia and seizures
	Selective serotonin reuptake inhibitors may induce or inhibit various hepatic enzymes that may alter anesthetic drug clearance
	Illicit drugs may have adverse effects on cardiorespiratory homeostasis and may potentiate the action of anesthetics
ENDOCRINE	
Diabetes	Greatest risk is unrecognized intraoperative hypoglycemia; intraoperative blood glucose level monitoring needed especially when insulin is administered
SKIN	
Burns	Difficult airway
	Fluid shifts
	Bleeding
	Risk of rhabdomyolysis and hyperkalemia from succinylcholine after burns for many months
IMMUNOLOGIC	
	Retroviral drugs may inhibit benzodiazepine clearance
	Immunodeficiency requires careful infection control practices
	Cytomegalovirus-negative blood products, irradiation, or leukofiltration may be required
METABOLIC	
	Careful assessment of glucose homeostasis in infants

in water [D5W]) facilitate gastric emptying, prevent hypoglycemia, and may be given up to 2 hours before anesthesia. Breast milk may be given to infants up to 4 hours before surgery. Solids should be avoided for 6-8 hours before surgery. Conditions associated with delayed gastric emptying may require prolonged periods of fasting. The optimal duration of preoperative fasting in otherwise well patients without risk factors for delayed gastric emptying remains a source of controversy. Many efforts have sought to shorten NPO duration for clear liquids from 2 hours to 1 hour in order to preserve fluid and glycemic balance in children presenting for surgery.

Table 91.4 American Society of Anesthesiology Physical Status Classification

Class 1: Healthy patient, no systemic disease
Class 2: Mild systemic disease with no functional limitations (mild chronic renal failure, iron-deficiency anemia, mild asthma)
Class 3: Severe systemic disease with functional limitations (hypertension, poorly controlled asthma or diabetes, congenital heart disease, cystic fibrosis)
Class 4: Severe systemic disease that is a constant threat to life (critically and/or acutely ill patients with major systemic disease)
Class 5: Moribund patients not expected to survive 24 hr, with or without surgery
Additional classification: "E"—emergency surgery

Smith-Lemli-Opitz syndrome
Treacher-Collins syndrome
Trisomy 21
Turner syndrome

The Full Stomach

Gastric emptying may be delayed for up to 96 hours after an acute episode of trauma or surgical illness. To mitigate risk of aspiration, it is desirable to secure the airway as rapidly as possible during induction of anesthesia in patients at risk for having a full stomach. Under these circumstances, rapid sequence induction of anesthesia is indicated (**rapid sequence induction**; see Chapter 86).

Parental Presence During Induction of Anesthesia

Parents or guardians may expect to be with their child during the induction of anesthesia. Removing a fearful child from a parent is stressful for the child and caregivers. Premedication with an oral benzodiazepine (e.g., midazolam) frequently provides calm, smooth parental separation conditions. When parental separation cannot be achieved comfortably with premedication and behavioral modification (patient education and desensitization to the operative environment), PPI may be indicated. Although PPI in the hands of a confident, competent anesthesia practitioner may replace the need for preoperative medication, it does not reliably predict smooth induction. PPI has not been shown to decrease emergence delirium or postoperative behavioral changes, and it does not appear to be superior to premedication with oral midazolam.

GENERAL ANESTHESIA

Analgesia

Pediatric anesthesiologists are responsible for providing analgesia to children for procedures within operating room (OR) and non-OR settings (Table 91.7). Multimodal techniques exist to provide pain relief during operative procedures for children of all ages, including critically ill infants. Effective analgesia is essential to blunt physiologic responses to painful stimuli (surgery) and modulate the deleterious physiologic and metabolic consequences. The response to painful and stressful stimuli may provoke **systemic inflammatory response syndrome (SIRS)**, which has been linked to increased catabolism, physiologic instability, and mortality (see Chapter 85).

Table 91.6 Guidelines for Preoperative Fasting ("2-4-6-8 Rule")*

TIME BEFORE SURGERY (hr)	ORAL INTAKE
2	Clear, sweet liquids
4	Breast milk
6	Infant formula, fruit juices, gelatin
8	Solid food

*These are general guidelines and may differ among hospitals.

Hypnosis and Amnesia

The attenuation of both consciousness **(hypnosis)** and conscious recall **(amnesia)** is critical during pediatric anesthesia care. Awareness during procedures may be as physically and psychologically deleterious as the experience of pain. A primary goal of anesthetic management is to minimize fear and anxiety during both painful and nonpainful procedures. Many drugs provide anxiolysis and amnesia for such events (Table 91.8). However, it is important to remember that sedative-hypnotic agents may alter consciousness without producing analgesia; *analgesia* and *hypnosis* are not synonymous. It is also possible to provide analgesia (local, spinal, or epidural) without altering consciousness.

Sedation describes a medically induced state in the continuum between wakefulness and general anesthesia in which patients maintain the ability to respond purposefully to varying degrees of stimulation (see Table 91.7). *Light (minimal) sedation* is defined as anxiolysis with minimally reduced reflexes or airway patency with normal response to verbal commands. In *moderate sedation,* the patient continues to respond purposefully to verbal commands, either alone or with light touch. *Deep sedation* is defined by preservation of purposeful movement with repeated or painful stimulation. **General anesthesia** is characterized by unconsciousness, amnesia, and reduced physiologic reflexes, including cardiorespiratory reflexes (**airway-protective** and **vasomotor reflexes**). It is common to transition between states of sedation and general anesthesia with loss of consciousness, airway patency, and airway-protective reflexes; in this scenario, loss of cardiovascular stability may occur. Individuals providing sedation and anesthesia for children must be able to identify the anesthetic state of the patient and support cardiorespiratory insufficiency.

Akinesia (Immobility or Muscular Relaxation)

Akinesia, the absence of movement, is commonly indicated to ensure safe and adequate operative conditions. Neuromuscular blocking agents (NMBAs) may be used to produce akinesia (see Table 91.8). However, the absence of movement is not indicative of hypnosis, amnesia, or analgesia. Whenever NMBAs are used, *sedation and analgesia must be provided.*

Monitoring

Administration of anesthesia increases the need to monitor and support physiologic integrity and homeostasis because of potentially life-threatening physiologic consequences (see Tables 91.7 and 91.8). Consequently, the ASA mandates routine monitoring of oxygenation, ventilation, and circulation during the provision of anesthesia. This includes assessment of continuous pulse oximetry, capnography, electrocardiography, intermittent blood pressure measurements (every 5 minutes), and temperature when temperature instability is anticipated. The use of advanced invasive (arterial and central venous pressure) or noninvasive (near-infrared spectroscopy) monitoring varies based on procedural complexity and ASA-PS.

Table 91.7 Definitions of Anesthesia Care

MONITORED ANESTHESIA CARE

A designated anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.

Monitored anesthesia care includes all aspects of anesthesia care: a preprocedure assessment, intraprocedure care, and postprocedure anesthesia management.

During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, which may include but are not limited to the following:

- Discussing anesthesia care with the family and child, obtaining consent for anesthesia, allaying anxiety and answering questions—family-centered anesthesia care.
- Monitoring of vital signs, maintenance of the patient's airway, and continual evaluation of vital functions.
- Diagnosing and treating clinical problems that occur during the procedure.
- Administering sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort.
- Providing other medical services as needed to accomplish the safe completion of the procedure.

Anesthesia care often includes the administration of medications for which the loss of normal protective reflexes or loss of consciousness is likely.

Monitored anesthesia care refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure.

If the patient is rendered unconscious and/or loses normal protective reflexes for an extended period, this is considered a general anesthetic.

LIGHT SEDATION

Administration of anxiolysis or analgesia that obtunds consciousness but does not obtund normal protective reflexes (cough, gag, swallow, hemodynamic) or spontaneous ventilation; patient responds normally to verbal commands.

MODERATE SEDATION

No interventions are required to maintain a patent airway or spontaneous ventilation; patient responds purposefully to verbal commands either on their own or with light touch.

DEEP SEDATION

Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes (cough, gag, swallow, hemodynamic); hemodynamic and respiratory insufficiency may occur.

GENERAL ANESTHESIA

Administration of hypnosis, sedation, and analgesia that results in the loss of normal protective reflexes.

REGIONAL ANESTHESIA

Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade.

Consciousness is not obtunded.

Special expertise is required.

Frequently, in children, anxiolysis and sedation are also necessary for this technique to be successful.

Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia.

LOCAL ANESTHESIA

Provision of analgesia by local infiltration of an appropriate anesthetic agent.

Does not require the presence or involvement of an anesthesiologist, although an anesthesiologist may provide local anesthesia services.

Specific Medications

Inhalational Anesthetics

Inhalational anesthetics are frequently used for the induction and maintenance of general anesthesia in children. Pediatric inhalational anesthetics include sevoflurane, isoflurane, and desflurane. Although halothane is the prototypical pediatric inhalational anesthetic and may be used in other parts of the world, it has been replaced by sevoflurane and is no longer used in the United States and Europe.

The **minimum alveolar concentration (MAC)** of an inhalational anesthetic is the alveolar concentration (expressed as percent at 1 atmosphere) that provides sufficient depth of anesthesia for surgery in 50% of patients. For potent inhalational agents, the alveolar concentration of an anesthetic reflects the arterial concentration of anesthetic in the blood perfusing the brain. MAC is a measure of anesthetic potency analogous to the $\mathbf{ED_{50}}$ (effective dose in 50% of recipients) of a drug. MAC is age dependent; it is lower in premature than in full-term infants and decreases from term through infancy to preadolescence. In adolescence, MAC again increases, falling thereafter.

Respiratory Effects. The advantages of inhalational anesthesia are rapid onset and offset with the convenient route of delivery and respiratory excretion. These agents provide profound analgesia and amnesia. Inhalational volatile anesthetic agents are poorly soluble in blood but rapidly equilibrate between alveolar gas and blood. They may irritate the airway and provoke laryngospasm. All inhalational anesthetics depress ventilation in a dose-dependent manner. Thus expired carbon dioxide (CO_2) and $Paco_2$ (arterial partial pressure of CO_2) will increase in spontaneously breathing children. Volatile anesthetics shift the CO_2 response curve to the right, thus decreasing the normal increase in minute ventilation with increasing $Paco_2$. Inhalational anesthesia decreases end-expiratory lung volume (functional residual capacity). Small lung volumes are associated with reduced lung compliance, increased pulmonary vascular resistance, and restrictive lung defects. Volatile agents depress normal hypoxic pulmonary vasoconstriction, increasing intrapulmonary arteriovenous shunting and hypoxemia.

Cardiovascular Effects. All volatile anesthetics reduce cardiac output and peripheral vascular resistance; hypotension is common. This is accentuated in hypovolemic patients and more pronounced in neonates. Inhalational anesthetics also depress baroreceptor and heart rate responses. The administration of inhalational anesthesia may result in decreased tissue oxygen delivery. Perioperatively, cellular metabolism increases, creating a potential imbalance between oxygen demand and oxygen delivery. Development of intraoperative dysoxia is a sign of this imbalance. All volatile inhalational anesthetic agents cause **cerebrovasodilation** and uncouple cerebral blow flow with cerebral metabolic rate. Although inhalational anesthetics decrease cerebral oxygen consumption, they may disproportionately increase cerebral oxygen blood flow. Thus inhalational anesthetics should be used with caution in children who have elevated intracranial pressure (ICP) or impaired cerebral perfusion (i.e., traumatic brain injury).

Sevoflurane

Sevoflurane is the most commonly used inhalational agent for induction and maintenance of general anesthesia in children. Sevoflurane possesses minimal airway irritant properties and is a useful induction agent when co-administered with nitrous oxide. Emergence from sevoflurane anesthesia is rapid; however, there is a significant incidence of **emergence delirium**, especially with inadequate pain control. This effect may be attenuated with adequate analgesia and supplemental hypnotic agents (e.g., midazolam, dexmedetomidine, propofol). Metabolism of sevoflurane by cytochrome P450 (CYP) yields free fluoride, which may be nephrotoxic. Sevoflurane degradation by desiccated CO_2 absorbents at low fresh gas flows (<2 L/min) may produce

Table 91.8 Selected Drugs Used in Anesthesia

DRUG	USES AND IMPLICATIONS
MUSCLE RELAXANTS	
Succinylcholine	A depolarizing neuromuscular blocking agent with rapid onset and offset properties Used to facilitate endotracheal intubation and maintain muscle relaxation in emergency situations; rarely used Associated with the development of malignant hyperthermia in susceptible patients Degraded by plasma cholinesterase, which may be deficient in some individuals; such a deficiency may result in prolonged effect Fasciculations may be associated with immediate increases in intracranial and intraocular pressures and postoperative muscle pain
Vecuronium, rocuronium, cisatracurium, all aminosteroids	Nondepolarizing neuromuscular blockers Have less rapid onset than succinylcholine but are longer acting Prolonged ICU use may lead to profound muscle weakness Vecuronium and rocuronium are metabolized by the liver and excreted in bile; they are the most commonly used neuromuscular blocking agents Cisatracurium is metabolized by plasma cholinesterase and therefore may be of benefit in patients with hepatic or renal disease
HYPNOTICS	
Propofol	Rapid-acting hypnotic amnestic agent No analgesic properties Respiratory depressant Increases seizure threshold Antiemetic Propofol infusion syndrome may occur with prolonged intravenous infusion (>24 hr)
Etomidate	Cardiovascular stability on induction Inhibits corticosteroid synthesis Increases ICU mortality after use Associated with myoclonus and pain on injection
Ketamine	Hypnotic analgesic Causes sialorrhea and may be co-administered with an antisialagogue, such as atropine or glycopyrrolate Induces endogenous catecholamine release and tachycardia Bronchodilator Increases intracranial and intraocular pressures Decreases the seizure threshold
SEDATIVE-ANXIOLYTICS	
Benzodiazepines	Produce sedation, anxiolysis, amnesia, and hypnosis All agents raise the seizure threshold, are metabolized by the liver, and depress respiration, especially when administered with opioids Effective as premedication Diazepam may be painful on injection and has active metabolites Midazolam can be administered by various routes Lorazepam has no active metabolites Reversed with flumazenil
Dexmedetomidine	Produces anxiolysis, sedation, and sympatholysis by α_2-receptor stimulation centrally; has mild analgesic properties Side effects include hypertension, hypotension, and bradycardia Commonly used for procedural sedation; IV, IN, and IM dosing available Continuous infusion useful for ICU sedation
ANALGESIC-SEDATIVES	
Opioids	Gold standard for providing analgesia All cause respiratory depression Morphine and, to a lesser extent, hydromorphone may cause histamine release The synthetic opioids fentanyl, sufentanil, and short-acting alfentanil may have a greater propensity to cause chest wall rigidity when administered rapidly or in high doses and are also associated with the rapid development of tolerance; these drugs have particular utility in cardiac surgery because of the hemodynamic stability associated with their use Remifentanil is an ultrashort-acting synthetic opioid that is metabolized by plasma cholinesterase; it may have particular utility when deep sedation and analgesia are required along with the ability to assess neurologic status intermittently
INHALATIONAL AGENTS	
Nitrous oxide	Produces amnesia and analgesia at low concentrations Danger of hypoxic gas mixture if the oxygen concentration is not monitored and preventive safety mechanisms are not in place
Potent vapors, sevoflurane, desflurane, isoflurane	"Complete anesthetics"—induce hypnosis, analgesia, and amnesia All are myocardial depressants, and some are vasodilators May trigger malignant hyperthermia in susceptible individuals Sevoflurane is used for induction of anesthesia in children All bronchodilate at equipotent concentrations Isoflurane and desflurane are associated with laryngospasm and should not be used for anesthesia induction

IV, Intravenous; IN, intranasal; IM, intramuscular.

the nephrotoxin Compound A. Large-scale studies of sevoflurane-associated renal injury in humans are lacking. However, the U.S. Food and Drug Administration (FDA) has recommended maintenance of fresh gas flow rates >2 L/min for surgical cases lasting more than 2 hours of monitored anesthesia care.

Isoflurane

Isoflurane is a pungent volatile anesthetic and airway irritant and is not suitable for induction because of the high incidence of complications, such as laryngospasm. However, maintenance of anesthesia with isoflurane is common after induction with sevoflurane or an intravenous (IV) hypnotic. Emergence from anesthesia with isoflurane is slower than for sevoflurane. Isoflurane administration in the setting of desiccated CO_2 absorbents may yield the production of carbon monoxide.

Desflurane

Desflurane is a potent airway irritant associated with coughing, breath holding, and laryngospasm and is *not* useful for induction. Desflurane has the lowest solubility and potency of all commonly used volatile agents. It is frequently administered for maintenance of anesthesia. Emergence from desflurane anesthesia is rapid because of its low tissue solubility.

Nitrous Oxide

Nitrous oxide (N_2O) is a tasteless, colorless, odorless gas with potent analgesic properties. It produces a state of euphoria (thus its nickname, "laughing gas"). The MAC of N_2O is >100; consequently, it may not be used as a sole agent to maintain anesthesia. N_2O produces little hemodynamic or respiratory depression. It is typically used in combination with volatile and IV anesthetic agents during maintenance of general anesthesia. The deleterious effects of N_2O include postoperative nausea and vomiting (PONV) and, with long-term use (i.e., days), bone marrow suppression. N_2O diffuses out of blood rapidly and is contraindicated in patients with closed gas-filled body cavities (pneumothorax, lung cysts, bowel injury).

Intravenous Anesthetic Agents

IV anesthetics may be administered for induction and maintenance of anesthesia in bolus form or as continuous infusions. Common IV agents include propofol, opioids, benzodiazepines, ketamine, dexmedetomidine, and barbiturates. For children with vascular access, IV induction should be routine. All IV agents affect cardiorespiratory function.

Propofol

Propofol is the most commonly administered IV induction agent. Administered in doses of 2-5 mg/kg, propofol rapidly produces unconsciousness. Propofol may burn and itch on injection. After induction of anesthesia, propofol is a useful agent for maintaining hypnosis and amnesia and may be used as a sole anesthetic agent for nonpainful procedures (e.g., radiation therapy) and imaging studies. When combined with opioids, propofol provides excellent anesthesia for brief painful procedures, such as lumbar puncture and bone marrow aspiration. Although hemodynamic stability, and even spontaneous respirations, may be maintained during propofol administration, it remains a potent anesthetic that can obtund airway reflexes, respiration, and hemodynamic function. As such, some hospitals have limited its use to anesthesia professionals. Propofol may produce both respiratory depression and hypotension. Extrapyramidal symptoms are a rarer complication. Prolonged use may cause hemodynamic collapse, bradycardia, metabolic acidosis, cardiac failure, rhabdomyolysis, hyperlipidemia, profound shock, and death (**propofol infusion syndrome**). Prolonged propofol administration (>24-48 hours) in the ICU in children is not recommended. Propofol is formulated in 10% soy emulsion with egg emulsifiers and was once thought to be contraindicated in patients with soy or egg allergy. According to the American Academy of Allergy, Asthma, and Immunology, patients with soy and egg allergies may safely receive propofol for anesthesia.

Etomidate

Etomidate is an imidazole derivative used for the induction of anesthesia, frequently in emergent situations. Its onset of action is slower than propofol. Etomidate lacks significant cardiovascular depressant effects, making it a popular induction agent in patients with hemodynamic compromise and cardiac disease. However, etomidate inhibits 11β-hydroxylase, thereby suppressing mineralocorticoid and glucocorticoid synthesis for up to 72 hours after a single induction dose. Etomidate is associated with increased mortality when used as a sedative in the ICU (for which it is contraindicated); the effect of a single induction dose on mortality remains controversial. Any decision to use etomidate must weigh the short-term benefits of hemodynamic stability with the serious risks of adrenal suppression.

Ketamine

Ketamine (1-3 mg/kg IV) produces rapid induction of general anesthesia that lasts for 15-30 minutes. Ketamine is effective when given intramuscularly (IM), subcutaneously (SC), intranasally (IN), or orally (PO). However, the dose must be increased for alternative routes. Ketamine dissociates connections between the cerebral cortex and limbic system *(dissociative anesthesia)* through inhibition of *N*-methyl-D-aspartate receptors. Ketamine is also an analgesic and may be used as a sole IV agent to provide general anesthesia. It has few side effects and generally preserves blood pressure and cardiac output. However, ketamine increases myocardial oxygen demand and should be used cautiously in patients with impaired myocardial oxygen delivery or ventricular outflow tract obstruction. With low-dose (1-2 mg/kg) ketamine, airway reflexes and spontaneous ventilation may be maintained; at higher doses (3-5 mg/kg), loss of airway reflexes, apnea, and respiratory depression occur. Aspiration of gastric contents remains a risk during deep sedation with ketamine. IV ketamine is a useful general anesthetic agent for short procedures.

Ketamine has been linked to disturbing postanesthetic dreams and hallucinations after emergence from anesthesia. In adults the incidence of this effect is 30–50%; in prepubertal children it may be 5–10%. Benzodiazepines (e.g., midazolam) reduce these sequelae and may be given to children receiving ketamine. Ketamine is also a potent secretagogue, enhancing oral and bronchial secretions. An antisialagogue, such as atropine or glycopyrrolate, should also be considered before the administration of ketamine. Ketamine is a bronchodilator and is a useful agent for sedating patients with asthma in the ICU. Ketamine has been reported to increase ICP and therefore is contraindicated in patients with elevated ICP.

Opioids

Opioids are superb analgesics for painful procedures and postprocedural pain (see Chapters 92 and 93). Opioids are respiratory depressants that suppress CO_2 responsiveness and can produce apnea. Importantly, in equianalgesic doses, all opioids are equally potent respiratory depressants. Other inhalational or IV anesthetics generally potentiate opioid-induced respiratory depression.

Morphine is a long-acting opioid analgesic with important age-dependent pharmacokinetics. Equivalent doses of morphine per kilogram are associated with higher blood levels in neonates than in older children, with plasma concentrations approximating three times those of adults. Morphine exhibits a longer elimination half-life (14 hours) in young children than in adults (2 hours). The immature blood-brain barrier of neonates is more permeable to morphine. Morphine is often associated with hypotension and bronchospasm from histamine release and should be used with caution in children with asthma. Morphine has renally excreted active metabolites and is relatively contraindicated in renal failure. Because of morphine's prolonged duration of action and cardiorespiratory side effects, the fentanyl class of synthetic opioids has increased in popularity for perioperative analgesia.

Fentanyl is a potent synthetic opioid with a shorter duration of action and a more stable hemodynamic profile than morphine. Fentanyl attenuates the hemodynamic response to surgery and provides stable operating conditions. Effective analgesia and anesthesia may be provided with IV fentanyl administered as a 2-3 μg/kg bolus followed

by a 1-3 μg/kg/hr continuous infusion. Nitrous-narcotic anesthetic techniques that incorporate fentanyl are effective for maintenance of stable hemodynamics while still providing adequate hypnosis and analgesia. Fentanyl is the most commonly used *synthetic* opioid, but other formulations of varying potency are available (alfentanil < fentanyl < sufentanil). *Sufentanil* is ten times more potent than fentanyl and is frequently used during pediatric cardiac anesthesia. *Alfentanil* is approximately 25% as potent as fentanyl. *Remifentanil* has very rapid onset and offset of action. In doses of 0.25 μg/kg/min, surgical anesthesia can be maintained with this agent. Remifentanil is metabolized through nonspecific ester hydrolysis and has a short elimination half-life (<10 minutes), advantageous for rapid emergence from anesthesia. Unfortunately, this short duration of action has been linked to inadequate postprocedural analgesia and increased need for postprocedural opioid analgesic supplementation, limiting remifentanil's use.

Benzodiazepines

Benzodiazepines induce hypnosis, anxiolysis, sedation, and amnesia and have anticonvulsant properties. In high doses, benzodiazepines cause respiratory depression and are synergistic with opioids and barbiturates in their respiratory depressant effects. Benzodiazepines are γ-aminobutyric acid (GABA) agonists.

Midazolam is the most commonly used benzodiazepine in pediatric anesthesia. Short acting and water soluble, it can be injected without pain. It is a potent hypnotic-anxiolytic-anticonvulsant and is approximately four times more potent than diazepam. Midazolam may be administered orally, nasally, rectally, intravenously, or intramuscularly. Midazolam (0.10-0.15 mg/kg IV) has minimal effect on respiratory rate, heart rate, or blood pressure and provides excellent preoperative anxiolysis and amnesia. Premedication with oral midazolam (0.5-1.0 mg/kg) mixed in sweet-flavored syrup induces anxiolysis in approximately 90% of children without hemodynamic or respiratory depressant effects. However, children may experience loss of coordination (head control), blurred vision, and rarely, dysphoria. A child sedated with midazolam should not be left unattended. Most children readily accept an inhalational anesthetic by face mask after oral midazolam premedication. The widespread use of preoperative oral midazolam has decreased the practice of PPI.

Dexmedetomidine

Dexmedetomidine is a central α_2 adrenergic receptor agonist similar to clonidine. Dexmedetomidine lacks respiratory depressant effects and produces anxiolysis, sedation, mild analgesia, and sympatholysis. Rapid administration may produce hypertension and bradycardia, whereas continuous infusions may produce hypotension and bradycardia. Dexmedetomidine is frequently used for sedation in ICU patients and for procedures. Dexmedetomidine has become a popular adjuvant for general anesthesia during pediatric cardiac surgery.

Barbiturates

Sodium thiopental is the classic barbiturate IV induction agent, although it is now rarely used. Side effects of thiopental include respiratory depression, apnea, and hypotension. Induction with 3-5 mg/kg of thiopental produces unconsciousness within seconds, lasting 5-10 minutes. Thiopental is not useful for maintenance of anesthesia, which requires other IV or inhalational anesthetics. Pentobarbital is a barbiturate traditionally administered IV for sedation in children during imaging procedures of intermediate duration (e.g., diagnostic studies) that require akinesia. **Pentobarbital** is a potent respiratory depressant, particularly when combined with opioids and benzodiazepines. Pentobarbital has a prolonged duration of action. Pentobarbital sedation for nonpainful procedures generally results in delayed emergence. **Sodium methohexital** (Brevital) is another IV induction agent, similar to sodium thiopental in respiratory depressant effects. Barbiturates lack analgesic properties, and painful procedures require supplemental analgesia.

Neuromuscular Blocking Agents

Neuromuscular blockade is performed to facilitate endotracheal intubation and akinesia during surgery. NMBAs may be *depolarizing* (e.g., succinylcholine) or *nondepolarizing* (e.g., vecuronium, rocuronium, cisatracurium). **Succinylcholine** has a high-risk profile in children. Its use is associated with postoperative pain from muscle spasms; hyperkalemia; elevated intracranial, intraocular, and intragastric pressures; malignant hyperthermia; myoglobinuria; and renal damage. Consequently, succinylcholine is rarely used, except to provide rapid relief of laryngospasm. Endotracheal intubation is most often facilitated with nondepolarizing NMBAs. **Rocuronium** is most commonly used for intubation because of its rapid onset of action. For procedures that last >40 minutes, **vecuronium** and **cisatracurium** are also suitable to induce muscle relaxation for intubation. After intubation, repeat administration of NMBAs may be indicated to maintain muscle relaxation to facilitate surgery. Prolonged use of nondepolarizing NMBAs in critical illness may contribute to myopathy, especially when combined with high-dose corticosteroids.

INDUCTION OF GENERAL ANESTHESIA

The goal of induction of general anesthesia is the safe transition to a state of unconsciousness. Induction in children is typically achieved with inhalational anesthetics, although IV agents are indicated when patients have IV access. Many children will not tolerate the establishment of vascular access before induction of anesthesia, and it is routine to induce anesthesia by face mask with inhaled anesthetics. Before the induction of anesthesia, monitors applied may include pulse oximetry, ECG, and noninvasive blood pressure cuff. The child is then cautiously introduced to the face mask, which contains a high gas flow (5-7 L/min O_2), frequently mixed with N_2O. Inhalation of N_2O and O_2 for 60-90 seconds induces a state of euphoria. Nitrous oxide blunts the airway responses to potent volatile inhalational agents, and sevoflurane may then be safely introduced into the inhaled gas mixture. This leads to unconsciousness within 30-60 seconds while the child continues to breathe spontaneously.

After induction, IV access is obtained and standard intraoperative monitoring initiated. Thereafter, definitive airway management is performed. Airway management for short procedures (i.e., myringotomy tubes) frequently includes a mask airway and spontaneous ventilation; this is safe when the airway is secure and patent and aspiration risk is low. Longer procedures (>30-60 minutes) are not usually performed with mask airways. Definitive artificial airways include laryngeal mask airways and endotracheal tubes (ETTs). The **laryngeal mask** is a supraglottic airway generally reserved for procedures in spontaneously ventilating patients and does not effectively prevent the aspiration of gastric contents.

For complex surgical procedures, **endotracheal intubation** is generally required (e.g., intraabdominal, intrathoracic, airway procedures). Although endotracheal intubation may be performed under deep inhalational anesthesia, the depth of anesthesia required to attenuate airway reflexes may produce hemodynamic instability. Therefore NMBAs are frequently administered to facilitate intubation. The depolarizing NMBA succinylcholine is rarely used, and nondepolarizing NMBAs such as rocuronium and vecuronium are most frequently used (see earlier). After muscle relaxation, direct laryngoscopy and endotracheal intubation can be performed. Correct ETT placement is confirmed by direct laryngoscopy, end-tidal CO_2 measurement, and assessment of bilaterally equal breath sounds. Additional confirmatory tests include chest radiograph and fiberoptic bronchoscopy. After endotracheal intubation, controlled mechanical ventilation is required in the setting of neuromuscular blockade (see Chapter 86).

Children with full stomach precautions may require **rapid sequence induction**. Before performing a rapid sequence induction, preoxygenation with 100% oxygen for 2-5 minutes increases alveolar oxygen content and delays hypoxemia if intubation is difficult. Rapid sequence induction involves concurrent administration of hypnotic agents and NMBAs. Assisted ventilation before or after drug administration is avoided because of the risk of gastric distention, regurgitation, and aspiration. Traditionally, after administering a sedative and NMBA, the Sellick maneuver (cricoid pressure) was performed by applying firm pressure in a posterior direction against the cricoid cartilage. This displaces the cricoid cartilage into the esophagus and was thought to form an artificial sphincter to prevent reflux of the gastroesophageal contents. However, evidence suggests that cricoid pressure may be counterproductive, as it does not appear to prevent pulmonary aspiration

and may increase time to intubation. Because of this controversy, the clinician must consider the risks and benefits of cricoid pressure in each case.

The major risk of rapid sequence induction is intubation failure. In this situation the child is paralyzed without a protected airway, and ventilation may be hazardous or impossible. Only experienced airway specialists should undertake rapid sequence induction. It should be avoided in patients with a history of failed endotracheal intubation or features (micrognathia) associated with difficult intubation. Under these circumstances, bronchoscopic awake intubation may be indicated.

Complications During Induction

During induction of anesthesia, the transition between full wakefulness to unconsciousness is fraught with potential complications, including laryngospasm, bronchospasm, vomiting, and aspiration. Concerns for vomiting and aspiration dictate adherence to preanesthetic fasting guidelines and may be an indication for rapid sequence anesthetic induction.

During induction of anesthesia, especially with inhalational anesthetics, a period of excitement may occur. This period is associated with heightened airway reflexes, which can lead to coughing, gagging, laryngospasm, and bronchospasm. **Laryngospasm** is the reflex closure of the larynx, which prevents spontaneous or assisted ventilation. The child may make violent inspiratory efforts against a closed glottis, generating significantly negative intrathoracic pressure and resulting in postobstructive pulmonary edema. Laryngospasm can be prolonged, and hypoxia may ensue. Laryngospasm occurs in up to 2% of all anesthetic inductions in children <9 years old and is much less common in older patients. Laryngospasm occurs twice as frequently in children with active or recent upper respiratory tract infection. A history of tobacco exposure increases the likelihood of laryngospasm significantly.

Laryngospasm can be relieved by increasing the depth of anesthesia, either intravenously or through inhalation (although with the glottis closed, further administration of inhalational anesthesia is not possible). Neuromuscular blockade relieves laryngospasm, and an acute situation may be an indication for succinylcholine administration. Continuous positive airway pressure administration may be beneficial in alleviating laryngospasm. Laryngospasm may also occur during emergence from anesthesia because airway tone is increased during the transition to wakefulness.

Bronchospasm may result from increased airway reactivity during the hyperexcitable stage of induction or secondary to histamine release induced by anesthetic agents. Endotracheal intubation may provoke bronchospasm, especially in patients with asthma, which may be associated with life-threatening hypoxemia and inability to ventilate. Alternative airway management strategies such as laryngeal mask should be considered when appropriate in children with severe reactive airway disease. The use of histamine-releasing anesthetic agents has been associated with severe bronchospasm and, in rare instances, cardiorespiratory failure. Environmental tobacco smoke is another risk factor.

Hypoxemia during induction may be secondary to reduced functional residual capacity, atelectasis, and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. Volatile anesthetics blunt hypoxic pulmonary vasoconstriction, further contributing to $\dot{V}/\dot{Q}$ abnormalities. **Hypersecretion** may result in airway obstruction and should managed with antisialagogues, such as glycopyrrolate and atropine. The newer inhalation agents are less potent secretagogues, and the routine use of atropine premedication is much less common but often indicated when ketamine is used.

Hemodynamic complications may also develop during induction of anesthesia. **Hypotension** is common and may be exaggerated in the setting of hypervolemia, decreased myocardial function, or congenital heart disease. Inhalational anesthetics sensitize the myocardium to circulating catecholamines, and induction and excitement are associated with a hypercatecholaminergic state.

MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia is the period between induction and emergence. The child should be unaware of pain, unresponsive to painful stimuli, and physiologically supported. Anesthesia is typically maintained with a volatile anesthetic (e.g., isoflurane, sevoflurane) supplemented with opioid-based analgesia. IV hypnotic agents (e.g., dexmedetomidine, benzodiazepines) may be administered to augment hypnosis and amnesia. Choice of ventilatory strategy (spontaneous, assisted, or controlled) varies according to procedure type and patient condition (see Chapter 86). Surgical trauma may result in hypothermia and hypovolemia caused by blood loss and significant fluid shifts (third spacing). Management of these physiologic disturbances is the responsibility of the anesthesiologist during maintenance.

Temperature Management

Thermoregulation is critical during anesthesia. The absence of movement and inhibition of shivering reduce thermogenesis. Although temperature sensing may remain normal, the autonomic response to hypothermia is reduced. Anesthetic agents cause vasoparesis, which further impairs thermoregulation and increases heat loss. In newborns, inhalational anesthetics inhibit nonshivering thermogenesis from brown fat, increasing the risk for hypothermia. Mechanisms of heat loss during anesthesia include radiation, convection, evaporation, and conduction. Radiant and convective heat loss are most common and may be minimized by preheating the operating room and by use of radiant heat lamps and forced-air warming blankets. Humidification and warming of inspired gases may also be useful.

Fluid Management

Most anesthetics produce vasodilation and increase venous capacitance, effectively reducing myocardial preload. Surgical bleeding and insensible/third space fluid losses further contribute to intravascular volume depletion. Volume expansion with isotonic salt-containing solutions (normal saline, lactated Ringer, Plasma-Lyte) may be required to maintain cardiac output and organ perfusion. Increased renin-angiotensin-aldosterone axis activation and antidiuretic hormone (ADH) secretion further complicate fluid regulation.

Intraoperative fluid management must account for (1) deficits acquired during preoperative fasting, (2) maintenance fluid requirements, (3) surgical blood loss, and (4) insensible fluid loss. Infants should receive glucose-containing isotonic fluid to prevent perioperative hypoglycemia. Table 91.9 is a guideline for determining fluid deficits and maintenance requirements in the OR. For longer procedures, fluid deficits should be replaced with isotonic fluid over the first 3 hours of intraoperative management. Deficits are generally calculated as the number of hours of fasting status multiplied by the hourly maintenance rate for the child. Half the deficit is replaced during the first hour and half during the subsequent 2 hours. If hypotension or tachycardia persists in the early stages of anesthesia, more rapid replacement of the fluid deficit may be indicated.

Third space interstitial fluid losses should be replaced with isotonic salt solutions. For smaller operations, such as herniorrhaphy, pyloromyotomy, and minor procedures, fluid replacement at 3-5 mL/kg/hr is indicated for insensible losses. Complex abdominal or thoracic procedures with large insensible losses may require an additional 8-10 mL/kg/hr of IV fluid replacement. Crystalloid solution is indicated for blood loss as a 3:1 ratio. Allogenic blood products should be replaced as a 1:1 ratio. Colloid (albumin) administration also may decrease the amount of crystalloid replacement needed for blood loss. During large-volume transfusions, active fluid warming should be performed to prevent hypothermia. With major surgery and resultant SIRS, capillary

Table 91.9 Intraoperative Pediatric Fluid Replacement

INFUSION RATE	PATIENT WEIGHT
4 mL/kg/hr	1-10 kg
2 mL/kg/hr	10-20 kg
1 mL/kg/hr	per kg >20 kg
Example: 22 kg child requires (4 × 10) + (2 × 10) + (1 × 2) = 62 mL/hr	

integrity is lost, and third space losses are common. Failure to replace fluid loss and restore intravascular volume may lead to shock.

Perioperative **hypoglycemia** may result from preoperative fasting, most often in neonates or in children with metabolic disorders. In neonates, perioperative glucose monitoring is indicated, and glucose replacement is frequently required. In older children with normal nutritional status, isotonic salt solutions without glucose are adequate. In patients receiving total parenteral alimentation containing high glucose concentrations (>10%), continuous glucose administration should be ensured to avoid rebound hypoglycemia.

Postprocedural care includes supervision of emergence and recovery from anesthesia and surgery. **Emergence** describes the transition period between the anesthetized state and consciousness. During emergence, patients experience decreased anesthetic effect and increased physiologic and psychologic responses to painful stimuli (e.g., reactive autonomic tone, excitement, anxiety). Inhalational anesthetic agents are rapidly excreted during ventilation, and muscle relaxants can be reversed; however, the effects of opioids, benzodiazepines, and IV hypnotics may be prolonged. Normal physiologic functions such as spontaneous ventilation resume, and hemodynamic function improves. Before leaving the OR after routine elective procedures, the child should be conscious with intact airway reflexes and a patent airway. The effects of muscle relaxants should be reversed. Ideally, emergence should be as brief as possible, with maintenance of analgesia and anxiolysis and restoration of cardiorespiratory function. However, critically ill patients scheduled for ICU admission may require postoperative endotracheal intubation and mechanical ventilation. In these patients, deeper levels of sedation and analgesia should be maintained after the procedure.

During emergence, it is essential to assess whether **residual neuromuscular blockade** (NMB) exists. If weakness or respiratory depression is observed in the postoperative phase, prolonged NMB should be considered. *Reversal of residual NMB is standard anesthetic practice.* With the virtual abandonment of succinylcholine, only nondepolarizing NMBAs are routinely used for intubation. The termination of NMB depends on metabolism and elution away from the neuromuscular junction. Classically, nondepolarizing muscle relaxants are reversed by increasing the acetylcholine concentration at the neuromuscular junction with acetylcholine esterase inhibitors (neostigmine, edrophonium), which work through competitive antagonism. Vagolytic agents (e.g., atropine, glycopyrrolate) must be co-administered to prevent bradycardia. This process, even for the shortest-acting muscle relaxant, rocuronium, can take several minutes. An intubating dose of rocuronium to rapidly induce paralysis in emergency situations may not spontaneously reverse for 20 minutes or longer (compared with about 3 minutes for succinylcholine). The effects of long-acting, nondepolarizing NMBAs (vecuronium, pancuronium) are invariably reversed. Acetylcholine esterase inhibitor efficacy is dependent on the degree of NMB at the time of administration, and residual NMB is common despite reversal with these agents. **Sugammadex** is an alternative reversal agent that has a very low rate of residual NMB induced by the aminosteroids rocuronium and vecuronium. Its mechanism of action involves noncompetitive antagonism through encapsulation of neuromuscular agents.

POSTANESTHESIA CARE UNIT

In the postanesthesia care unit (PACU), the child is observed until there is adequate recovery from anesthesia. Achievement of spontaneous breathing, adequate pulse oximetry saturation (>95%), and hemodynamic stability are key recovery end-points. The child should be arousable, responsive, and oriented before discharge from the PACU. The amount of time spent in the PACU varies based on disposition (transfer to acute care or ICU, transfer to day surgery postrecovery unit, or discharge to home). Parents should be permitted to comfort their children in the PACU. Discharge from the PACU depends on the child's overall functional status, which includes physiologic endpoints, adequate analgesia, and control of PONV. Various scoring systems have been used for determining readiness for discharge from the PACU (Table 91.10).

Postanesthetic Complications

Respiratory insufficiency after general anesthesia is common. Prolonged emergence from anesthesia and respiratory depression may be caused by the residual effects of opioids, hypnotic agents, or NMBAs. Pain may also cause significant hypoventilation, especially after thoracic or abdominal surgery. Delayed emergence from anesthesia may result from retention of inhaled anesthetics worsened by hypoventilation. Hypothermia, especially in neonates, delays metabolism and excretion of anesthetics and prolongs neuromuscular blockade. Hypoventilation after surgery is associated with the development of **atelectasis**. Microatelectasis may lead to postoperative infections. When airway obstruction is present, maintenance of airway patency may necessitate oropharyngeal or nasopharyngeal airway placement. In the setting of profound respiratory depression, endotracheal intubation and mechanical ventilation may be indicated.

Opioid reversal with naloxone may be indicated in rare instances when excessive **opioid effect** is suspected. However, naloxone reverses both the respiratory depressant and the analgesic properties. After naloxone administration, a somnolent child with respiratory depression may experience increased pain. Opioid reversal requires bedside attention by the physician to monitor the child's behavioral, hemodynamic, and respiratory status. Importantly, naloxone is shorter acting than most opioid analgesics, which may result in renarcotization.

Postoperative stridor occurs in up to 2% of all pediatric patients. The use of appropriately sized ETTs and assurance of an air leak <30 cm H_2O

Maintaining patent airway	1
Requires airway maintenance	0

pressure decreases the risk of airway trauma or edema. A history of stridor increases the likelihood of postoperative complications. Stridor may be severe enough after extubation to require reintubation. Racemic epinephrine aerosols and dexamethasone are commonly employed therapies; their use requires prolonged observation because of the potential for rebound stridor. Stridor in infants may be an indication for overnight observation.

Cardiovascular complications are less frequently encountered in the PACU. Fluid administration may be required to augment cardiac output, perfusion, and urine output. Large-volume fluid resuscitation (>30 mL/kg) in the postoperative period may be an indication of evolving shock physiology, and sources of hypovolemia (e.g., occult bleeding) or myocardial dysfunction (e.g., tamponade, pneumothorax) should be considered.

Emergence delirium immediately after anesthesia is noted in 5–10% of children and is more common in those 3-9 years old. Manifestations include restlessness, combativeness, disorientation, and inconsolability. Almost all anesthetic agents have been linked to the development of delirium, especially newer volatile anesthetic agents (e.g., sevoflurane, desflurane). Potential postoperative complications, such as hypoglycemia and hypoxemia, should also be ruled out. Occasionally, it is necessary to provide additional sedation (e.g., propofol, dexmedetomidine, benzodiazepines), although these agents prolong postanesthesia recovery time and may not effectively reduce delirium.

Awareness During Anesthesia

A fundamental aim of anesthesia is to prevent recall by inducing hypnosis and amnesia. In adults, certain anesthetic techniques and surgical procedures have been associated with increased incidence of recall. The long-term sequelae of recall in children are unknown. Continuous cerebral bispectral index (BIS) electroencephalographic monitoring has been used to assess consciousness and aid in the prevention of intraoperative awareness. Unfortunately, pediatric studies have not confirmed the usefulness of BIS monitoring as a means of determining anesthetic depth. Existing data do not support the routine use of BIS monitoring during pediatric anesthesia. Volatile anesthetic agents reliably produce dose-dependent hypnotic and amnestic effects and remain a mainstay of general anesthesia.

Postoperative Nausea and Vomiting

After general anesthesia, 40–50% of children may experience PONV that generally lasts for several hours. This complication prolongs recovery room times and requires significant nursing attention. The etiology is not completely understood but is likely multifactorial and related to the emetic effects of anesthetics, pain, and surgical stress. Opioid analgesics may also provoke nausea and vomiting. Other risk factors for PONV include surgery lasting greater than 30 minutes, age ≥3 years, strabismus surgery, and a history of PONV in the patient or their relatives. Importantly, preoperative fasting does not decrease the incidence of PONV. Indeed, hydration and glucose supplementation appear to be important factors in decreasing PONV. Multimodal analgesia with nonopioid agents (e.g., acetaminophen, ibuprofen, ketorolac) and regional or local anesthesia may be associated with reduced PONV. The serotonin antagonist ondansetron is an effective treatment of PONV. Ondansetron prophylaxis is recommended for patients at increased risk of PONV. Serotonin antagonists are contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. Dexamethasone may also be used for the treatment of PONV.

Thermoregulation and Malignant Hyperthermia

After anesthesia, thermoregulation remains abnormal for several hours. **Hypothermia**, especially in neonates, may be associated with cardiorespiratory depression and prolongation of the effect of opioids and NMBAs. Although hypothermia has deleterious effects, active rewarming should be performed cautiously to avoid hyperthermia and cutaneous burns. Postoperative shivering is common and may occur in the absence of hypothermia. **Hyperthermia**, with temperatures in excess of 39°C (102.2°F), is of concern in the postoperative period. When high fevers occur within hours of the use of an inhalational anesthetic, especially if succinylcholine was used, malignant hyperthermia (MH) must be ruled out.

Malignant hyperthermia is a hypermetabolic syndrome triggered by volatile anesthetic agents and succinylcholine. The onset of MH may be acute, fulminant, and lethal without appropriate interventions. The disease is genetically heterogeneous, with >10 genes contributing to susceptibility, but typically displays an autosomal dominant inheritance pattern. A family history of death or febrile reactions during anesthesia should alert the anesthesiologist to its potential. Pathogenic variants within the gene encoding for the ryanodine receptor (the calcium channel of the sarcoplasmic reticulum) predispose to MH susceptibility and have been identified in 20–40% of humans with MH. Certain **myopathies** are associated with the risk of MH, including Duchenne muscular dystrophy, central core disease, and King Denborough syndrome.

The pathophysiology of MH involves uncontrolled intracellular calcium release from skeletal muscle sarcolemma, resulting in prolonged muscle contraction, adenosine triphosphate (ATP) depletion, and muscle cell death. Rhabdomyolysis results in the release of myoglobin, creatine phosphokinase (CPK), and potassium into the blood. The clinical course of MH is characterized by rapid onset of high fever (>38.5°C [101.3°F]), muscle rigidity, acidosis (metabolic and respiratory), high end-tidal CO_2, and multiorgan dysfunction. Death may ensue secondary to hemodynamic collapse from shock and cardiac dysrhythmias. Signs of MH generally occur within the first 2 hours of anesthesia but (rarely) can occur up to 24 hours later.

When MH is suspected, treatment involves discontinuation of all inhalational anesthetics, correction of the metabolic acidosis, and administration of the muscle relaxant dantrolene. The initial dose of dantrolene is 2.5 mg/kg, and repeat doses, up to a maximum of 10 mg/kg, are indicated for persistent fever, muscle rigidity, acidosis, and tachycardia. Once symptoms are controlled, the patient should be observed for at least 24 hours, because recrudescence may occur. The MH mortality rate was once >70% and is now <5% with standardized treatment algorithms. An MH cart with sufficient supplies of dantrolene should be present at every site where pediatric anesthesia is provided.

Certain phenomena suggest an increased risk of MH. Masseter spasm during induction, with rigid clenching of the masseter muscles and an inability to open the mouth, may signal MH susceptibility. Acute myoglobinuria associated with an MH-triggering agent is another clue. The child may not be hypermetabolic or febrile but may have dark urine, high CPK levels, and risk of myoglobin-induced renal tubular damage. The finding of dark urine after administration of an anesthetic requires further investigation, including measurement of electrolytes and CPK. Prevention of MH in susceptible patients requires the avoidance of triggering agents, which include inhalational anesthetics and succinylcholine. IV anesthesia and nitrous-opioid techniques are safe. MH-safe anesthesia machines devoid of trace concentrations of volatile anesthetic vapors should be used. Dantrolene prophylaxis is not recommended because MH is rapidly treatable, and the drug causes respiratory depression and muscle weakness. For a child in whom MH is suspected, the MH hotline, 1-800-MHHYPER (1-800-644-9737), should be used to notify the Malignant Hyperthermia Association of the United States (MHAUS). MHAUS registers susceptible patients and provides diagnostic and therapeutic information. Preanesthesia susceptibility testing includes genetic analysis of the ryanodine receptor gene, muscle biopsies, in vitro contraction studies, and possibly measurement of muscle CO_2 production in response to intramuscular caffeine.

Mediastinal Masses

Children with anterior mediastinal masses such as lymphomas, teratomas, and other primary mediastinal tumors are at serious risk for cardiorespiratory failure during anesthesia secondary to airway compromise, difficult ventilation, cardiac tamponade, vascular obstruction, and circulatory collapse. These patients generally require surgical tissue diagnosis before treatment is initiated. Significant compression of vital structures can occur with seemingly mild symptoms. Tachypnea, orthopnea, wheezing, and avoidance of prone or supine positions are significant indications of serious risk. Echocardiographic or CT evidence of pericardial tamponade, right ventricular compression, or compression of the pulmonary artery suggests severe risk. Biopsy with light sedation under local anesthesia may be indicated. When anesthesia is required, preservation of spontaneous ventilation is critical during

induction of anesthesia. Rigid bronchoscopy may be used to assist with ventilation in the setting of external airway compression. Provisions to provide mechanical circulatory support (cardiopulmonary bypass) should also be available. In high-risk children, consideration should be given to initiating treatment with corticosteroids, radiation therapy, and chemotherapy before obtaining a tissue diagnosis.

Postoperative Apnea

Neonates and infants are at increased risk for the development of postoperative apnea after exposure to potent hypnotic and analgesic medications. Both central and obstructive apnea may occur. Postanesthetic apnea is most common within the first 12 hours, although apnea has been reported in premature infants up to 48 hours later. Risk factors for postoperative apnea include history of apnea, caffeine treatment, chronic hypoventilation, and anemia. The risk of apnea is inversely proportional to postconceptual age (PCA) at surgery and is highest in premature neonates less than 36 weeks estimated gestational age. This risk is minimal by the time premature infants have reached 60 weeks PCA. When surgery is required in early infancy, overnight observation and monitoring may be indicated. In term infants >44 weeks PCA without risk factors, management should include observation and monitoring for 6 hours with at least one sleep-wake-feed cycle without hypoxia, bradycardia, or supplemental oxygen. Premature infants with risk factors <52 weeks PCA require admission for observation for 12 hours after anesthesia.

POSTOPERATIVE PAIN MANAGEMENT

Postprocedural pain management should ensure adequate analgesia and anxiolysis (see Chapter 93). Preoperative education focusing on pain management through development of skills designed to decrease anticipatory anxiety and participation in treatment planning can be helpful for children and families. Pediatric pain management relies on multimodal therapy, including opioid and nonopioid analgesics. Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, acetaminophen, opioids, and regional analgesia all have roles in postoperative pain management. Repeated evaluation is critical to effective pain management. Adjunctive therapy, such as pet therapy, may also decrease the need for potent analgesics postoperatively.

Patient-controlled analgesia (PCA) and **parent/nurse-controlled analgesia (PNCA)** are widely accepted postoperative pain regimens. PCA/PNCA may be used to administer a low-dose continuous (basal) infusion of opioid with intermittent (bolus) supplements as needed. The practitioner must determine the basal rate, bolus dose, lockout interval, and acceptable number of bolus doses per hour. PCA/PNCA safety requires appropriate medication dosing and assumes that patients are unlikely to overdose because somnolence will limit repeated self-administration. In young children, proper PCA/PNCA use may be more difficult to ensure, although children as young as 5 years have been able to use PNCA successfully. In older children and adolescents, PCA is a standard modality of postoperative pain management.

Regional Anesthesia

Regional anesthesia is the use of anesthetics to block the conduction of afferent neural impulses to the central nervous system. Forms of regional anesthesia include local anesthesia, peripheral nerve blocks, nerve plexus blocks, and neuraxial (epidural and subarachnoid/spinal) blocks. Anesthetics may be administered as a single injection or as a continuous infusion. Regional anesthesia may be used for both intraoperative and postoperative analgesia and has been linked to shortened recovery times and hospital stays in children. A major benefit of regional anesthesia is lesser central cardiorespiratory depressant effects. Injection of local anesthetics (e.g., lidocaine, bupivacaine) into the affected area may provide procedural analgesia lasting for hours to days. Wound infiltration with local anesthetics at the conclusion of surgery may also decrease early postoperative pain.

Neuraxial (epidural, spinal) analgesia is common in pediatric practice. The epidural space lies between the dura and the pia and arachnoid membranes, an area through which all nerve roots pass. Caudal epidural analgesia is placed through the sacral hiatus, inferior to the distal end of the spinal cord. This site is often used for pelvic and lower-limb anesthesia during urologic and orthopedic surgery in infants and toddlers. A single dose of caudal epidural anesthesia may provide hours of pain relief, and a continuous infusion may provide effective pain relief for hours to days. The epidural injection of opioids can provide analgesia for 12-24 hours and is a potential supplement to postoperative analgesia. Longer-acting local anesthetics (e.g., bupivacaine, ropivacaine) combined with an opioid (e.g., fentanyl, preservative-free morphine) are typically used in single-injection and continuous epidural therapy. It is also possible to provide epidural PCA with a continuous infusion pump and the patient's ability to self-administer analgesia as needed. Epidural analgesia can also provide pain relief in patients with chronic pain or pain caused by advanced malignant conditions.

Complications of neuraxial anesthesia include cephalad spread of blockade with respiratory depression, paralysis of respiratory muscles, and brainstem depression. Common complications of neuraxial analgesia are paresthesias and, if opioids are used, pruritus, nausea, and vomiting. Neuraxial opioid use necessitates antipruritic and antiemetic therapy. Infection and epidural hematoma are extremely rare. Neuraxial opioids, especially when administered intrathecally, may cause respiratory depression and require postoperative monitoring.

91.1 Anesthetic Neurotoxicity

John P. Scott

Laboratory animal studies have suggested a link between anesthetic exposure at an early age and neurotoxicity in developing brains. Existing nonclinical data implicate *N*-methyl-D-aspartate and γ-aminobutyric acid (GABA) pathways in apoptosis and neuronal cell death. Histopathologic changes and adverse neurodevelopmental outcomes have been associated with exposure to both inhalational and IV anesthetics, including isoflurane, sevoflurane, ketamine, benzodiazepines, and propofol. Animal studies were initially performed in nonprimates (rodents), and controversy remains concerning experimental design (dose, duration of treatment, species differences). However, work in nonhuman primates has also shown an increased incidence of adverse neurodevelopmental outcomes after prolonged and/or multiple exposures to volatile anesthetics.

Human studies of anesthesia-induced neurotoxicity have yielded conflicting results. Further complicating the situation are other potential triggers for adverse neurodevelopmental outcomes, including comorbidities, surgical trauma, and perioperative cardiorespiratory status. Multiple population-based epidemiologic studies have suggested a potential association between anesthetic exposure and adverse neurodevelopmental outcomes after multiple or prolonged anesthetic exposures. Large-scale European and Canadian cohort studies using national registries have revealed subtle differences in standardized psychometric testing of early school-age children after exposure to general anesthesia. Interestingly, other studies in children have failed to yield similar results. The Pediatric Anesthesia and Neurodevelopmental Assessment (PANDA), a multicenter matched-sibling control study, revealed no association between brief anesthetic exposure for inguinal hernia repair and aptitude on psychometric testing. Similarly, the General Anaesthesia and Awake-Regional Anaesthesia in Infancy (GAS) study, a prospective multicenter randomized controlled trial comparing general and neuraxial spinal anesthesia in infants for hernia repair, *did not* demonstrate any significant differences in neurodevelopment at 2 years of age between groups. A follow-up study at 5 years of age similarly showed no difference in neurodevelopment between groups receiving general and spinal anesthesia. Importantly, studies have not shown an association between adverse neurodevelopmental outcomes and anesthetic exposure <3 hours.

Alternatives to general anesthesia for many procedures in young children do not exist. Regional anesthetic techniques and narcotic-based anesthetics may gain popularity. Dexmedetomidine may also have some neuroprotective properties. Currently, there are insufficient data to make conclusions regarding the safety of one anesthetic approach over another. Ultimately, the potential for neurotoxicity must be balanced against the necessity of providing adequate anesthesia for children presenting for surgery.

Chapter 92

Procedural Sedation

John P. Scott

See also Chapters 91 and 93.

Sedation describes the continuum between wakefulness and general anesthesia (see Table 91.7). Many of the same medications used to induce general anesthesia may be used to provide sedation (see Table 91.8). Analogous to the provision of anesthesia, performance of procedural sedation requires a comprehensive presedation evaluation, intraprocedural monitoring, and postsedation recovery care. The term **conscious sedation** refers to a condition in which a patient is sleepy, comfortable, and cooperative but maintains airway-protective and ventilatory reflexes. Depending on the choice of pharmacotherapy, sedation may not provide analgesia. Sedation that is sufficient to obtund painful responses describes deep sedation. **Deep sedation** is a state of unarousability to voice and may be accompanied by suppression of reflex responses, with preservation of ability to respond purposefully to repeated or painful stimulation.

Pediatric procedural sedation requires vigilance and knowledge to ensure safety and is governed by the same guidelines as anesthesia care (Table 92.1). Adherence to guidelines for appropriate monitoring and management of sedation in children is imperative. Sedative doses that cause minimal sedation in one patient may produce complete unconsciousness and apnea in another. Anxiolysis or light sedation with chloral hydrate, benzodiazepines, and dexmedetomidine is often sufficient for nonpainful procedures. The use of dexmedetomidine for procedural sedation is safe, but recovery time can be prolonged and success variable. For painful procedures (e.g., bone marrow aspiration), the combination of hypnosis and analgesia is required. The addition of opioids to sedation regimens increases the risk of respiratory insufficiency. Short-acting anesthetics (e.g., propofol, methohexital, remifentanil) provide effective procedural sedation, but their use carries a higher likelihood of inadvertent induction of general anesthesia. Use of these medications requires the presence of an anesthesiologist and/or specially trained, experienced, credentialed, and qualified physicians.

Many pediatric subspecialists provide sedation and anesthesia care for children. The use of anesthetic agents is not limited to anesthesiologists, but anesthesiology departments are obligated to help develop, manage, and oversee sedation services. Together, hospitals and providers, including anesthesiologists, share responsibility for the oversight and credentialing of individuals administering sedation and anesthesia.

The elements of a safe pediatric procedural sedation system include the following:

- Clearly defined knowledge and skill sets
- Adequate prerequisite training
- Credentialing of providers
- Maintenance of certification
- Ensuring that sedation sites meet recognized standards
- Continuous quality improvement

Table 92.2 provides an approach to proper language to help the child cope with procedural pain.

Chapter 93

Pediatric Pain Management

Stacy J.B. Peterson and Steven J. Weisman

Pain is both a sensory and an emotional experience. Infants, children, and adolescents experience a wide range of acute and chronic pain etiologies. When unrecognized and undertreated, pain extracts a significant physiologic, biochemical, and psychologic toll on both the child and the family. Many disease processes and most interventional diagnostic or treatment procedures in pediatrics are associated with pain. Similarly, traumatic, developmental, cognitive, psychologic, and social experiences can also trigger and maintain chronic pain.

DEFINITION AND CATEGORIES OF PAIN

The International Association for the Study of Pain (IASP) defines **pain** as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage." Furthermore, the IASP expanded the definition to include the following six key notes:

1. Pain is always a personal experience that is influenced to varying degrees by biologic, psychologic, and social factors.
2. Pain and nociception are different phenomena. Pain cannot be inferred solely from activity in sensory neurons.
3. Through their life experiences, individuals learn the concept of pain.
4. A person's report of an experience as pain should be respected.
5. Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychologic well-being.
6. Verbal description is only one of several behaviors to express pain; inability to communicate does not negate the possibility that a human experiences pain.

Important elements to emphasize in this definition are (1) pain encompasses both peripheral physiologic and central neural components and (2) pain may or may not be associated with ongoing tissue damage. The experience of pain lies primarily in the strength and patterning of central neural connectivity (Fig. 93.1). Although immediate upstream neural activation can originate from inflammatory, structural, or biochemical events, processes not only in the periphery but also in the spinal cord and the brain influence the intensity and duration of pain. Similarly, central neural processes in the brain are associated with the location, intensity, and distress associated with pain. Chronic pain can develop when the upstream neural signaling continues to activate central neural circuits, such as with continued peripheral inflammatory or structural pain-associated processes. Sometimes, this signaling does not regress and the individual experiences ongoing chronic pain after the resolution of the original process.

Often, however, pediatricians face the most difficult problems when either acute pain becomes chronic or chronic pain develops and is maintained without a definable infectious, inflammatory, metabolic, or structural cause. When no "cause" can be found, patients are often referred to mental health specialists, or the cause for the pain is labeled as "stress." Children read this message as, "The doctor thinks I am faking pain, or I am crazy." Parents see their child suffering and often seek care from additional providers, with the child undergoing numerous tests, procedures, medication trials, and visits and many physicians looking for the cause of the pain so it can be "fixed" or to "get an answer." Meanwhile, the child is often missing school, social, and physical activities. In addition, they often develop poor sleep habits, nonrestorative sleep, and exhibit increasing fatigue.

It is recognized that chronic pain, in the absence of a specific identified structural, biochemical, or inflammatory cause, develops through the initiation, maintenance, and strength of central neural connectivity patterns (see Chapter 212). *Centrally mediated pain* derives from neural connectivity patterns in the brain that include centers involved in autonomic nervous system control, memory, and other cognitive centers, as well as emotional centers of the brain. In pediatrics, birth history and child development overlay these central patterns that contribute to the development of chronic pain. Parents may understand the concept of a "sticky nervous system" as the perpetuator of the continued pain in such a child. This model of brain connectivity patterns, or "top-down" mediators of chronic pain, is important, because it explains how psychologic and other nonpharmacologic interventions work to reduce chronic pain and suffering.

Table 93.1 specifies important pain categories typically treated (somatic, visceral, and neuropathic) and defines the elements and characteristics of **nociception**, the peripheral physiologic aspect of pain perception. Nociception refers to how specialized fibers (largely, but not exclusively, the small, unmyelinated A-delta and C fibers) in the peripheral nervous system transmit nerve impulses (usually transmitting signals originating from peripheral mechanoreceptors and chemoreceptors) through synapses in the spinal cord's dorsal horn through (but not exclusively through) the spinothalamic tracts to the brain's higher centers, where the development of neural connectivity patterns creates the experience of pain.

ASSESSMENT AND MEASUREMENT OF PAIN IN CHILDREN

Assessing pain entails much more than merely quantifying it. Whenever feasible, the physician should ask the patient about the character, location, quality, duration, frequency, and intensity of the pain. Depending on their age, children may be able to answer some or all the questions independently or with assistance from their parents. Severity can also be assessed via utilization of various scales, which will be discussed later. Some children may not report pain because of fears of talking to strangers, disappointing, or bothering others, receiving an injection if they report pain, returning to the hospital if they admit to pain, and other negative reactions. For infants and nonverbal children, their parents, pediatricians, nurses, and other caregivers are constantly challenged to interpret whether the child's distressed behaviors represent pain, fear, hunger, or a range of other perceptions or emotions. Similarly, lack of normal interest in play without behavioral distress signals can be manifestations of pain. Therapeutic trials of comfort measures (cuddling, feeding) and analgesic medication may be helpful in clarifying the triggers of the behaviors.

Behavior and physiologic signs are useful but can be misleading. A toddler may scream and grimace during an ear examination because of fear rather than pain. Conversely, children with inadequately relieved persistent pain from cancer, sickle cell disease, trauma, or surgery may withdraw from their surroundings and appear very quiet, leading observers to conclude falsely that these children are comfortable or sedated. In adolescents, increased reports of pain may be misinterpreted as "drug seeking" behaviors. In these situations, it is important to assess pain appropriately and determine how to best improve pain and function. Although this may be best accomplished by adjustment to analgesic medications, it may also involve the optimization of other nonpharmacologic techniques. This approach, although increasing the number or amount of interventions, may make the child become more, not less, interactive and alert as pain control improves. Similarly, neonates and young infants may close their eyes, furrow their brows, and clench their fists in response to pain. Adequate analgesia is often associated with eye opening and increased involvement in surroundings. A child who is experiencing significant chronic pain may play normally to distract attention away from pain. These coping behaviors are sometimes misinterpreted as evidence of the child's "faking" or exaggerating pain.

Age-Specific and Developmentally Specific Measures

Because infants, young children, and nonverbal children cannot express the quantity of pain they experience, several pain scales have been devised attempting to quantify pain in these populations (Fig. 93.2 and Table 93.2).

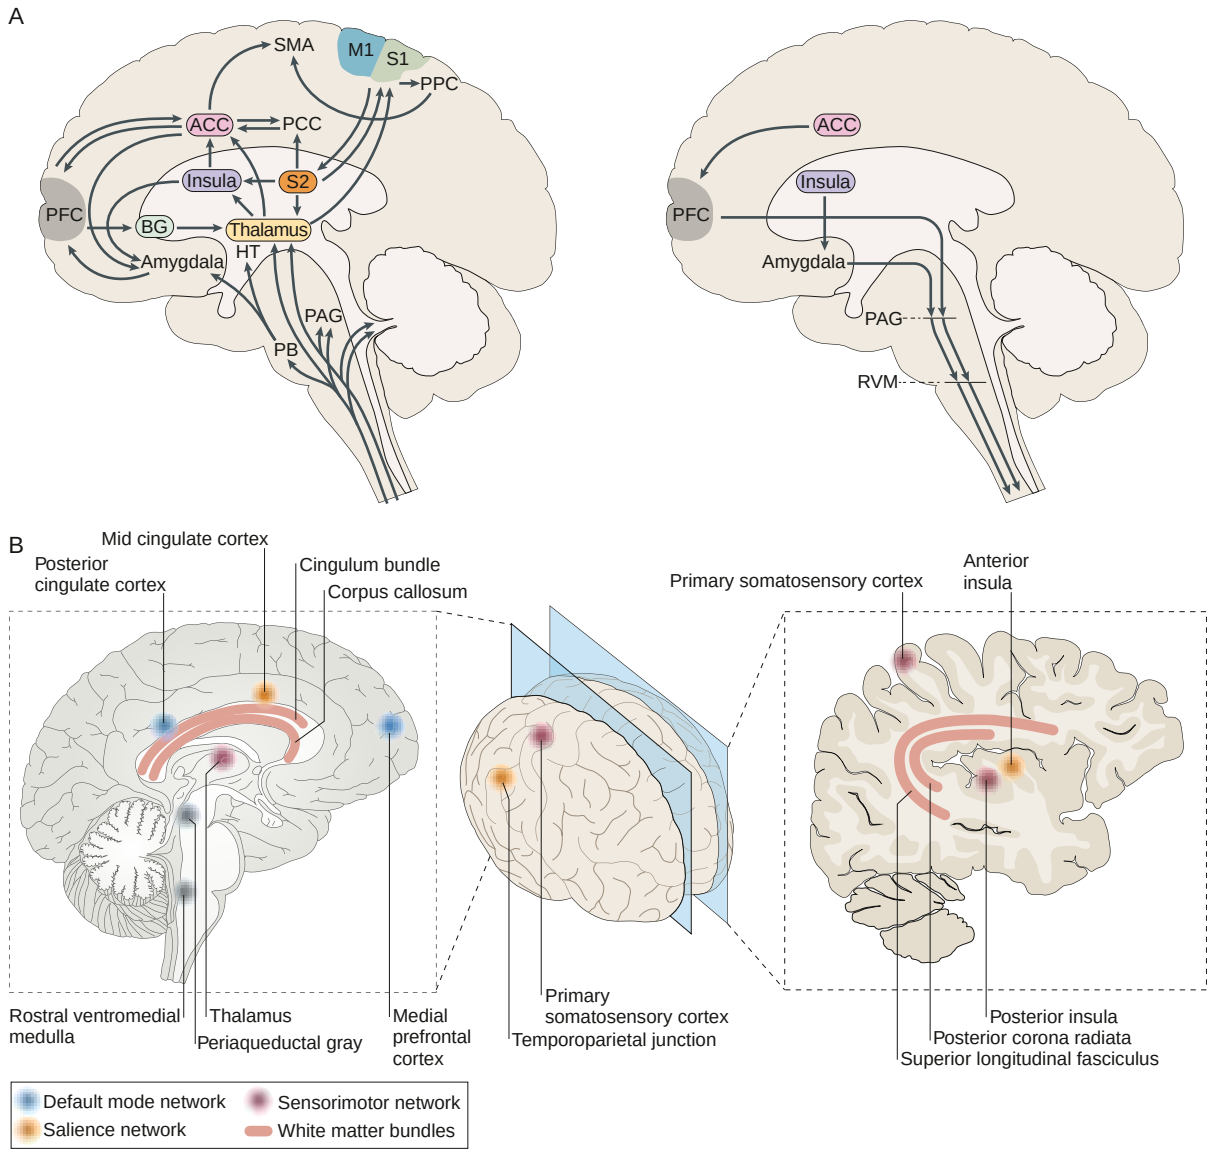

Fig. 93.1 Brain pathways, regions, and networks involved in acute and chronic pain. ACC, Anterior cingulate cortex; PCC, posterior cingulate cortex; BG, basal ganglia; HT, hypothalamus; PAG, periaqueductal gray; PB, parabrachial nuclei; PFC, prefrontal cortex; PPC, posterior parietal cortex; SMA, supplementary motor area; RVM, rostral ventromedial medulla. (**A**, *left panel from Apkarian AV, Bushnell MC, Treede RD, Zubieta JK. Human brain mechanisms of pain perception and regulation in health and disease. Table 93.1 Pain Categories and Characteristics

PAIN CATEGORY	DEFINITION	EXAMPLES	CHARACTERISTICS
Somatic	Pain resulting from injury to or inflammation of tissues (e.g., skin, muscle, tendons, bone, joints, fascia, vasculature)	Burns, lacerations, fractures, infections, inflammatory conditions	*In skin and superficial structures:* sharp, pulsatile, well localized *In deep somatic structures:* dull, aching, pulsatile, not well localized
Visceral	Pain resulting from injury to or inflammation of viscera	Angina, hepatic distention, bowel distention or hypermobility, pancreatitis	Aching and cramping; nonpulsatile; poorly localized (e.g., appendiceal pain perceived around umbilicus) or referred to distant locations (e.g., angina perceived in shoulder)
Neuropathic	Pain resulting from injury to, inflammation of, or dysfunction of the peripheral or central nervous system	Complex regional pain syndrome (CRPS), phantom limb pain, Guillain-Barré syndrome, sciatica	Spontaneous; burning; lancinating or shooting; dysesthesias (pins and needles, electrical sensations); **hyperalgesia** (amplification of noxious stimuli); **hyperpathia** (widespread pain in response to a discrete noxious stimulus); **allodynia** (pain in response to nonpainful stimulation); pain may be perceived distal or proximal to site of injury, often corresponding to innervation pathways (e.g., sciatica)

Behavioral Indicators

Facial grimacing: The Neonatal Facial Coding System uses several facial actions that may be indicators of pain. Pain is characterized by a bulging brow with tight creases in between; tightly closed eyelids; a deeply furrowed nasolabial groove; a horizontal, wide opened mouth; and a taut tongue that may be quivering along with the chin.

Crying: May be an indicator of pain.

Activity: Withdrawal or immobilization of a limb may be an indicator of pain.

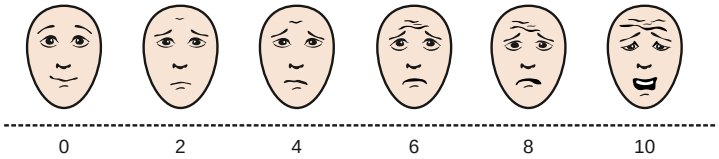
Response to comfort measures: Feeding, swaddling, holding, and ensuring that the infant is neither wet nor cold may help to discriminate between pain and other conditions.

Physiologic indicators: Alterations in heart rate, blood pressure, SpO_2, respiratory rate, or alterations in pattern of respiration may be nonspecific indicators of pain.

Self-Report of Pain

Categorical description: Toddlers or young children are asked to say if they are having "a little bit," a "middle amount," or "a lot" of pain.

Faces Scales: Children who do not have an appreciation of ordinal numbering are asked to rate their pain based upon cartoons depicting facial indicators of distress.



Numerical Rating Scale (NRS): Older children and teenagers are asked to rate their pain on a scale of "0" (no pain) to "10" (worst pain).

Visual Analog Scale (VAS): Children or teenagers are asked to move an indicator along a mechanical slide to depict the level of pain; the clinician reads a number along a 10-cm indicator on the back to determine the numeric score.

Fig. 93.2 Clinically useful pain assessment tools. *(Adapted from Burg FD, Ingelfinger JR, Polin RA, et al., eds. Current Pediatric Therapy, 18th ed. Philadelphia: Saunders; 2006:16; and Hicks CL, von Baeyer CL, Spafford P, et al. The Faces Pain Scale—revised: Toward a common metric in pediatric pain measurement. Pain. 2001;93:173–183.)*

Table 93.2 Pain Measurement Tools

NAME	FEATURES	AGE RANGE	ADVANTAGES	VALIDATION AND USES	LIMITATIONS
Visual Analog Scale (VAS)	Horizontal 10-cm line; subject marks a spot on the line between anchors of "no pain" and "most pain imaginable"	6-8 yr and older	Good psychometric properties; validated for research purposes	Acute pain Surgical pain Chronic pain	Cannot be used in younger children or in those with cognitive limitations Requires language skills and numerical processing; upper anchor of "most pain" requires an experiential reference point that is lacking in many children
Numerical Rating Scale (NRS)	Integers from 0 to 10, inclusive, corresponding to a range from no pain to most pain	6-8 yr and older	Good psychometric properties; validated for research purposes	Acute pain Surgical pain Chronic pain	Same as for VAS
Faces Scales (e.g., FACES-R, Wong-Baker, Oucher, Bieri, McGrath scales)	Subjects rate their pain by identifying with line drawings of faces or photos of children	3 yr and older	Can be used at younger ages than VAS and NRS	Acute pain Surgical pain	Choice of "no pain" face affects responses (neutral vs smiling); not culturally universal
Behavioral or combined behavioral-physiologic scales (e.g., FLACC, N-PASS, CHEOPS, OPS, FACS, NIPS)	Scoring of observed behaviors (e.g., facial expression, limb movement) ± heart rate and blood pressure	Some work for any ages; some work for specific age-groups, including preterm infants	May be used in both infants and nonverbal children	FLACC, N-PASS: Acute pain Surgical pain	Nonspecific; overrates pain in toddlers and preschool children; underrates persistent pain; some measures are convenient, but others require videotaping and complex processing; vital sign changes unrelated to pain can occur and may affect total score
Autonomic measures (e.g., heart rate, blood pressure, heart rate spectral analyses)	Scores changes in heart rate, blood pressure, or measures of heart rate variability (e.g., "vagal tone")	All ages	Can be used at all ages; useful for patients receiving mechanical ventilation		Nonspecific; vital sign changes unrelated to pain may occur and may artifactually increase or decrease score
Hormonal-metabolic measures	Plasma or salivary sampling of "stress" hormones (e.g., cortisol, epinephrine)	All ages	Can be used at all ages		Nonspecific; changes unrelated to pain can occur; inconvenient; cannot provide "real-time" information; standard normal values not available for every age bracket

VAS, visual analog scale; NRS, numerical rating scale; FLACC, face, legs activity, cry, and consolability pain scale for preverbal/nonverbal patients; N-PASS, neonatal pain agitation and sedation scale.

The Newborn and Infant

There are several behavioral distress scales for the infant and young child, mostly emphasizing the patient's facial expressions, crying, and body movement. Facial expression measures appear most useful and specific in neonates. Autonomic and vital signs can indicate pain, but because they are nonspecific, they may reflect other processes, including fever, hypoxemia, and cardiac or renal dysfunction (Tables 93.3 and 93.4).

Table 93.3 Signs and Symptoms of Pain in Infants and Young Children

PHYSIOLOGIC CHANGES	BEHAVIORAL CHANGES
• Increase in heart rate, respiratory rate, blood pressure, muscle tone • Oxygen desaturation • Sweating • Flushing • Pallor	• Change in facial expression (grimacing, furrowing of the brow, nasal flaring, deep nasolabial groove, curving of the tongue, quivering of the chin) • Finger clenching • Thrashing of limbs • Writhing • Back arching • Head banging • Poor feeding • Sleep disturbance • Pseudoparalysis

Table 93.4 CRIES Neonatal Pain Assessment Scale

	0	1	2
Crying	No	High pitched but consolable	Inconsolable
Requires oxygen for saturation >95%	No	FiO_2 <30%	FiO_2 >30%
Increased vital signs	No	HR or BP <20%	HR or BP >20%
Expression	No	Grimace	Grimace and grunt
Sleepless	No	Wakes often	Constantly awake

Score <4 initiate nonpharmacologic measures
Score >4 initiate pharmacologic and nonpharmacologic measures
BP, Blood pressure; HR, heart rate.
From Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children,* 10th ed. Philadelphia: Elsevier; 2022, Table 23.2, p. 487.

The Older Child

Children age 3-7 years old become increasingly articulate in describing the intensity, location, and quality of pain. Pain is occasionally referred to adjacent areas; referral of hip pain to the thigh or area above the knee is common in this age range. Self-report measures for children this age include using drawings, pictures of faces, or graded color intensities. Children ≥8 years old can usually use verbal numerical rating scales (NRS) or visual analog pain scales (VAS) accurately (see Fig. 93.2). Verbal numerical ratings are preferred and considered the gold standard: valid and reliable ratings can be obtained from children ≥8 years of age. The NRS consists of numbers from 0 to 10, in which 0 represents no pain and 10 represents very severe pain. There is debate about the label for the highest pain rating, but the current agreement is *not* to use the phrase "worst pain possible," because children can always imagine a greater pain. In the United States, regularly documented pain assessments are required for hospitalized children and children attending outpatient hospital clinics and emergency departments. Pain scores do not always correlate with changes in heart rate or blood pressure.

The Cognitively Impaired Child

Measuring pain in cognitively impaired children remains a challenge. Understanding pain expression and experience in this population is important because behaviors may be misinterpreted as indicating that cognitively impaired children are more insensitive to pain than neurotypical children. Children with trisomy 21 may express pain less precisely and more slowly than the general population. Pain in children with autism spectrum disorder (ASD) may be difficult to assess because these children may be both *hyposensitive* and *hypersensitive* to many different types of sensory stimuli, and they may have limited communication abilities. Although self-reports of pain can be elicited from some children who are cognitively impaired, observational measures have better validation among these children. The **Noncommunicating Child's Pain Checklist—Postoperative Version** is recommended for children up to 18 years old. In addition, the FLACC pain scale has been validated in nonverbal and cognitively impaired children (Table 93.5). Maladaptive behaviors and reduction in function may also indicate pain. Children with severe cognitive impairments experience pain frequently, and children with the fewest abilities experience the most pain. For this reason, providers must be able to recognize subtle signs and symptoms of pain (see Table 93.3)

Table 93.5 Revised FLACC for Pain Assessment in the Cognitively Impaired*

	0	1	2
Face	No particular expression or smile	Occasional grimace/frown; withdrawn or disinterested (appears sad or worried)	Consistent grimace or frown; frequent/constant quivering chin, clenched jaw (distressed-looking face; expression of fright or panic)
Legs	Normal position or relaxed	Uneasy, restless, tense (occasional tremors)	Kicking or legs drawn up (marked increase in spasticity, constant tremors, or jerking)
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense (mildly agitated [e.g., head back and forth, aggression]; shallow, splinting respirations, intermittent sighs)	Arched, rigid, or jerking (severe agitation, head banging; shivering [not rigors]; breath-holding, gasping or sharp intake of breath; severe splinting)
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint (occasional verbal outburst or grunt)	Crying steadily, screams or sobs, frequent complaints (repeated outbursts, constant grunting)
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or talking; distractible	Difficult to console or comfort (pushing away caregiver, resisting care or comfort measures)

*Revised descriptors for children with disabilities shown in brackets.
0= Relaxed/comfortable
1–3 = Mild discomfort
4–6 = Moderate pain
7–10 = Severe pain
FLACC Scoring System: May be used in preverbal, mechanically ventilated, or cognitively impaired patients; it is an acronym that includes 5 indicators, each scored as a 0, 1, or 2, that form a 10-point composite scale with a range from 0 (no pain) to 10 (worst pain). FLACC: Score each category between 0 and 2. The total score may be any number from 0 to 10.
From Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children,* 10th ed. Philadelphia: Elsevier; 2022, Table 23.3, p. 488.

CONCEPTUAL FRAMEWORK FOR TREATMENT OF PEDIATRIC PAIN

Many models of pain focus on factors that explain the interindividual variability in pain perception and the chronicity and impairment experienced with pain. Central to these models are interrelationships among biologic, cognitive, affective, and social factors that influence children's pain and disability, commonly referred to as *biopsychosocial models* of pain. **Biologic** factors include the child's physical health, central nervous system (CNS) factors (pain processing), gender, pubertal status, and genetic factors. Individual child **cognitive and affective** factors related to perception of pain include anxiety, fear, negative affect, pain behaviors, and functional disability, whereas **social** factors include such areas as culture, socioeconomic status, school environment, social and peer interactions, adverse childhood events, and parental and family factors. For children, **developmental** factors need to be considered, such as cognitive and motor development, birth history, and epigenetic factors (the interaction in development between genetic and environmental factors).

A framework that considers the interplay of biologic, psychologic, and social factors is useful for understanding pediatric pain and to guide pain assessment and the delivery of pain prevention and management. Many simple interventions designed to promote relaxation and patient control can work either alone or synergistically with pain medications for relief of pain and related distress. Moreover, psychologic interventions are often coupled with physical therapy interventions to assist in the management of disabling chronic pain.

Pharmacologic Treatment of Pain

The pharmacokinetics and pharmacodynamics of analgesics vary with age. This results in drug responses in infants and young children that differ from those in older children and adults. The elimination half-life of most analgesics is prolonged in neonates and young infants because of their immature hepatic enzyme systems and reduced glomerular filtration. Clearance of analgesics may also be variable in young infants and children. Renal blood flow, glomerular filtration, and tubular secretion increase dramatically in the first few weeks after birth, approaching adult values by 3-5 months of age. Renal clearance of analgesics is often greater in toddlers and preschool-age children than in adults, whereas in premature infants, clearance is reduced. Age-related differences in body composition and protein binding also exist. Total body water as a fraction of body weight is greater in neonates than in children or adults. Tissues with high perfusion, such as the brain and heart, account for a larger proportion of body mass in neonates than do other tissues, such as muscle and fat. Because of decreased serum concentrations of albumin and α_1-acid glycoprotein, neonates have reduced protein binding of some drugs, resulting in higher amounts of free, unbound, pharmacologically active drugs.

Acetaminophen, Aspirin, and Nonsteroidal Antiinflammatory Drugs

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) have replaced aspirin as the most used antipyretics and oral, nonopioid analgesics (Table 93.6). This is because of the association of Reye syndrome with the use of aspirin in children with a viral infection, such as influenza or chickenpox.

Acetaminophen, a generally safe, nonopioid analgesic and antipyretic, has the advantage of intravenous (IV), rectal, and oral routes of administration. Acetaminophen is not associated with the gastrointestinal (GI) or antiplatelet effects of aspirin and NSAIDs, making it a particularly useful drug in patients with cancer. Unlike aspirin and NSAIDs, acetaminophen has only mild antiinflammatory action. Although acetaminophen alone may not adequately treat various types of pain, in conjunction with other agents, it can lead to improved pain control and decreased opioid use. One effective management strategy can be to schedule acetaminophen and/or NSAIDs to decrease the need for opioids, while still maintaining good pain control.

Acetaminophen toxicity can result from a large single dose or cumulative excessive dosing over days or weeks (see Chapter 94). Toxicity manifests as fulminant hepatic necrosis and liver failure in infants, children, and adults. Drug biotransformation processes are immature in neonates, very active in young children, and somewhat less active in adults. Young children are more resistant to acetaminophen-induced hepatotoxicity than are adults as a result of metabolic differences. Sulfation predominates over glucuronidation in young children, leading to a reduction in NAPQI production.

Aspirin is indicated for certain rheumatologic conditions and for inhibition of platelet adhesiveness, as in the treatment of Kawasaki disease. Concerns about Reye syndrome have resulted in a substantial decline in pediatric aspirin use. In general, aspirin should not be used for routine pain control in children. It is important to be aware of

Table 93.6 Commonly Used Nonopioid Medications (Antiinflammatory Medications)

MEDICATION	DOSAGE	COMMENT(S)
Acetaminophen	10-15 mg/kg PO q4h 10 mg/kg IV q4h 15 mg/kg IV q6h 10 mg/kg IV q6h (<2 yr) 20-30 mg/kg/PR q4h 40 mg/kg/PR q6-8h *Maximum daily dosing:* 75 mg/kg/24 hr (children) 60 mg/kg/24 hr (<2 yr) 30-45 mg/kg/24 hr (neonates)	Minimal antiinflammatory action; no antiplatelet or adverse gastric effects; overdosing can produce fulminant hepatic failure.
Ibuprofen	8-10 mg/kg PO q6h 10 mg/kg IV q4-6h to maximum of 400 mg *Maximum daily dose:* 2,400 mg	Antiinflammatory; transient antiplatelet effects; may cause gastritis; extensive pediatric safety experience.
Naproxen	5-7 mg/kg PO q8-12h *Maximum daily dose:* 1,000 mg	Antiinflammatory; transient antiplatelet effects; may cause gastritis; more prolonged duration than that of ibuprofen.
Ketorolac	Loading dose 0.3 mg/kg, then 0.25-0.3 mg/kg IV q6h to a maximum of 5 days; maximum single dose 15 mg for those < 50 kg and 30 mg for those ≥ 50 kg	Antiinflammatory; reversible antiplatelet effects; may cause gastritis; useful for short-term situations in which oral dosing is not feasible.
Diclofenac sodium	2-3 mg/kg/day divided in 2 or 3 doses *Maximum daily dose:* 150 mg	Antiinflammatory; reversible antiplatelet effects; lower risk of gastritis and ulceration compared with other NSAIDs.
Celecoxib	Only approved for children ≥2 yr; ≥10 kg to ≤25 kg: 50 mg PO bid >25 kg: 100 mg PO bid	Antiinflammatory; no or minimal antiplatelet or gastric effects; cross-reactivity with sulfa allergies.

aspirin-containing medications that may be available over the counter when treating patients.

NSAIDs are used widely to treat pain and fever in children. Most currently available NSAIDs are nonselective cyclooxygenase (COX) inhibitors, that is, drugs that nonselectively block the activity of both COX-1 (found in gastric mucosa and platelets) and COX-2 (active in inflammatory pathways and cortical renal blood flow regulation) enzymes that synthesize prostaglandins. In children with juvenile idiopathic arthritis, ibuprofen and aspirin are equally effective, but ibuprofen is associated with fewer side effects and better drug adherence. NSAIDs, used adjunctively in surgical patients, reduce opioid requirements (and therefore opioid side effects) by as much as 35–40%. Although NSAIDs can be useful postoperatively, they should be used as an adjunct to, not as a substitute for, opioids in patients with acute moderate to severe pain.

Ketorolac is useful in treating moderate to severe acute pain in patients who are unable or unwilling to take oral NSAIDs. Intravenous diclofenac is also available in other countries. U.S. Food and Drug Administration (FDA) recommendations limit ketorolac to five consecutive days of administration. IV ibuprofen (Caldolor) is FDA approved for the management of pain and fever in infants and children >6 months of age, but is not widely available.

Adverse effects of NSAIDs are uncommon but may be serious when they occur, including gastritis with pain and bleeding; decreased renal blood flow that may reduce glomerular filtration and enhance sodium reabsorption, in some cases leading to tubular necrosis; hepatic dysfunction and liver failure; inhibition of platelet function; and an increased incidence of cardiovascular events in patients predisposed to stroke and myocardial infarction. Although the overall incidence of bleeding is very low, gastric bleeding is the most common cause of serious morbidity related to this class of analgesics. NSAIDs should not be used in the child with a bleeding diathesis or at risk for bleeding and should be used with caution postsurgically. Use after surgeries such as tonsillectomy has been debated, but current postoperative guidelines do include the use of NSAIDs. Renal injury from short-term use of ibuprofen in euvolemic children is quite rare; the risk is increased by hypovolemia or cardiac dysfunction. The safety of both ibuprofen and acetaminophen for short-term use is well established (see Table 93.6).

The only **COX-2 specific NSAID** currently available in the United States is oral celecoxib, whereas in other countries parenteral parecoxib and oral rofecoxib are also available. The coxib drugs are selective COX-2 enzyme inhibitors. Therefore they are effective antiinflammatory and analgesic molecules that generally do not result in platelet inhibition with enhanced bleeding or in gastric inflammation or ulceration, findings that may be seen with the nonselective COX inhibitors in the NSAID class. COX-2 selective NSAIDs do inhibit regulation of cortical renal blood flow and therefore carry the same risk of renal toxicity and acute tubular necrosis, particularly in the setting of low cardiac output states or dehydration. Celecoxib is therefore an appropriate primary or adjunctive analgesic to use in children after surgery, in children with gastric mucosal pathology, or in oncology patients in whom concern for hemostasis contraindicates conventional NSAIDs.

Use of NSAIDs for pain management in children less than 6 months is not generally recommended due to immature glomerular filtration. However, limited use between 3 and 6 months may be appropriate.

Opioids

Opioids are analgesic substances either derived from the opium poppy **(opiates)** or synthesized to have a similar chemical structure and mechanism of action **(opioids)**. The term "narcotics" (narcotic analgesics) should be avoided for these agents, as it connotes criminality and lacks pharmacologic descriptive specificity. Opioids are administered for moderate and severe pain, such as acute postoperative pain, pain from trauma, sickle cell crisis pain, and cancer pain. Opioids can be administered by the oral, rectal, oral transmucosal, transdermal, intranasal, epidural, intrathecal, IV, subcutaneous (SC), or intramuscular (IM) route. Regardless of route of administration, the site of action is at mu (μ) opioid receptors in the peripheral nervous system, spinal cord, brainstem, and higher CNS centers. Infants and young children are sometimes underdosed with opioids because of concern about significant respiratory side effects. Opioids' respiratory depressant effects result from infants' lower metabolic clearance of opioids and higher blood levels with frequent dosing. With proper understanding of the pharmacokinetic and pharmacodynamics of opioids, children can receive effective relief of pain and suffering with a good margin of safety, regardless of pharmacokinetic maturity, age, or size (Tables 93.7-93.9).

Opioids act by mimicking the actions of endogenous opioid peptides, binding to receptors in the brain, brainstem, spinal cord, and to a lesser extent in the peripheral nervous system, thus leading to inhibition of nociception. Opioids also bind to μ receptors in the pleasure centers of the midbrain, particularly in genetically susceptible individuals, a factor responsible for the euphoric effect in some individuals and the predilection to psychologic dependence and addictive behavior. Opioids also have dose-dependent respiratory depressant effects when interacting with the μ-opioid receptors in the respiratory centers of the brainstem, depressing ventilatory drive and blunting ventilatory responses to both hypoxia and hypercarbia. These respiratory depressant effects are increased with co-administration of other sedating drugs, particularly benzodiazepines or barbiturates.

Optimal use of opioids requires proactive and anticipatory management of side effects (see Table 93.8) as well as dose adjustments for renal or hepatic disease (Table 93.10). Common side effects include sedation, constipation, nausea, vomiting, urinary retention, and pruritus. Tolerance usually develops to the side effect of **nausea**, which typically subsides with long-term dosing, but nausea may require treatment with antiemetics, such as a phenothiazine, butyrophenones, antihistamines, or a serotonin receptor antagonist such as ondansetron or granisetron. Pruritus and other complications during patient-controlled analgesia with opioids may be effectively managed by low-dose IV naloxone.

The most common troubling, but treatable, side effect is **constipation**. Patients who take opioids for chronic pain for long periods predictably develop tolerance to the sedative and analgesic effects of opioids over time, but tolerance to constipation does not occur, and constipation remains a troublesome and distressing problem in almost all patients with long-term opioid administration. Stool softeners and stimulant laxatives should be administered to most patients receiving opioids for more than a few days. Osmotic and bulk laxatives are less effective, usually producing more distention and discomfort. A peripherally acting opiate μ-receptor antagonist, **methylnaltrexone**, promptly and effectively reverses opioid-induced constipation in patients with chronic pain who are receiving opioids daily. Methylnaltrexone is approved for use as either an injectable or oral formulation, but only the SC injection is commercially available, which most children will object to receiving. Naldemedine and naloxegol are other agents with actions similar to methylnaltrexone. **Lubiprostone** is a colonic chloride channel inhibitor that impairs water reabsorption in the colon and is very effective for opioid-induced constipation.

Media and government attention to the "opioid epidemic" has reasonably led to scrutiny of the prescription of opioids to children, and FDA approval of opioid formulations for children has raised alarm and criticism by some vocal critics of the use of opioids for medical purposes. Thus one of the potent barriers to effective management of pain with opioids is the fear of addiction held by many prescribing pediatricians and parents alike. Pediatricians should understand the phenomena of tolerance, dependence, withdrawal, and addiction (Table 93.11). **Opioid addiction** is the result of the complex interplay of genetic predisposition, psychiatric pathology, and social forces, including poverty, joblessness, hopelessness, and despair. The dramatic increase in the amount of opioid abuse and overdoses and opioid-related deaths, although highest in the adult non-Hispanic American Indian or Alaska Native population age 35–44 years old, has also significantly risen in children and adolescents. Among persons 14–18 years, overdose deaths increased 114% from 2019 to 2021 with 2,037 (91.3%) of adolescent overdose deaths in 2021 involving at least one opioid. Despite this rise in abuse of opioids, a longitudinal study of children and adolescents treated for medical reasons with opioids found that there was no increased risk of the development of substance abuse, at least until their

Table 93.7 Pediatric Dosage Guidelines for Opioid Analgesics

DRUG	EQUI-ANALGESIC DOSES		PARENTERAL DOSING		IV:PO DOSE RATIO	ORAL DOSING		COMMENTS
	IV	ORAL	<50 kg	≥50 kg		<50 kg	≥50 kg	
Fentanyl	10 µg	100 µg	0.5-1 µg/kg q1-2h 0.5-1.5 µg/kg/hr	0.5-1 µg/kg q1-2h 0.5-1.5 µg/kg/hr	Oral transmucosal: 1:10 Transdermal: 1:1	Oral transmucosal: 10 µg/kg Transdermal: 12.5-50 µg/hr	Transdermal patches available; patch reaches steady state at 24 hr and should be changed q72h	70-100 times as potent as morphine with rapid onset and shorter duration. With high doses and rapid administration, can cause chest wall rigidity. Useful for short procedures; transdermal form should be used only in opioid-tolerant patients with chronic pain.
Hydrocodone	N/A	1.5 mg	N/A	N/A	N/A	0.15 mg/kg	10 mg	Weak opioid; only available in form with acetaminophen.
Hydromorphone	0.2 mg	0.6 mg	0.01 mg q2-4h 0.002 mg/kg/hr	0.01 mg q2-4h 0.002 mg/kg/hr	1:3	0.04-0.08 mg/kg q3-4h	2-4 mg q3-4h	Five times the potency of morphine; no histamine release and fewer adverse events than morphine.
Methadone	1 mg	2 mg	0.1 mg/kg q8-24h	0.1 mg/kg q8-24h	1:2	0.2 mg/kg q8-12h PO; available as liquid or tablet	2.5 mg TID	Duration 12-24 hr; useful in certain types of chronic pain; requires additional vigilance because it will accumulate over 72 hr and produce delayed sedation. When patients tolerant of opioids are switched to methadone, they show incomplete cross-tolerance and improved efficacy. Because methadone is associated with prolonged QTc, monitoring is needed for children receiving high and extended dosing.
Morphine	1 mg	3 mg	0.05 mg/kg q2-4h 0.01-0.03 mg/kg/hr	0.1 mg/kg q2-4h 0.01-0.03 mg/kg/hr	1:3	Immediate release: 0.3 mg/kg q3-4h Sustained release: 20-35 kg: 10-15 mg q8-12h 35-50 kg: 15-30 mg q8-12h	Immediate release: 15-20 mg q3-4h Sustained release: 30-90 mg q8-12h	Potent opioid for moderate/severe pain; may cause histamine release. Sustained-release form must be swallowed whole; if crushed, becomes immediate acting, leading to acute overdose.
Oxycodone	N/A	3 mg	N/A	N/A	N/A	0.1-0.2 mg q3-4h; available in liquid (1 mg/mL)	Immediate release: 5-10 mg q4h Sustained release: 10-120 mg q8-12h	Strong opioid only available as an oral agent in North America; more potent than and preferable to hydrocodone. Sustained-release form must be swallowed whole; if crushed, becomes immediate acting, leading to acute overdose.

N/A, not available.

Table 93.8 Management of Opioid-Induced Adverse Effects

Respiratory depression	*Naloxone:* 0.01-0.02 mg/kg up to a full reversal dose of 0.1 mg/kg. May be given IV, IM, IN, SC, or via ETT. The full reversal dose should initially be used for apnea in opioid-naive patients. In opioid-tolerant patients, a reduced dose should be given and titrated up slowly to treat symptoms but prevent acute withdrawal. Ventilation may need to be supported during this process. Dose may be repeated every 2 min to a total of 10 mg. Adult maximum dose is 2 mg/dose. Give with caution to patients who are receiving long-term opioid therapy, as it may precipitate acute withdrawal. Duration of effect is 1-4 hr; therefore close observation for recurrent symptoms is essential.
Excessive sedation without evidence of respiratory depression	Change opioid or decrease the dose. In palliative patients or other special circumstances, can consider treating with stimulants. *Methylphenidate**:* 0.3 mg/kg per dose PO (typically 10-20 mg/dose to a teenager) before breakfast and lunch. Do not administer to patients receiving clonidine, because dysrhythmias may develop. *Dextroamphetamine*: 2.5-10 mg on awakening and at noon. Not for use in young children or in patients with cardiovascular disease or hypertension. *Modafinil:* Pediatric dose not established. May be useful in selected patients. Typical adult dose: 50-200 mg/day.
Nausea and vomiting	*Metoclopramide*†*:* 0.15 mg/kg IV up to 10 mg/dose q6-12h for 24 hr. *Trimethobenzamide:* if weight <15 kg, 100 mg PO or PR q6h; if >15 kg, 200 mg PO or PR q6h. (*Note:* Suppository contains benzocaine 2%.) Not for use in newborn infants or premature infants. 5-HT_3 receptor blockers: *Ondansetron:* 0.15 mg/kg up to 8 mg IV q6-8h not to exceed 32 mg/day (also available as a sublingual tablet). *Granisetron:* 10 to 20 µg/kg IV q12-24h. *Prochlorperazine**‡ (Compazine): >2 yr or >20 kg, 0.1 mg/kg per dose q8h IM or PO up to 10 mg/dose. Change opioid.
Pruritus	*Hydroxyzine*: 0.5 mg/kg PO q6h. *Nalbuphine:* 0.1 mg/kg IV q6h for pruritus caused by intraaxial opioids, especially fentanyl. Administer slowly over 15-20 min. May cause acute reversal of systemic µ-receptor effects and leave κ-agonism intact. *Naloxone:* 0.5-2 mcg/kg/hr IV infusion (titrate up to decrease pruritus and reduce infusion if pain increases). *Ondansetron:* 0.05-0.1 mg/kg IV or PO q8h. *Cyproheptadine*†*:* 0.1-0.2 mg/kg PO q8-12h. Maximum dose 12 mg. Change opioid.
Constipation	Encourage water consumption, high-fiber diet, and vegetable fiber. *Bulk laxatives:* Metamucil, Maltsupex. *Lubricants:* Mineral oil 15-30 mL PO daily as needed (not for use in infants because of aspiration risk). *Surfactants:* Sodium docusate (Colace): <3 yr: 10 mg PO q8h 3-6 yr: 15 mg PO q8h 6-12 yr: 50 mg PO q8h >12 yr: 100 mg PO q8h *Stimulants:* Bisacodyl suppository (Dulcolax): <2 yr: 5 mg PR qhs >2 yr: 10 mg PR qhs *Senna syrup* (218 mg/5 mL): >3 yr: 5 mL qhs *Enema:* Fleet hypertonic phosphate enema (older children; risk of hyperphosphatemia). *Electrolytic/osmotic:* Milk of magnesia; for severe impaction: polyethylene glycol (GoLYTELY, MiraLAX). Methylnaltrexone is an opioid antagonist that works in the colon and does not cross the blood-brain barrier to reverse analgesia; given as subcutaneous injection every day or every other day (0.15 mg/kg) and is effective in producing stool in 30-60 min in most patients.
Urinary retention	Straight catheterization, indwelling catheter. Decrease opioids, use naloxone drip.

*Avoid in patients taking monoamine oxidase inhibitors.
†May be associated with extrapyramidal side effects, which may be more often seen in children than in adults.
‡Consider pretreatment with diphenydramine to decrease risk of anti-dopaminergic adverse events (e.g., dystonia).
ETT, Endotracheal tube; IV, intravenously; IM, intramuscularly; IN, intranasally; PO, orally; PR, rectally; SC, subcutaneously.
Modified from Burg FD, Ingelfinger JR, Polin RA, et al., eds. *Current Pediatric Therapy,* 18th ed. Philadelphia: Saunders; 2006, p 16.

mid-20s. Thus the rational short- or even long-term use of opioids in children does not lead to a predilection for or risk of addiction in a child not otherwise at risk because of genetic background, economic factors, or social milieu.

It is equally important for pediatricians to realize that even patients with recognized substance abuse diagnoses are entitled to effective analgesic management, which often includes the use of opioids. If legitimate concerns exist about addiction in a patient, safe, effective opioid pain management is often best provided by specialists in pain management and addiction medicine. Table 93.12 outlines the U.S. Centers for Disease Control and Prevention (CDC) opioid recommendations for **chronic pain** (primarily in adults).

There is no longer a reason to administer opioids by IM injection. Continuous IV infusion of opioids is an effective option that permits more constant plasma concentrations and clinical effects than intermittent IV bolus dosing without the pain associated with IM injection. The most common approach in pediatric centers is to administer a low-dose basal opioid infusion while permitting patients to use a **patient-controlled analgesia (PCA)** device to titrate the dosage above the infusion (Fig. 93.3) (see Chapter 91). Compared with children given intermittent IM morphine, children using PCA reported better pain scores. PCA has several other advantages: (1) dosing can be adjusted to account for individual pharmacokinetic and pharmacodynamic variation and for changing pain intensity during the day; (2) psychologically the patient is more in control, actively coping with the pain; (3) overall opioid consumption tends to be lower; (4) fewer opioid side effects occur; and (5) patient satisfaction is generally much higher. Children as young as 5-6 years old can effectively use PCA. The device can also

be activated by parents or nurses, known as **PCA-by-proxy (PCA-P) or parent-nurse controlled analgesia (PNCA)**, which produces analgesia in a safe, effective manner for children who cannot activate the PCA demand button themselves because they are too young or intellectually or physically impaired. PCA overdoses have occurred when well-meaning, inadequately instructed parents pushed the PCA button in medically complicated situations, with or without the use of PCA-P, highlighting the need for patient and family education, use of protocols, physiologic monitoring, and adequate nursing supervision.

Because of the high risk of adverse side effects (respiratory depression), the FDA has issued **contraindications** for the pediatric use of codeine and tramadol (Table 93.13).

Table 93.9 Equianalgesic Doses and Half-Life ($T_{1/2\beta}$) of Some Commonly Used Opioids

OPIOID	IM/IV DOSE (mg)	ORAL DOSE (mg)	$T_{1/2\beta}$ (hr)
Morphine	10	30	2-3
Oxycodone	15	20-30	2-3
Fentanyl	0.15-0.2	—	3-5
Alfentanil	0.75-1.5	—	1-2
Sufentanil	0.02	—	2-3
Methadone	10	10-15	15-40
Hydromorphone	1.5	7.5	3-4
Tramadol†	100	100	5-7
Buprenorphine	0.4	0.8 (sublingual)	3-5
Pentazocine	60	150	3-5
Nalbuphine	10-20	—	2-4
Butorphanol	2	—	2-3

†Only part of its analgesic action results from action on μ-opioid receptors.
NOTES:
- Published reports vary in the suggested doses considered to be equianalgesic to morphine. Therefore titration to clinical response in each patient is necessary.
- Suggested doses are the results of single-dose studies only. Therefore use of the data to calculate total daily dose requirements and repeated or continuous doses may not be appropriate.
- There may be incomplete cross-tolerance between these drugs. In patients who have been receiving one opioid for a prolonged period, it is usually necessary to use a dose lower than the expected equianalgesic dose when changing to another opioid and to titrate to effect.

Modified from Macintyre PE, Ready LB. *Acute Pain Management: A Practical Guide*, 2nd ed. Philadelphia: Saunders; 2001, p 19.

Local Anesthetics

Local anesthetics are widely used in children for topical application, cutaneous infiltration, peripheral nerve block, neuraxial blocks (intrathecal or epidural infusions), and IV infusions (see Chapter 91). Local anesthetics can be used with excellent safety and effectiveness. Local anesthetics interfere with neural transmission by blocking neuronal sodium channels. Excessive systemic dosing can cause seizures, CNS depression, and (by cardiac and arteriolar sodium channel blockade) hypotension, arrhythmias, cardiac depression, and cardiovascular collapse. Local anesthetics therefore require a strict maximum dosing schedule. Pediatricians should be aware of the need to calculate these doses and adhere to guidelines.

Topical local anesthetic preparations do not generally result in measurable systemic blood levels and can reduce pain in diverse circumstances: suturing of lacerations, placement of peripheral IV catheters, lumbar punctures, and accessing indwelling central venous ports (Table 93.14). The application of tetracaine, epinephrine (adrenaline), and cocaine (TAC) results in good anesthesia for suturing wounds but should not be used on mucous membranes or the hypervascular faces of young children. An alternative combination of lidocaine, epinephrine, and tetracaine (LET) is preferred to avoid the psychomimetic properties of cocaine. EMLA, a topical eutectic mixture of lidocaine and prilocaine used to anesthetize intact skin, is frequently applied for venipuncture, lumbar puncture, and other needle procedures. A 5% liposomal lidocaine cream (LMX4) is also effective as a topical anesthetic. Another unique device is the needle-free J-tip, which uses a CO_2 cartridge to deliver lidocaine into the subcutaneous tissue via a micro-atomizing tip. This can be used to

Table 93.10 Opioid Use Guidelines in Hepatic and Renal Dysfunction

DRUG	PKA	PROTEIN BINDING (%)	PHASE 1 METABOLISM	PHASE 2 METABOLISM	ACTIVE METABOLITE	BILIARY EXCRETION[1] (%)	RENAL EXCRETION[2]	USE IN RENAL FAILURE
Morphine	8.0	30	None	Glucuronidation	M6G	10	Metabolites	Use with caution[a,c]
Fentanyl	8.4	80	CYP3A4	None	None		Norfentanyl	Preferred[b,e]
Hydromorphone	8.2	20	None	Glucuronidation	H6G		H3G & H6G	Use with caution[a,d]
Methadone	8.3	90	CYP2B6 CYP3A4, CYP2D6	None	None	20-40	Metabolites	Use with caution[b,e]
Codeine	8.2	25	CYP2D6	None	Morphine, Hydrocodone M6G		M6G	No[b,d]
Oxycodone	8.5	45	CYP3A4, CYP2D6	None	Oxymorphone		Noroxycodone	Use with caution[f]
Oxymorphone	8.2	10	CYP3A4	Glucuronidation	None		Noroxymorphone	Use with caution[a,c]
Remifentanil	7.1	70	Esterase	None	None		Metabolite	

[1]In the setting of hepatic dysfunction, all opioids should be used cautiously ("go low, go slow"). Meperidine (inactive metabolite associated with seizures) and codeine (cannot be metabolized into active metabolite, morphine) should not be used. Fentanyl may be the best opioid to use (in severe liver dysfunction, plasma cholinesterase may not be available to metabolize remifentanil).
[2]In the setting of renal failure, metabolites of morphine, codeine, hydromorphone, hydrocodone, and meperidine can accumulate, producing increased therapeutic and adverse effects.

From Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*, 10th ed. Philadelphia: Elsevier; 2022, Table 23.6, p. 496.

Table 93.11 Practical Aspects of Prescribing Opioids

- Morphine, hydromorphone, or fentanyl is regarded as first choice for severe pain.
- Dosing should be titrated and individualized. There is no "right" dose for everyone.
- The right dose is the dose that relieves pain with a good margin of safety.
- Dosing should be more cautious in infants, in patients with coexisting diseases that increase risk or impair drug clearance, and with concomitant administration of sedatives.
- Hydromorphone is metabolized by CYP2D6 and fentanyl by CYP3A4 and to some extent 2D6; drugs that compete for 2D6 enzyme will raise blood levels and increase risk of respiratory depression.
- Morphine is metabolized by glucuronidation to an active metabolite, morphine-6-glucuronide, which accumulates and causes CNS toxicity in renal impairment.
- Anticipate and treat peripheral side effects, including constipation, nausea, and itching.
- Give doses at sufficient frequency to prevent the return of severe pain before the next dose.
- Use a drug delivery method, such as patient-controlled anesthesia or continuous infusions, that avoids the need for "prn" decision-making.
- With opioid dosing for >1 wk, taper gradually to avoid abstinence syndrome.
- When converting between parenteral and oral opioid doses, use appropriate potency ratios (see Table 93.9).
- *Tolerance* refers to decreasing drug effect with continued administration of a drug. Over time a patient will need higher dosing to achieve the same clinical effect; however, tolerance to sedation and respiratory depression develop more rapidly than tolerance to analgesia. Thus with higher doses, patients do not experience oversedation or respiratory depression.
- *Dependence* refers to the need for continued drug dosing to prevent abstinence syndrome when a drug is abruptly discontinued or its dose reduced. Abstinence syndrome is characterized by irritability, agitation, autonomic arousal, nasal congestion, piloerection, diarrhea, jitteriness, and yawning; it is produced by administration of potent opioids for >5-7 days.
- *Addiction*, a psychiatric pathology, refers to psychologic craving, compulsive drug-seeking behavior, and drug use despite medical harm. Addiction has strong genetic and environmental determinants. Opioid therapy will not lead to addiction in nonsusceptible individuals, and opioid underdosing does not prevent addiction; it may in fact increase drug-seeking behavior for relief of pain (e.g., watching the clock), referred to as "pseudoaddiction."

start IVs or provide superficial analgesia before a procedure (e.g., lumbar puncture).

Lidocaine is the most commonly used local anesthetic for cutaneous infiltration. Maximum safe doses of lidocaine are 5 mg/kg without epinephrine and 7 mg/kg with epinephrine. Although concentrated solutions (2%) are commonly available from hospital pharmacies, more dilute solutions (0.25% and 0.5%) are equally as effective as 1–2% solutions. The diluted solutions cause less burning discomfort on injection and permit use of larger volumes without achieving toxic doses. In the surgical setting, cutaneous infiltration is more often performed with bupivacaine 0.25% or ropivacaine 0.2% because of the much longer duration of effect; maximum dosage of these long-acting amide anesthetics is 2-3 mg/kg and 3-4 mg/kg, respectively. Liposomal bupivacaine injectable suspension (Exparel) is approved for children age 6 years old and above. It is an excellent choice for surgical wound infiltration. The maximum dose for children is 4 mg/kg.

Neuropathic pain may respond well to the local application of a 5% lidocaine topical patch (Lidoderm) for 12 hours/day (see Table 93.14), although access to lidocaine topical patches may be limited by insurance coverage. Over-the-counter 4% lidocaine patches are available without prescription. Peripheral and central neuropathic pain also may respond to IV lidocaine infusions, which may be used in hospital settings for refractory pain, complex regional pain syndromes, and pain associated with malignancies or the therapy of malignancies, such as oral mucositis after bone marrow transplantation. In these patients, 1-2 mg/kg/hr should be administered and the infusion titrated to achieve a blood lidocaine level in the 2-5 μg/mL range, with use of twice-daily therapeutic blood monitoring.

UNCONVENTIONAL MEDICATIONS IN PEDIATRIC PAIN

Unconventional analgesic medication refers to a wide number of drugs developed for other indications but found to have analgesic properties. These drugs have been used for acute and chronic pain and include antidepressants, antiepileptic drugs, and neurotropic drugs (Tables 93.15 and 93.16).

The unconventional analgesics are generally used to manage neuropathic pain conditions, migraine disorders, fibromyalgia syndrome, and some forms of functional chronic abdominal pain syndromes. These agents also are used as components of multimodal analgesia in the management of surgical, somatic, and musculoskeletal pain. Figure 93.4 presents a decision-making tree to help the physician select the appropriate analgesic category for various types of pain.

Although several unconventional pain medications are FDA approved for analgesic use, most are not approved for use in youth with acute or chronic pain. Thus these drugs should be used with caution, with a focus on mitigating pain to allow a child to participate effectively in therapies and return to normal activity as soon as possible. The use of psychotropic medications should be guided by the principles applied to pharmacologic treatment of any symptom or disease. Target symptoms should be identified and medication side effects monitored. To determine dosing regimens, the physician should consider the child's weight and the effects that the medical condition and other medications, such as psychotropic drugs, may have on the child's metabolism. Therapeutic blood level monitoring can be considered. Side effects should be addressed in detail with both parent and child and specific instructions given for responding to possible adverse events. Directly addressing concerns about addiction, dependence, and tolerance may be necessary to decrease treatment-related anxiety and improve medication adherence.

Antidepressant Medications

Antidepressants are useful in adults with chronic pain, including neuropathic pain, headaches, and rheumatoid arthritis, independent of their effects on depressive disorders. Antidepressants' analgesic mechanism of action is inhibition of norepinephrine reuptake in the CNS. In children, because clinical trials have been limited, the practitioner should use antidepressants cautiously to treat chronic pain or associated depressive or anxiety symptoms. The FDA has issued a "black box warning" to inform the public of a small but significant increase in suicidal thoughts and attempts in children and adolescents receiving antidepressants. A meta-analysis of studies involving children and adolescents receiving antidepressants for pain indicated that no suicides had been completed. The pediatrician should address this issue with parents of patients being treated with antidepressants and should develop monitoring plans consistent with current FDA recommendations (see Table 93.16).

Tricyclic antidepressants (TCAs) have been studied in children with chronic pain and found to be effective in pain relief for symptoms that include neuropathic pain, functional abdominal pain, and migraine. TCA efficacy may be based on inhibition of the neurochemical pathways involved in norepinephrine and serotonin reuptake and interference with other neurochemicals involved in the perception or neural conduction of pain. Because sedation is a common side effect, TCAs may also be effective in treating the sleep disorders that frequently accompany pediatric pain. Biotransformation of TCAs is extensive in healthy children. Typically, TCAs are administered only at bedtime, especially the more sedating tricyclic medications such as amitriptyline. Alternatively, the patient can be started on a bedtime dose of a TCA, which may be able to then be titrated to a daily divided dose, with the larger dose given at bedtime. It should be noted that pain symptoms usually remit at lower doses than those recommended

Table 93.12 CDC Practice Guideline for Prescribing Opioids for Pain (2022) Excluding Sickle Cell Anemia, Cancer, Palliative Care and End of Life Care

DETERMINING WHETHER OR NOT TO INITIATE OPIOIDS FOR PAIN

All patients with pain should receive treatment that provides the greatest benefits relative to risks. (See *Recommendation 1* for determining whether or not to initiate opioids for acute pain [i.e., pain lasting <1 month] and *Recommendation 2* for determining whether or not to initiate opioids for subacute pain [i.e., pain lasting 1–3 months] or chronic pain [i.e., pain lasting >3 months].)

Recommendation 1

Nonopioid therapies are at least as effective as opioids for many common types of acute pain. Clinicians should maximize use of nonpharmacologic and nonopioid pharmacologic therapies as appropriate for the specific condition and patient and only consider opioid therapy for acute pain if benefits are anticipated to outweigh risks to the patient. Before prescribing opioid therapy for acute pain, clinicians should discuss with patients the realistic benefits and known risks of opioid therapy.

Recommendation 2

Nonopioid therapies are preferred for subacute and chronic pain. Clinicians should maximize use of nonpharmacologic and nonopioid pharmacologic therapies as appropriate for the specific condition and patient and only consider initiating opioid therapy if expected benefits for pain and function are anticipated to outweigh risks to the patient. Before starting opioid therapy for subacute or chronic pain, clinicians should discuss with patients the realistic benefits and known risks of opioid therapy, should work with patients to establish treatment goals for pain and function, and should consider how opioid therapy will be discontinued if benefits do not outweigh risks.

SELECTING OPIOIDS AND DETERMINING OPIOIDS DOSAGES

Recommendation 3

When starting opioid therapy for acute, subacute, or chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release and long-acting (ER/LA) opioids.

Recommendation 4

When opioids are initiated for opioid-naïve patients with acute, subacute, or chronic pain, clinicians should prescribe the lowest effective dosage. If opioids are continued for subacute or chronic pain, clinicians should use caution when prescribing opioids at any dosage, should carefully evaluate individual benefits and risks when considering increasing dosage, and should avoid increasing dosage above levels likely to yield diminishing returns in benefits relative to risks to patients.

Recommendation 5

For patients already receiving opioid therapy, clinicians should carefully weigh benefits and risks and exercise care when changing opioid dosage. If benefits outweigh the risks of continued opioid therapy, clinicians should work closely with patients to optimize nonopioid therapies while continuing opioid therapy. If benefits do not outweigh risks of continued opioid therapy, clinicians should optimize other therapies and work closely with patients to gradually taper to lower dosages or, if warranted based on the individual circumstances of the patient, appropriately taper and discontinue opioids. Unless there are indications of a life-threatening issue such as warning signs of impending overdose (e.g., confusion, sedation, or slurred speech), opioid therapy should not be discontinued abruptly, and clinicians should not rapidly reduce opioid dosages from higher dosages.

DECIDING DURATION OF INITIAL OPIOID PRESCRIPTION AND CONDUCTING FOLLOW-UP

Recommendation 6

When opioids are needed for acute pain, clinicians should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids.

Recommendation 7

Clinicians should evaluate benefits and risks with patients within 1–4 weeks of starting opioid therapy for subacute or chronic pain or of dosage escalation. Clinicians should regularly reevaluate benefits and risks of continued opioid therapy with patients.

ASSESSING RISK AND ADDRESSING POTENTIAL HARMS OF OPIOID USE

Recommendation 8

Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk for opioid-related harms and discuss risk with patients. Clinicians should work with patients to incorporate into the management plan strategies to mitigate risk, including offering naloxone.

Recommendation 9

When prescribing initial opioid therapy for acute, subacute, or chronic pain, and periodically during opioid therapy for chronic pain, clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or combinations that put the patient at high risk for overdose.

Recommendation 10

When prescribing opioids for subacute or chronic pain, clinicians should consider the benefits and risks of toxicology testing to assess for prescribed medications as well as other prescribed and nonprescribed controlled substances.

Recommendation 11

Clinicians should use particular caution when prescribing opioid pain medication and benzodiazepines concurrently and consider whether benefits outweigh risks of concurrent prescribing of opioids and other central nervous system depressants.

Recommendation 12

Clinicians should offer or arrange treatment with evidence-based medications to treat patients with opioid use disorder. Detoxification on its own, without medications for opioid use disorder, is not recommended for opioid use disorder because of increased risks for resuming drug use, overdose, and overdose death.

From Dowell D, Ragan KR, Jones CM, et al: CDC clinical practice guidelines for prescribing opioids for pain – United States, 2022. *MMWR* 2022;71(3):1-95.

or required for the treatment of mood disorders. Most children and adolescents do not require more than 0.25-1 mg/kg of amitriptyline or nortriptyline once daily at bedtime.

Attention should also be paid to hepatic microsomal enzyme metabolism, because CYP2D6 inhibitors, such as cimetidine and quinidine, can increase levels of TCAs. Anticholinergic side effects, which are less common in children than in adults, may remit over time. Constipation, orthostatic hypotension, and dental caries from dry mouth should be addressed by emphasizing the importance of hydration, good oral hygiene, and regular dental visits. Other side effects include weight gain, mild bone marrow suppression, and liver dysfunction. Some practitioners recommend monitoring CBC and liver function values at baseline and periodically during therapy. TCA blood levels can be obtained as well, but the need for therapeutic blood monitoring should be assessed on an individual basis. Reasons for blood level monitoring include concerns for altered metabolism, adherence, overdose, or sudden change in mental status.

All TCAs inhibit cardiac conduction pathways and prolong the QT interval. Sudden cardiac death has been reported in children taking TCAs, principally desipramine, probably related to QTc prolongation. There is no general agreement for monitoring the electrophysiologic effects of these drugs, but it is prudent to obtain a careful personal and family history focusing on cardiac arrhythmias, heart disease, and syncope before the initiation of treatment. A baseline electrocardiogram (ECG) should be obtained, with care taken to ensure that

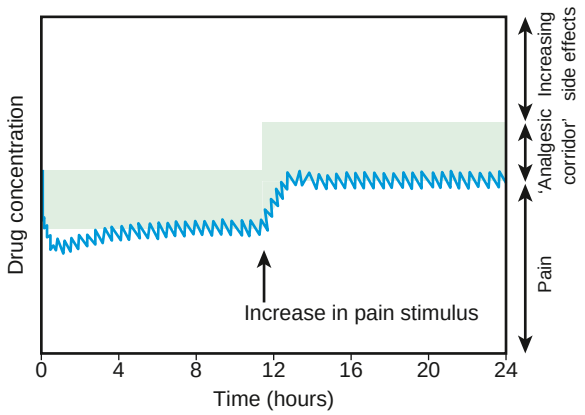

Fig. 93.3 Patient-controlled analgesia is more likely to keep blood concentrations of opioid within the "analgesic corridor" and allows rapid titration if there is an increase in pain stimulus requiring higher blood levels of opioid to maintain the analgesia. *(From Burg FD, Ingelfinger JR, Polin RA, et al., eds. Current Pediatric Therapy,18th ed. Philadelphia: Saunders; 2006:16.)*

Table 93.13 Summary of FDA Recommendations

- Use of codeine to treat pain or cough in children <12 yr old is contraindicated.
- Use of tramadol to treat pain in children <12 yr old is contraindicated.
- Use of tramadol for treatment of pain after tonsillectomy or adenoidectomy in patients <18 yr old is contraindicated. (Codeine was already contraindicated in such patients.)
- Use of codeine or tramadol in children 12-18 yr old who are obese or who have an increased risk of serious breathing problems, such as those with obstructive sleep apnea or severe lung disease, is not recommended.
- Use of codeine or tramadol in breastfeeding women should be avoided.

From FDA warns against use of codeine and tramadol in children and breastfeeding women. *Med Lett.* 2017;59(1521):86–88.

the QTc is <450 msec. If the dose of amitriptyline or nortriptyline is increased beyond 0.5 mg/kg/day, an ECG should be performed for each dosing increase. With TCAs, as with other antidepressants, physical dependence and a known discontinuation syndrome can occur. The **discontinuation syndrome** includes agitation, sleep disturbances, appetite changes, and GI symptoms. These medications should be tapered slowly to assist in distinguishing among symptoms that indicate rebound, withdrawal, or the need for continuing the medication.

Selective serotonin reuptake inhibitors (SSRIs) have minimal efficacy in the treatment of a variety of pain syndromes in adults. SSRIs are very useful when symptoms of depression or anxiety are present and cannot be addressed adequately by nonpharmacologic means. Escitalopram (Lexapro), fluoxetine (Prozac), and sertraline (Zoloft) have been approved by the FDA for use in children and adolescents. SSRIs have a significantly milder side effect profile than TCAs (most side effects are transient), and they have no anticholinergic side effects. Chief side effects include GI symptoms, headaches, agitation, insomnia, sexual dysfunction, and anxiety. Rarely, hyponatremia, or the syndrome of inappropriate antidiuretic hormone secretion (SIADH), may occur. Interactions with other medications that have serotonergic effects may also occur. When multiple medications with serotonergic activity are used in combination, there may be increased likelihood that a life-threatening **serotonin syndrome** may occur, with associated symptoms of myoclonus, hyperreflexia, autonomic instability, muscle rigidity, and delirium (see Chapter 94). It is important to note that although triptans have serotonergic effects, it is unlikely that the combination will lead to serotonin syndrome. This is because it is hypothesized that serotonin receptors 2A and 1A are the receptors involved in serotonin syndrome, whereas triptans are selective for serotonin antagonists 1B and 1D. There is also a **discontinuation syndrome** associated with shorter-acting SSRIs (e.g., paroxetine), which includes dizziness, lethargy, paresthesias, irritability, and vivid dreams. To avoid this, dosages of medications should be tapered slowly over several weeks.

The **selective serotonin-norepinephrine reuptake inhibitors (SNRIs)** duloxetine and venlafaxine have demonstrated significant efficacy with chronic neuropathic and other pain syndromes because they inhibit both serotonin and norepinephrine reuptake, and they may directly block associated pain receptors as well. Venlafaxine has no pain indication labeling. Duloxetine is FDA approved for managing neuropathic pain (specifically, diabetic neuropathy) and fibromyalgia

Table 93.14 Topical Pharmacologic Management of Acute Pain in Children

DRUG	DOSE	NOTES
INTACT SKIN		
Lidocaine 2.5% and prilocaine 2.5% (EMLA cream)	<3 mo old or <5 kg: 1 g 3-12 mo and >5 kg: 2 g 1-6 yr and >10 kg: 10 g 7-12 yr and >20 kg: 20 g	60 min is needed to achieve maximum effect; cover cream with an occlusive dressing (Tegaderm)
Lidocaine, liposomal 5% (LMX4)	1-20 g as noted earlier	30-60 min needed to achieve maximum effect; cover with an occlusive dressing (Tegaderm)
Lidocaine 70 mg and tetracaine 70 mg (Synera patch)	Age ≥3 yr: apply patch	20-30 min needed to achieve maximum effect
Tetracaine 4% (Ametop)	>1 mo and <5 yr: apply 1 tube of gel (1 g) >5 yr: apply up to 5 tubes of gel (5 g)	30 min before venipuncture 45 min before intravenous cannulation
WOUNDS		
Lidocaine, epinephrine, tetracaine (LET) solution or gel*	Age ≥1 yr: apply to wound	20 min needed for maximum effect

*Also referred to as ALA on the basis of alternative names for the constituents: adrenaline, lignocaine, amethocaine. These mixtures are locally made by hospital formularies, with a common formula being lidocaine 4% plus epinephrine 0.1% plus tetracaine 0.5%. The cocaine-based formulation was historically avoided on wounds of digits, ears, penis, nose, mucous membranes, close to the eye, or deep wounds involving bone, cartilage, tendon, or vessels. The lidocaine-based formulation can be used in such settings.

Table 93.15 Commonly Used Adjunctive Analgesics

DRUG NAME (TRADE NAME)	SUGGESTED STARTING DOSE AND DOSING INTERVAL MAXIMUM DOSE PER DAY	ADVANTAGES (INDICATION FOR USE)	DISADVANTAGES (SIDE EFFECTS)
Gabapentin (Neurontin)	10-15 mg/kg per day divided bid or tid Max dose: 50 mg/kg per day (3 g/day)	Adjunct for the management of pediatric neuropathic pain, epilepsy	Drug reaction with eosinophilia and systemic symptoms (DRESS), anaphylaxis, somnolence, dizziness, peripheral edema, emotional lability, respiratory depression when combined with opioids
Pregabalin (Lyrica)	2.5 mg/kg per day divided bid or tid Max dose: 600 mg per day	Adjunct for the management of neuropathic pain associated with spinal cord injury, fibromyalgia, and epilepsy	Ataxia, blurred vision, visual field loss, constipation, drowsiness, headaches, peripheral edema, weight gain, tremor
Clonidine (Catapres)	5-25 mcg/kg per day divided every 4-8 hours if PO dosing Max dose: 2.4 mg/day	Used to treat hypertension and mitigate drug withdrawal symptoms; also used as a pain or peripheral nerve block additive	Drowsiness, dizziness, fatigue, headache, dry mouth, hypotension
Dexmedetomidine (Precedex)	Loading dose: 0.5-1 mcg/kg Infusion rate: 0.2-0.7 mcg/kg per hour titrated to effect Suggested max dose: 2.5 mcg/kg per hour	Sedative and analgesic properties; intraoperative bolus dose of 1 mcg/kg decreases postoperative morphine consumption and 2 mg/kg decreases emergence delirium	Bradycardia, hypotension
Tizanidine (Zanaflex)	Patients >18 yr: starting dose 2 mg q6-8h Max single dose: 16 mg Max daily dose: 36 mg	Antispasmodic agent	Dizziness, drowsiness, bradycardia, hypotension, fatigue, hallucinations, xerostomia
Diazepam (Valium)	PO: 0.1-0.8 mg/kg/day IV: 0.05-0.3 mg/kg/dose every 4-8 hr Max dose: 10 mg Use lowest needed dose; use lower dose when combined with opioids or other sedating medications	Antispasmodic, anxiolytic, sedative, seizure prophylaxis, promotes sleep	Somnolence, unsteady gait
Cyclobenzaprine (Flexeril)	Patients >15 yr: 5 mg PO bid-tid Max dose: 10 mg PO tid	Antispasmodic	Blurry vision, dizziness, drowsiness, lightheadedness, xerostomia
Ketamine	Loading dose: 0.25-0.5 mg/kg IV before incision Infusion rate: 0.1-1 mg/kg per hr intraoperatively 0.05-0.1 mg/kg per hr postoperatively Max parenteral dose 3,600 mg/day	Sedation, analgesic adjunct, especially beneficial for opioid-tolerant or chronic pain patients	Hallucinations, double/blurry vision, jerky muscle movements, drowsiness, loss of appetite, nausea
Lidocaine	Loading dose: 1-1.5 mg/kg IV Infusion rate: 1-2 mg/kg per hr intraoperatively Max dose: 4.5 mg/kg (not to exceed 300 mg in 2 hr)	Used during intraabdominal procedures to prevent severe postoperative pain	Cardiac arrhythmia, epilepsy/seizures, renal failure

Modified from Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children,* 10th ed. Philadelphia: Elsevier; 2022, Table 23.12, p. 510.

syndrome. It is approved for the treatment of pediatric fibromyalgia in adolescents 13-17 years of age and for the treatment of generalized anxiety disorder in children 7-17. A significant advantage of SNRIs over TCAs when used for headache prophylaxis or neuropathic pain is that they have therapeutic effects on mood and anxiety at dosages effective for pain control.

Because both SSRIs and SNRIs have fewer anticholinergic side effects than TCAs, adherence to them is better than in psychiatric populations taking TCAs. Side effects of both types of drugs include GI symptoms, hyperhidrosis, dizziness, and agitation, but these effects generally wane over time. Hypertension and orthostatic hypotension may occur; in addition, the patient's blood pressure should be closely followed, and appropriate hydration should be stressed. Note that whereas appetite stimulation and weight gain are associated with all TCAs, duloxetine is often associated with weight loss, frequently a desirable side effect, especially in overweight adolescents.

All antidepressants, including the TCAs, SSRIs, and SNRIs, are thought to have the potential to increase the risk of suicidal ideation and the risk of suicide in patients, as noted earlier. The FDA states, "All pediatric patients being treated with antidepressants for any indication should be observed closely for clinical worsening, suicidality, and unusual changes in behavior, especially during the initial few months of a course of drug therapy, or at times of dose changes, either increases or decreases." However, the FDA also notes, "Although there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients, a causal role for antidepressants in inducing such behaviors has not been established. Nevertheless, patients being treated with antidepressants should be observed closely for clinical worsening and suicidality, especially at the beginning of a course of drug therapy, or at the time of dose changes, either increases or decreases."

Table 93.16 Medications for Pediatric Chronic Pain

MEDICATION	DOSING	COMMENTS
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline, nortriptyline	For patients ≥50 kg: Initial dose 5-10 mg PO qhs; titrate over 2-3 weeks to 25-50 mg PO qhs For patients 25-50 kg: Initial dose 0.1 mg/kg PO qhs. Titrate over 2-3 weeks to max dose of 0.5 mg/kg	Obtain 12-lead ECG for prolonged QT interval Side effects are related to anticholinergic effects, including tachycardia, dry mouth, urinary retention, and sedation Use with caution with other antidepressants because of risk of serotonin syndrome Concomitant use with CYP2D6 inhibitors may lead to increased serum concentration
SELECTIVE SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS		
Duloxetine (Cymbalta)	For patients > 13 yr: Dose 30-60 mg PO daily; max 600 mg/day	Review risk of suicidality
ANTICONVULSANTS		
Gabapentin (Neurontin)	For patients ≥50 kg: Initial dose 100-300 mg PO 1-2 times daily; titrate slowly to max dose of 1,800 mg/day divided tid; higher dosing possible in select patients For patients <50 kg: Initial dose 2-5 mg/kg PO daily; titrate slowly to max dose of 35 mg/day divided tid; higher dosing possible in select patients	Side effects include drowsiness, concentration and memory impairments, and peripheral edema (rare) Dose adjustment necessary with renal impairment
Pregabalin (Lyrica)	Patients >12 yr of age: Initial dose 25-75 mg PO 1-2 times daily; titrate up to max of 300 mg/day divided bid or tid	Side effects include drowsiness, headaches, peripheral edema (rare), and thrombocytopenia (rare)
Titrate all medications according to clinical benefit and side effects; use lowest effective dose. Antidepressants and anticonvulsants may increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Monitor closely for changes in mood or behavior.

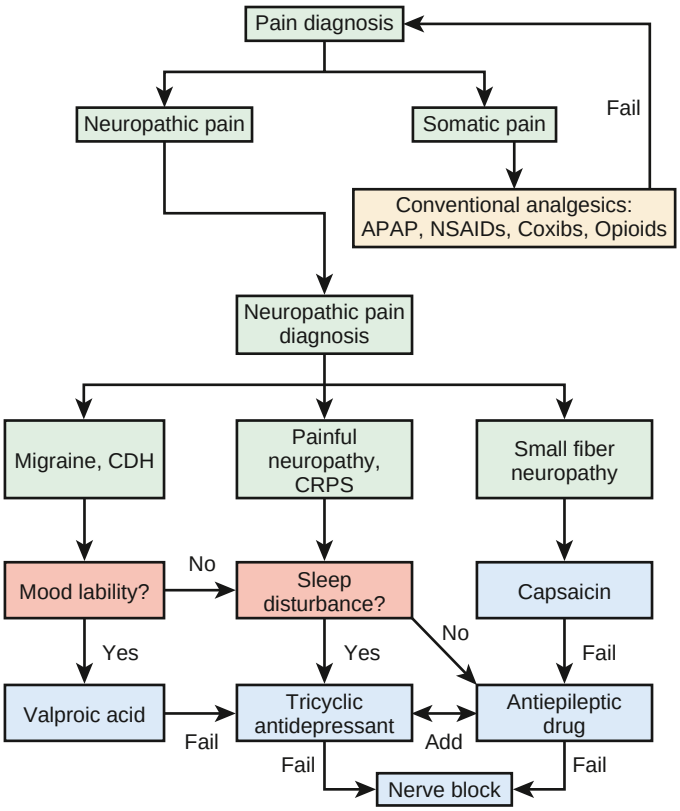

Fig. 93.4 Algorithm for selection of conventional and nonconventional analgesics. APAP, Acetaminophen; CDH, chronic daily headaches; CRPS, complex regional pain syndrome; NSAIDs, nonsteroidal antiinflammatory drugs.

Antiepileptic Drugs

Antiepileptic drugs (AEDs), such as gabapentin, pregabalin, carbamazepine, and valproic acid, are believed to relieve chronic pain by blocking sodium (valproate and the gabapentinoids) or calcium (carbamazepine and oxcarbazepine) channels at the cellular neuronal level, thereby suppressing spontaneous electrical activity and restoring the normal threshold to depolarization of hypersensitive nociceptive neurons, without affecting normal nerve conduction. These medications are particularly useful in patients with mood disorders who have neuropathic pain. In adults, the FDA has approved carbamazepine for trigeminal neuralgia; valproate for migraine prophylaxis; and pregabalin for neuropathic pain complicating diabetes, herpes zoster, and for management of fibromyalgia. AEDs generally have GI side effects in addition to sedation, anemia, ataxia, rash, and hepatotoxicity. The majority are also associated with weight gain. Carbamazepine and oxcarbazepine are also associated with Stevens-Johnson syndrome.

Liver function and CBC should be monitored at the start of therapy and periodically with AEDs. Carbamazepine and valproic acid have narrow therapeutic windows and variability in therapeutic blood medication levels, in addition to many drug-drug interactions, and may cause liver disease and renal impairment. Drug levels should be measured with each dose increase and periodically thereafter. Carbamazepine, in particular, causes autoinduction of hepatic microsomal enzymes, which can further complicate obtaining a therapeutic medication level. Female patients should have pregnancy testing before taking valproate, and those who are sexually active must be cautioned to use effective contraception, because neural tube defects are associated with carbamazepine.

Less toxic AEDs (gabapentin and pregabalin) have supplanted the use of valproate and carbamazepine in patients with pain. These agents have their own side effect profiles, but they are much less toxic than their predecessors and do not require monitoring of liver or bone marrow function or blood levels. Furthermore, they are also far less lethal in accidental or deliberate overdose.

Gabapentin is approved for treatment of postherpetic neuralgia and is also widely prescribed for other pain disorders. It has demonstrated some efficacy in treating children with chronic pain, particularly neuropathic pain, and is used in treatment of chronic headache disorders, complex regional pain syndromes, chemotherapy-induced neuropathy, and diabetic neuropathy in both children and adults. Gabapentin has a relatively benign side effect profile and no drug interactions. Side effects include somnolence, dizziness, and ataxia; children occasionally demonstrate side effects not reported in adults, such as impulsive

or oppositional behavior, agitation, and occasionally depression. These side effects do not seem to be dose related.

Pregabalin works by similar mechanisms as gabapentin and may have a lower side effect profile. It is most often dosed twice a day rather than three times a day, which may lead to increased adherence. Both gabapentin and pregabalin undergo virtually no hepatic metabolism, with no significant drug-drug interactions, a common concern in patients with chronic pain, who frequently take multiple medications—for both the pain and the underlying medical condition associated with the pain. However, because both AEDs depend on renal function for clearance, doses must be adjusted in the presence of renal dysfunction.

Topiramate also demonstrates greater success than traditional AEDs in treating trigeminal neuralgia in adults and in migraine prophylaxis. Topiramate is approved for migraine prophylaxis in children and adolescents from the age of 12-17. Topiramate therapy results more frequently in cognitive dysfunction and short-term memory loss than gabapentin or pregabalin, and although these neurocognitive effects are often well tolerated, they should be monitored. The pediatrician should also be aware that topiramate is associated with weight loss, whereas other AEDs are typically associated with significant weight gain. This side effect is particularly valuable in weight-conscious adolescents, whereas in the anorexic cancer patient, a TCA would be preferable to induce appetite and weight gain. In at-risk populations, routine weight checks are recommended.

Benzodiazepines

Children and adolescents with chronic pain may have comorbid psychologic conditions, such as depressed mood, sleep disturbances, and anxiety disorders, including generalized anxiety disorder, separation anxiety, posttraumatic stress disorder (PTSD), and panic attacks. Psychologic factors affect a youth's perception of pain and mechanisms of coping with a pain disorder. A *conditioned response* to pain may be to feel out of control and increase anxiety and pain, and conversely, *anticipatory anxiety* related to pain will inhibit activities and recovery. Feelings of helplessness sensitize the child to increasing amounts of pain, leading the child to perseverate on pain, think catastrophically, and feel hopeless. Changes in children's normal routines, with a negative impact on participation in valued activities, may further promote hopelessness, resulting in increased pain experiences and development of a depressive disorder.

Benzodiazepines are anxiolytic medications that also have muscle relaxant effects. They have a role in the treatment of acute pain in the hospital, where they are useful adjuncts because they inhibit painful muscle spasms in postsurgical patients. They also can suppress the anxiety that often occurs in hospitalized children, anxiety that interferes with restorative sleep and amplifies the child's perception of pain. Benzodiazepines are useful to calm children with anxiety and anticipatory anxiety about planned painful procedures. They are frequently used as a part of procedural sedation or preoperatively before surgical procedures.

Because dependence, tolerance, and withdrawal may occur with prolonged use, benzodiazepines are generally not recommended for the routine management of *chronic pain* or anxiety in children. Further, the risk of respiratory depression when benzodiazepines are combined with opioid therapy has contributed to the increasing number of opioid-related deaths in the United States. In concert with psychotherapy, benzodiazepines may help control anxiety symptoms that amplify the perception of pain, but we recommend the appropriate use of benzodiazepines in the chronic setting occur under the direction of a psychiatrist. In addition, other alternatives such as hydroxyzine may provide similar benefit without the negative aspects encountered with chronic benzodiazepine use.

Infrequently, benzodiazepines may cause behavioral disinhibition, psychosis-like behaviors, or, in large doses, respiratory depression. When dosing these medications, the pediatrician should consider that many benzodiazepines are metabolized by the cytochrome P450 microsomal enzyme system. This issue may be less significant with lorazepam and oxazepam, which undergo first-pass hepatic conjugation. Side effects common to benzodiazepines include sedation, ataxia, anemia, increased bronchial secretions, and depressed mood. If a benzodiazepine is administered for more than 5 consecutive days, the dosage should be slowly tapered. Abrupt discontinuation of therapy can lead to autonomic instability, delirium, agitation, seizures, and profound insomnia. The routine use of benzodiazepines to treat anxiety during hospitalization is not recommended and should only be used under expert guidance.

Antipsychotics and Major Sedatives

Low doses of antipsychotic medications are often used to address the more severe anxiety, agitation, and behavioral decompensation sometimes associated with severe pain. The use of these medications is controversial because associated adverse events may be severe and irreversible. Typical antipsychotics used in the past, including thioridazine (Mellaril), haloperidol (Haldol), and chlorpromazine (Thorazine), are associated with a decreased seizure threshold, dystonia, agranulocytosis, weight gain, cardiac conduction disturbances, tardive dyskinesia, orthostatic hypotension, hepatic dysfunction, and life-threatening laryngeal dystonia and have little role in the routine treatment of pain in children. Chlorpromazine is approved in adults for intractable hiccups, and its use may be appropriate in select settings such as the palliative setting, although this is not considered a first-line medication. Side effects are generally less severe with atypical antipsychotics. Because these effects may still occur, however, the pediatrician should obtain a baseline ECG, liver function values, and CBC and, if possible, obtain a child psychiatry consultation. If the pediatrician is using typical antipsychotics, an inventory of movement disturbances, such as the Abnormal Involuntary Movement Scale (AIMS) test, should be performed at baseline and at every follow-up visit, because movement disorders can worsen with abrupt withdrawal of medications or can become irreversible.

Atypical antipsychotics are generally associated with less severe side effect profiles, particularly dyskinesias and dystonias. Use of olanzapine (Zyprexa), which is particularly helpful with insomnia and severe anxiety, requires assessing and monitoring blood levels of glucose, cholesterol, and triglyceride; olanzapine's side effects may include diabetes, hypercholesterolemia, or significant weight gain. The anticholinergic side effects associated with quetiapine (Seroquel) warrant frequent monitoring of blood pressure. Risperidone at doses >6 mg may cause side effects similar to those of typical antipsychotics. Aripiprazole (Abilify) has been used for severe anxiety and/or for treatment-resistant depression. All antipsychotics are associated with the rare but potentially lethal **neuroleptic malignant syndrome**, which includes severe autonomic instability, muscular rigidity, hyperthermia, catatonia, and altered mental status (see Chapter 33).

Other Pain Control Medications

Alpha-adrenergic receptor agonists such as clonidine are typically used as antihypertensive agents. However, they are often helpful as both anxiolytics and sleep-onset agents in the anxious hospitalized child. The α-agonists also have central effects on pain reduction. **Clonidine** can be given orally or transdermally if the child's blood pressure permits. In certain settings, IV **dexmedetomidine**, an α-agonist sedating agent, can be used preoperatively for anxiety, in the intensive care unit (ICU) for sedation, and may be used for pain in certain circumstances. Weaning off dexmedetomidine can often be accomplished with a transition to clonidine. **Propranolol** and metoprolol are both β-blocking agents typically used for the child with autonomic instability and for thalamic storm. They may also be used in migraine prophylaxis. There are reports that β blockers can enhance depression in a child who already has a major depressive disorder, and discussion with a child psychiatrist may be helpful in decisions about using propranolol if needed. Both clonidine and propranolol have been found useful for the agitated child with ASD. Another α-agonist, **guanfacine**, is more likely to be used during the day for the child with ASD because it is less sedating than clonidine. Despite research on the impact of clonidine on chronic pain, no data are available to determine if guanfacine is as effective in reducing pain. **Ketamine**, a blocker of *N*-methyl-D-aspartate (NMDA) receptors, has been used for intractable pain in hospitalized children

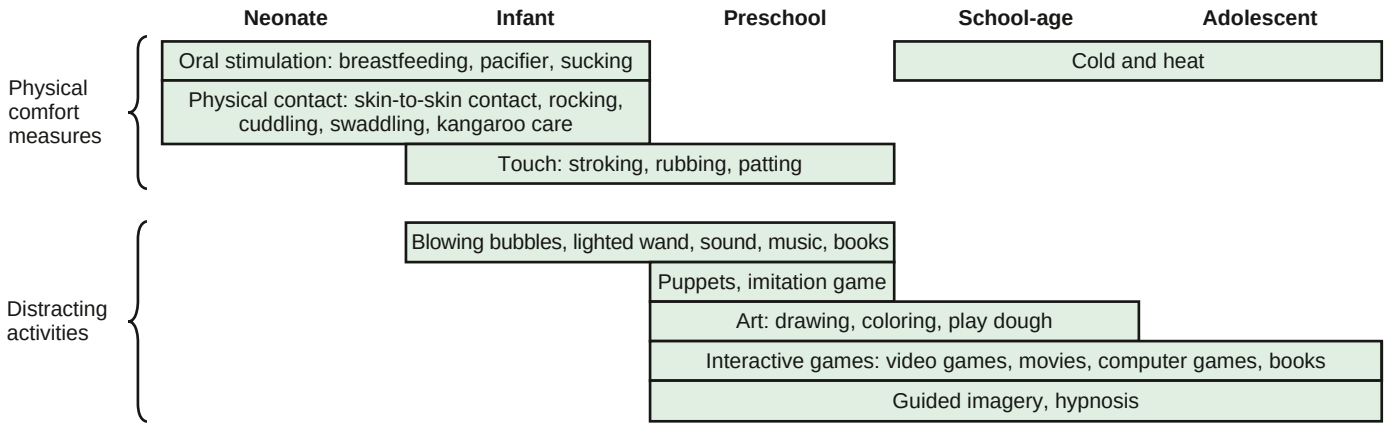

Fig. 93.5 Nonpharmacologic interventions for pediatric pain. *(From Krauss BS, Calligaris L, Green SM, Barbi E. Current concepts in management of pain in children in the emergency department. Lancet. 2016;387:83–92.)*

and in outpatients with severe sickle cell disease–related chronic pain, as well as others in palliative care for whom opioids are not sufficient to reduce pain. Recommended doses for pain management in non-ICU settings are between 0.1 and 0.3 mg/kg/hr. Higher doses may result in increased side effects, sedation with little benefit, and possible ICU admission. Because ketamine can have central hallucinatory effects, such children should be monitored closely.

NONPHARMACOLOGIC TREATMENT OF PAIN

Numerous psychologic and physical treatments for relieving pain, fear, and anxiety as well as enhancing functioning have excellent safety profiles and proven effectiveness and should always be considered for incorporation into pediatric pain treatment (Fig. 93.5). In acute and procedural pain, nonpharmacologic strategies have long been used to help reduce distress in children undergoing medical procedures and surgery. Many of these methods aim to help children shift attention from pain and alter pain perception (e.g., distraction, hypnosis, imagery). Similarly, in the treatment of chronic pain, several strategies, often falling under the umbrella category of **cognitive-behavioral therapies (CBTs)**, have been shown to reduce pain and improve functioning and quality of life. CBT was developed with the goal of modifying social/environmental and behavioral factors that may exacerbate the child's experience of pain and pain-related disability. Meta-analyses of randomized controlled trials (RCTs) of CBT interventions have found large positive effects of psychologic intervention on reductions in pain and/or its deleterious effects in children with headache, abdominal pain, and fibromyalgia, with relative or comparative effectiveness of different interventions examined in areas such as headache and abdominal pain in children. **Biofeedback** and **relaxation therapies** have been found to have superior effects to pharmacologic treatments in reducing headache pain in children and adolescents. Similarly, for recurrent abdominal pain, positive effects for CBT were found relative to attention-control conditions and pharmaceutical, botanical, and dietary interventions (which had very weak evidence). Positive results have even resulted from very brief (three sessions) and remotely delivered (telephone or internet) therapies, with outcomes lasting up to 12 months after intervention.

When deciding how to incorporate nonpharmacologic techniques to treat pain, the practitioner should (1) conduct a thorough assessment of individual, social, and environmental factors that may be contributing to the patient's pain and functioning limitations; (2) based on this assessment, decide whether nonpharmacologic techniques alone may be sufficient as a beginning to treatment or if these treatments should be integrated with appropriate analgesics; (3) give children (and family members) developmentally and situationally appropriate information as to the rationale for treatment selection and what to expect, given the child's medical condition, procedures, and treatments; (4) include patients and their families in decision-making to ensure an appropriate treatment choice and to optimize adherence to treatment protocols; and (5) above all, develop a communication plan among the different care providers, typically with the pediatrician as the case manager, so that the messages to the child and parent are consistent and the modes of therapy are organized into an integrative team approach. Finally, it is important to recognize that in addition to pain, other psychologic disorders (e.g., anxiety disorders, major depression) may affect the presenting pain complaint and may need to be identified and addressed as part of, or separate from, the pain management plan. Individual psychotherapy or psychiatric intervention may be warranted to adequately treat a comorbid disorder.

CBT strategies refer to a range of techniques that teach children (and their caregivers) how to manage pain by learning new ways to think about the pain and how to change behaviors associated with it. Strategies focusing on **cognitions** are typically aimed at enhancing parents' and children's confidence and self-efficacy to handle pain and decrease fear of pain. In addition, pain coping skills may shift the child's attentional focus away from pain and painful stimuli.

The goals of those strategies focusing on **behavior change** are to modify (1) contingencies in the child's environment, such as teaching parents how to respond to pain behaviors in ways that encourage wellness, rather than illness behaviors; (2) the ways parents model reactions to pain or discomfort; (3) child and parent coping techniques when psychosocial distress or problems in social relations exist; and (4) the child's behavioral reactions to situations, such as relaxation and exposure to previously avoided activities. Common examples of these strategies are discussed in the next several paragraphs. Whereas comprehensive CBTs are typically conducted by trained mental health specialists over several sessions, some basic CBT strategies can be briefly and easily introduced by practitioners into most medical settings. If more in-depth CBT treatment is needed, a referral to a qualified mental health specialist with CBT skills is warranted.

Parent and family education and/or **psychotherapy**, particularly within cognitive-behavioral family approaches, is one treatment modality through which these goals are accomplished and has been shown to be effective for treating chronic pain. Parents can learn to cope with their own distress and to understand pain mechanisms and appropriate treatment of pain. Key components include teaching parents to alter family patterns that may inadvertently exacerbate pain through developing behavior plans. Parents are taught to create plans for the child to manage the child's own symptoms and increase independent functioning. Often, adult caregivers (e.g., parents, teachers) need only guidance on developing a behavioral incentive plan to help the child return to school, gradually increase attendance, and receive tutoring after a prolonged, pain-related absence. *Suggested sample brief strategy:* Ask caregivers how they react to the child's pain complaints; assess whether they encourage wellness activities or give attention and "rewards" primarily when the child says he or she does not feel well; and suggest that caregivers respond to the child in ways that encourage wellness, both when complaining and not complaining.

Relaxation training is often employed to promote muscle relaxation and reduction of anxiety, which often accompanies and increases pain. Relaxation training, along with distraction and biofeedback, are treatments often included in CBT, but also are discussed in the literature without mention of CBT.

Controlled breathing and **progressive muscle relaxation** are commonly used relaxation techniques taught to preschool-age and older children. *Suggested sample brief strategy:* Ask the child (or instruct the caregiver to do so) to practice the following and use if pain is coming on: focus on the breath and pretend to be blowing up a big balloon while pursing the lips and exhaling slowly. This is one way to help induce controlled breathing.

Distraction can be used to help a child of any age shift attention away from pain and onto other activities. Common attention sustainers in the environment include bubbles, music, video games, television, the telephone, conversation, school, and play. Asking children to tell stories, asking parents to read to the child, and even mutual storytelling can be helpful distracters. Being involved with social, school, physical, or other activities helps the child in chronic pain to regain function. *Suggested sample brief strategy:* Encourage the child (or instruct the caregiver to do so) to shift attention away from the pain by continuing to engage in other activities and/or think of something else.

Biofeedback involves controlled breathing, relaxation, or hypnotic techniques with a computer synchronized device that provides visual or auditory feedback to the child when the desired action is approximated. Common targets of actions include muscle tension, peripheral skin temperature through peripheral vasodilation, and anal control through rectal muscle contraction and relaxation. Biofeedback also enhances the child's sense of mastery and control, especially for the child who needs more "proof" of change than that generated through hypnotherapy alone.

Hypnotherapy has also been used in the treatment of chronic pain in children, although the evidence for its effectiveness has not been as extensively studied as CBT. Hypnotherapy helps a child focus on an imaginative experience that is comforting, safe, fun, or intriguing. Hypnotherapy captures the child's attention, alters his or her sensory experiences, reduces distress, reframes pain experiences, creates time distortions, helps the child dissociate from the pain, and enhances feelings of mastery and self-control. Children with chronic pain can use *metaphor,* for example, imagining they have overcome something feared because of pain in real life. As the child increases mastery of imagined experiences, the enhanced sense of control can be used during actual pain rehabilitation. Hypnotherapy is best for children of school age or older.

Nonpharmacologic treatments of pain may also be applied to other treatment needs. A child who learns relaxation to reduce distress from lumbar punctures in cancer treatment may also apply this skill to other stressful medical and nonmedical situations, such as stressors caused by school.

Yoga is intended to achieve balance in mind, body, and spirit. **Therapeutic yoga** can be helpful in treating chronic pain; improving mood, energy, and sleep; and reducing anxiety. Yoga involves a series of *asanas* (body poses) oriented to the specific medical condition or symptoms. Some forms of yoga use poses within a movement flow and format. *Iyengar* yoga is an alignment-based system that uses props, such as blankets, bolsters, blocks, and belts, to support the body while the practitioner assumes more healing poses. Yoga promotes a sense of energy, relaxation, strength, balance, and flexibility and, over time, enhances a sense of mastery and control. Within a yoga practice, the child may learn certain types of breathing *(pranayama)* for added benefit. With a focus on body postures or in types of flow yoga, the child learns mindfulness or being present in the moment. By focusing on body and breath, the child can develop strategies to avoid ruminating about the past or worrying about the future.

Mindfulness meditation involves a focus on the present, "in-the-moment" experience using a variety of strategies. Many studies in adults report the value of meditation for chronic pain states and for anxiety and depression. These strategies help children learn how to be mindful and in the present with enhanced parasympathetic control. Many mindfulness smartphone applications are geared to children of different ages, as well as books for parents on how to help their children achieve a mindful state to enhance relaxation. Although there are different schools of mindfulness, such as *Vipassana* (insight-oriented meditation, often using a focus on the breath) and *transcendental* meditation (in which the child learns the use of a silent mantra to facilitate acquiring a deeper inner calmness), the goal is to help the child learn strategies that enhance self-competence in reducing stress and enhancing a state of well-being.

Massage therapy involves the therapist's touching and applying varied degrees of pressure on the child's muscles. Massage is very useful for children with chronic pain and especially helpful for those with myofascial pain. There are several types of massage, including craniosacral therapy. For young children, it can be helpful to have parents learn and perform brief massage on their children before bedtime. Massage therapy likely will not be helpful to or tolerated by the child with sensory sensitivity and sensory aversion.

Physical therapy can be especially useful for children with chronic musculoskeletal pain and for those deconditioned from inactivity. Exercise appears specifically to benefit muscle functioning, circulation, and posture while also improving body image, body mechanics, sleep, and mood. The physical therapist and the child can develop a graded exercise plan for enhancing the child's overall function for the child to continue at home. Research indicates that physical therapy affects central neurobiologic mechanisms that enhance "top-down" pain control.

Acupuncture/acupressure involves the placement of needles or pressure at specific points along a *meridian,* or energy field, after the acupuncturist has made a diagnosis of excess or deficient energy in that meridian as the primary cause of the pain. Acupuncture/acupressure is a feasible, popular part of a pain management plan for children with chronic pain. Acupuncture/acupressure alleviates chronic nausea, fatigue, and several chronic pain states, including migraine and chronic daily headaches, abdominal pain, and myofascial pain. Acupuncture/acupressure also has efficacy in adults with myofascial pain, primary dysmenorrhea, sickle cell crisis pain, and sore throat pain. The acupuncturist must relate well to children so that the experience is not traumatic, because added stress would undo the benefits gained.

Transcutaneous electrical nerve stimulation (TENS) is the use of a battery-operated tool worn on the body to send electrical impulses into the body at certain frequencies set by the machine. TENS is believed to be safe and can be tried for many forms of localized pain. Children often find TENS helpful and effective.

Music therapy and **art therapy** can be especially helpful for young and nonverbal children who would otherwise have trouble with traditional talk psychotherapies. Also, many creative children can more easily express fears and negative emotions through creative expression and, with the therapist's help, learn about themselves in the process. There is also increasing research on the impact of art and music therapy on altering central neural circuits that maintain and enhance pain.

Dance, movement, pet therapies, and **aromatherapy** have also been used and may be helpful, but these have not been as well studied in children for pain control as have other complementary therapies. Often, clinical experience helps guide the pediatrician in the benefits of these therapies with individual patients. For example, pet therapy is gaining favor in hospitals and in stress reduction for sick children. Pets often can become self-regulators for the child with ASD, although the neurobiologic mechanisms are not yet understood.

INVASIVE INTERVENTIONS FOR TREATING PAIN

Various interventional neuraxial and peripheral nerve blocks may have a role in the treatment of pain acutely (e.g., long-bone fracture), perioperatively, and for the patient with chronic pain (e.g., headache, abdominal pain, complex regional pain syndrome [CRPS], or cancer pain). Interventions also provide intraoperative anesthesia and postoperative analgesia (see Chapter 91). Use of interventional procedures varies greatly across institutions; they may be frequently used at some hospitals, whereas other institutions focus mainly on noninterventional treatment plans. Interventional procedures may be useful in some children who have specific types of chronic pain, but their use in children (as widely practiced in adult pain clinics) generally is not

recommended because the pediatric research is insufficient. Therefore the data are largely extrapolated from the adult population. Use of such procedures in children should generally not be considered or undertaken by an adult chronic pain provider who is willing to perform such a procedure on a child or adolescent. Rather, the potential procedure or block should be undertaken only at the direction or guidance of a pediatric pain specialist. Complications and lack of benefit can occur in children, as may occur in adults; however, more harm may be done in the pediatric populations. This is especially true as children and families may "pin their hopes" on a particular intervention "curing their child," when in reality chronic pain is a complex phenomenon that responds best to multidisciplinary management. This does not mean that no block should be recommended in children, but that procedural interventions should be used judiciously, appropriately, and in conjunction with other biopsychosocial treatments by or under the guidance of a pediatric pain expert.

Regional anesthesia provides several benefits, particularly in the acute perioperative setting. As an alternative to or in augmentation of opioid-based pain control, regional anesthesia minimizes opioid requirements and therefore opioid side effects, including nausea, vomiting, somnolence, respiratory depression, pruritus, constipation, and physical dependence. It can provide equal or improved analgesia, as it interrupts nociceptive pathways and may profoundly inhibit endocrine stress responses. Regional anesthesia also results in earlier ambulation in recovering surgical patients, helps prevent atelectasis in the patient with chest pain, and usually results in earlier discharge from the hospital. Theoretically, the interruption of nociceptive pathways in the periphery by regional anesthetics will prevent or reverse the process of amplification of pain signals induced by nociception (e.g., CNS windup, glial cell activation). For postoperative pain, effective regional anesthesia reduces the risks of acute pain evolving to chronic pain. Regional anesthesia is considered safe and effective if performed by trained staff with the proper instruments and equipment. Most frequently, nerve blocks are performed by an anesthesiologist or pain management physician; a few are easily performed by a nonanesthesiologist with appropriate training. The benefits of regional anesthesia are dependent on adequate coverage of the surgical area, the patient and family's expectation of the block, and the expertise of the provider performing the block. When procedures fail to provide adequate analgesia, it can lead to the need to "catch up" with pain control after surgery.

Head and Neck Blocks

Primary pain syndromes of the head, such as trigeminal neuralgia, are distinctly unusual in the pediatric population, and few surgical procedures in the head and neck are amenable to regional anesthesia. Headache disorders, very common in the pediatric age-group, may respond well to regional anesthesia of the greater occipital nerve. However, this is not generally considered a first-line treatment of pediatric headache. The greater occipital nerve (second cervical, C2) provides sensation to much of the cranial structures, from the upper cervical region, the occiput to the apex of the head, or even to the hairline. The greater occipital nerve can be blocked medial to the occipital artery, which can usually be identified at the occipital ridge midway between the occipital prominence and the mastoid process by palpation, Doppler sound amplification, or visualization by ultrasound. The short-term and especially long-lasting effects of nerve blocks for chronic headaches in children have not been documented by research. Studies are needed to determine which children with which types of headaches will benefit most from occipital nerve blocks. Sphenopalatine blocks are increasingly used in the treatment of multiple types of headaches in adults, including migraine and postdural puncture headache (PDPH). There is some evidence to support the benefit of this procedure in children and adolescents. The sphenopalatine ganglion (SPG) is a collection of cells closely related to the trigeminal nerve that plays a role in headache pathology. This block can be performed in a minimally invasive fashion through the nasal cavity. The procedure may be performed either with the use of marketed devices or with the use of cotton-tipped applicators. SPG blocks may be performed with or without fluoroscopic guidance.

Onabotulinum toxin A (Botox) may also be used for the treatment of chronic migraine in children and adolescents. As with many interventions, the available data for benefit of this treatment for pediatric migraine are lacking compared with the adult data. However, many children or adolescents, who may have experienced treatment failure with medical management of headache, may be considered as candidates for the use of Botox.

Upper Extremity Blocks

The brachial plexus block controls pain of the upper extremity. These blocks also protect the extremity from movement, reduce arterial spasm, and block sympathetic tone of the upper extremity. The brachial plexus, responsible for cutaneous and motor innervation of the upper extremity, is an arrangement of nerve fibers originating from spinal nerves C5 through T1, extending from the neck into the axilla, arm, and hand. The brachial plexus innervates the entire upper limb, except for the trapezius muscle and an area of skin near the axilla. If pain is located proximal to the elbow, the brachial plexus may be blocked above the clavicle (roots and trunks); if the pain is located distal to the elbow, the brachial plexus may be blocked at the axilla (cords and nerves). The block may be given as a single injection with a long-acting anesthetic such as bupivacaine or ropivacaine. This may provide up to 12-16 hours of analgesia. Use of a catheter and infusion pump may increase duration and provide continuous analgesia for several days.

Trunk and Abdominal Visceral Blocks

Trunk blocks provide somatic and visceral analgesia and anesthesia for pain or surgery of the thorax and abdominal area. Sympathetic, motor, and sensory blockade may be obtained. These blocks are often used in combination to provide optimal relief. Intercostal and paravertebral blocks may be beneficial in patients for whom a thoracic epidural injection or catheter is contraindicated (e.g., patient with coagulopathy). Respiratory function is maintained, and the side effects of opioid therapy are eliminated.

The intercostal, paravertebral, erector spinae, rectus sheath, and transverse abdominal plane blocks are most useful for pediatric chest and somatic abdominal pain. The celiac plexus and splanchnic nerve block can be useful for abdominal visceral pain, such as that caused by malignancy or pancreatitis. These blocks are best performed by an experienced anesthesiologist, pain physician, or interventional radiologist using ultrasound or CT imaging guidance.

The **intercostal block** is used to block the intercostal nerves, the anterior rami of the thoracic nerves from T1 to T11. These nerves lie inferior to each rib, between the inner and innermost intercostal muscles with their corresponding vein and artery, where they can be blocked, generally posterior to the posterior axillary line. Guidance with either fluoroscopy or ultrasound is often employed to decrease risks associated with this block. With use of ultrasound imaging, the intercostal nerves and the pleura can be identified, which can decrease risks such as pneumothorax or hemothorax that are associated with this procedure. The **erector spinae plane** block has also shown to be effective for blocking several levels of intercostal nerves while avoiding the attendant risks of multilevel intercostal nerve blocks.

The **paravertebral block**, another alternative to intercostal nerve block or epidural analgesia, is useful for pain associated with thoracotomy or with unilateral abdominal surgery, such as nephrectomy or splenectomy. Essentially this block results in multiple intercostal blocks with a single injection. The thoracic paravertebral space, lateral to the vertebral column, contains the sympathetic chain, rami communicantes, dorsal and ventral roots of the spinal nerves, and dorsal root ganglion. Because it is a continuous space, local anesthetic injection will provide sensory, motor, and sympathetic blockade to several dermatomes. The paravertebral block may be performed as a single injection or, for a very prolonged effect, as a continuous infusion over several days or weeks via a catheter. This block is best performed by an anesthesiologist or interventional pain physician under ultrasound guidance.

Ilioinguinal and iliohypogastric nerve blocks are indicated with surgery for inguinal hernia repair, hydrocele, or orchidopexy repair and for chronic pain subsequent to these procedures. The first lumbar (L1) nerve divides into the iliohypogastric and ilioinguinal nerves, which emerge from the lateral border of the psoas major muscle. The iliohypogastric nerve supplies the suprapubic area as it pierces the transversus abdominis muscle and runs deep to the internal oblique muscle. The ilioinguinal nerve supplies the upper medial thigh and superior inguinal region, as it also pierces the transversus abdominis muscle and runs across the inguinal canal. Ultrasound guidance helps ensure success for this nerve block.

The **celiac plexus block** is indicated for surgery or pain of the pancreas and upper abdominal viscera. The celiac plexus, located on each side of the L1 vertebral body, contains one to five ganglia. The aorta lies posterior, the pancreas anterior, and the inferior vena cava lateral to these nerves. The celiac plexus receives sympathetic fibers from the greater, lesser, and least splanchnic nerves, as well as from parasympathetic fibers from the vagus nerve. Autonomic fibers from the liver, gallbladder, pancreas, stomach, spleen, kidneys, intestines, and adrenal glands originate from the celiac plexus. This block is best performed with CT guidance to provide direct visualization of the appropriate landmarks, avoid vascular and visceral structures, and confirm correct needle placement. The close proximity of structures such as the aorta and vena cava make this a technical procedure best performed by an anesthesiologist, interventional pain physician, or interventional radiologist. The evidence for use of this block for chronic pediatric pain is lacking; as such, this block should not be routinely employed in the treatment of chronic noncancer pain.

Nerve blocks have been used for the treatment of *anterior cutaneous nerve entrapment syndrome (ACNES)*. ACNES is characterized by pain associated with use of abdominal muscles. On exam, this can be identified via Carnett sign. Pathology and causation in the pediatric population are not well understood. Treatment may include identification of a specific pain source under ultrasound guidance with infiltration of a local anesthetic or local anesthetic and steroid mixture. Evidence for use of this procedure is limited.

Lower Extremity Blocks

Lumbar plexus and sciatic nerve blocks provide pain control for painful conditions or surgical procedures of the lower extremities, with the benefit of providing analgesia to only one extremity while preserving motor and sensory function of the other. The lumbosacral plexus is an arrangement of nerve fibers originating from spinal nerves L2-L4 and S1-S3. The lumbar plexus arises from L2-L4 and forms the lateral femoral cutaneous, femoral, and obturator nerves. These nerves supply the muscles and sensation of the upper leg, with a sensory branch of the femoral nerve (saphenous nerve) extending below the knee to innervate the medial aspect of the foreleg, ankle, and foot. The sacral plexus arises from L4-S3 and divides into the major branches of the sciatic, tibial, and common peroneal nerves. These nerves in turn supply the posterior thigh, lower leg, and foot. Unlike the brachial plexus block, blockade of the entire lower extremity requires more than one injection because the lumbosacral sheath is not accessible. Separate injections are necessary for the posterior (sciatic) and anterior (lumbar plexus) branches, and the injections can be performed at any of several levels during the course of the nerve, as is clinically expedient. The lumbar plexus can be blocked in the back, resulting in analgesia of the femoral, lateral femoral cutaneous, and obturator nerves. Alternatively, any of these three nerves can be individually anesthetized, depending on the location of the pain. Similarly, the sciatic nerve can be anesthetized proximally as it emerges from the pelvis or, more distally, in the posterior thigh, or its major branches (tibial and peroneal nerves) can be individually anesthetized. These nerve blocks are generally best performed by an anesthesiologist, pain physician, or radiologist.

Sympathetic Blocks

Sympathetic blocks were once thought to be useful in the diagnosis and treatment of sympathetically mediated pain, CRPS (Table 93.17), and other neuropathic pain conditions (Table 93.18), but large meta-analyses have shown their utility to be minimal. When blocks of the sympathetic plexuses are performed, sympathectomy is obtained

Table 93.17 Budapest Criteria for Clinical Diagnosis of CRPS

1. **Pain** (ongoing and disproportionate to any inciting event)
2. **Symptoms (reported):** At least one symptom in three out of four of the following categories:
   - *Sensory* – Hyperesthesia and/or allodynia
   - *Vasomotor* – Temperature asymmetry and/or skin color changes and/or skin color asymmetry
   - *Sudomotor/Edema* – Edema and/or sweating changes and/or sweating asymmetry
   - *Motor/Trophic* – Decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
3. **Signs (examined):** At least one sign in two out of four of the following categories:
   - *Sensory* – Hyperalgesia (to pinprick) and/or allodynia (to light touch and/or temperature sensation and/or deep somatic pressure and/or joint movement)
   - *Vasomotor* – Temperature asymmetry (>1°C) and/or skin color changes and/or asymmetry
   - *Sudomotor/Edema* – Edema and/or sweating changes and/or sweating asymmetry
   - *Motor/Trophic* – Decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
4. **Diagnosis of exclusion:** No other diagnosis better explains the signs and symptoms.

Table 93.18 Examples of Neuropathic Pain Syndromes

PERIPHERAL NERVOUS SYSTEM FOCAL AND MULTIFOCAL LESIONS
Postherpetic neuralgia
Cranial neuralgias (e.g., trigeminal neuralgia, glossopharyngeal neuralgia)
Diabetic mononeuropathy
Nerve entrapment syndromes
Plexopathy from malignancy or irradiation
Phantom limb pain
Posttraumatic neuralgia (e.g., nerve root compression, after thoracotomy)
Ischemic neuropathy
Complex regional pain syndrome types 1 and 2
Erythromelalgia
PERIPHERAL NERVOUS SYSTEM GENERALIZED POLYNEUROPATHIES
Metabolic/nutritional: Diabetes mellitus, pellagra, beriberi, multiple nutritional deficiency, hypothyroidism
Toxic: Alcohol-, platinum-, or taxane-based chemotherapy; isoniazid; antiretroviral drugs
Infective/autoimmune: HIV, acute inflammatory polyneuropathy (Guillain-Barré syndrome), neuroborreliosis (Bannwarth syndrome)
Hereditary: Fabry disease
Malignancy: Carcinomatosis
Others: Idiopathic small fiber neuropathy, erythromelalgia
CENTRAL NERVOUS SYSTEM LESIONS
Spinal cord injury
Prolapsed disc
Stroke (brain infarction, spinal infarction)
Multiple sclerosis
Surgical lesions (e.g., rhizotomy, cordotomy)
Complex neuropathic disorders
Complex regional pain syndrome types 1 and 2

Adapted from Freynhagen R, Bennett MI. Diagnosis and management of neuropathic pain. *BMJ*. 2009;339:b3002.

without attendant motor or sensory anesthesia. Their use for pain management was grounded in the notion that many types of chronic pain were mediated via the sympathetic nerves. This mechanistic model has been proven to be false.

The **stellate ganglion block** was indicated for pain in the face or upper extremity and for CRPS, phantom limb pain, amputation stump pain, or circulatory insufficiency of the upper extremities. The lumbar sympathetic block addressed pain in the lower extremity, CRPS, phantom limb pain, amputation stump pain, and pain from circulatory insufficiency.

The analgesia produced by peripheral sympathetic blocks usually outlives the duration of the local anesthetic, often persisting for weeks or indefinitely. If analgesia is transient, the blocks may be performed with catheter insertion for continuous local anesthesia of the sympathetic chain over days or weeks. Because precise, radiographically guided placement of the needle and/or catheter is required for safety and success, sympathetic blocks are generally best performed by an anesthesiologist, interventional pain physician, or interventional radiologist.

While all these procedures can be considered for the treatment of certain chronic pediatric pain conditions, there is overall a lack of evidence to support routine use in children and adolescents. This information should be used for learning and awareness rather than as a guide map for specific treatment of these conditions. When needed, a dedicated pediatric pain provider should be consulted and these blocks used judiciously when appropriate.

In addition, any time these procedures are considered for the treatment of chronic pain, special consideration should be given to potential risks and complications.

Epidural Anesthesia (Thoracic, Lumbar, and Caudal)

Epidural anesthesia and analgesia are indicated for pain below the clavicles, management of regional pain syndromes, cancer pain unresponsive to systemic opioids, and pain limited by opioid side effects.

The three layers of the spinal meninges—dura mater (outer), arachnoid mater (middle), and pia mater (inner)—envelop the spinal neural tissue. The subarachnoid space contains cerebrospinal fluid between the arachnoid mater and pia mater. The epidural space extends from the foramen magnum to the sacral hiatus and contains fat, lymphatics, blood vessels, and the spinal nerves as they leave the spinal cord. The epidural space separates the dura mater from the periosteum of the surrounding vertebral bodies. In children, the fat in the epidural space is not as dense as in adults, predisposing to greater spread of the local anesthetic from the site of injection.

Epidural local anesthetics block both sensory and sympathetic fibers, and if the local anesthetic is of sufficient concentration, they also block motor fibers. Mild hypotension may occur, although it is unusual in children <6 years of age. Epidural local anesthetics high in the thoracic spine may also anesthetize the sympathetic nerves to the heart (the cardiac accelerator fibers), producing bradycardia. In addition to using local anesthetics, it is routine to use opioids and sometimes α-agonists as adjunctive medications in the epidural space. Clonidine and opioids have been well studied and shown not to be neurotoxic. Side effects of epidural opioid administration include delayed respiratory depression, particularly when hydrophilic opioids such as morphine are used. The risk of this effect requires that children receiving epidural opioids by intermittent injection or continuous infusion be monitored by continuous pulse oximetry and nursing observation, particularly during the first 24 hours of therapy or after significant dose escalations. Respiratory depression occurring after the first 24 hours of epidural opioid administration is distinctly unusual.

Epidural clonidine (an α_2-agonist with μ-opioid analgesic properties) is associated with minimal risk and side effects. Although product labeling indicates use only in children with severe cancer pain, clonidine may be used for treatment of routine postoperative pain as well as pain syndromes such as CRPS. Mild sedation is the most common side effect of epidural clonidine, and it is not associated with respiratory depression.

Because performing epidural blockade is technical and may result in spinal cord injury, it is best done by an anesthesiologist or pain physician skilled in the technique. Caution is advised in the use of epidural anesthesia/analgesia for CRPS in children because no published RCTs have shown these procedures superior to a combination of less invasive physical and psychologic therapy, with or without neuropathic pain-focused medications.

INTRATHECAL ANALGESIA

Intrathecal catheters infused with opioids, clonidine, ziconotide (derived from a marine neurotoxin produced by the cone snail), and local anesthetics are occasionally applicable in pediatric patients with intractable pain from cancer or other life-threatening conditions. Typically, intrathecal catheters are attached to an implanted electronic pump containing a drug reservoir sufficient for several months of dosing. The technique is technical and best performed by an experienced pain management physician or neurosurgeon.

NERVE ABLATION AND DESTRUCTION

In some cases, pain remains refractory despite maximal reliance on oral and IV medications and nerve blockade. In these patients, temporary (pulsed radiofrequency ablation) or permanent neurolytic destruction (phenol or alcohol) of one or more nerves may be performed. The techniques should be carefully weighed against the consideration of permanent nerve destruction in a growing child with decades of life ahead. On the other hand, when pain is severe in life-limiting disease processes, the long-term considerations are less concerning, and these techniques should be discussed with a skilled pain management specialist.

CONSIDERATIONS FOR SPECIAL PEDIATRIC POPULATIONS

Pain Perception and Effects of Pain on Newborns and Infants

Pain may result from a number of circumstances in the newborn period, including acute pain (diagnostic and therapeutic procedures, minor surgery, monitoring), continuous pain (pain from thermal/chemical burns, postsurgical and inflammatory pain), and chronic or disease-related pain (necrotizing enterocolitis, nerve injury, chronic conditions, thrombophlebitis). The most common sources of pain in healthy infants are acute procedures, such as heel lances, surgical procedures, and in males, circumcision.

Many procedures are performed for premature infants in the neonatal intensive care unit (NICU). In the first week of life, approximately 94% of preterm infants <28 weeks gestational age are mechanically ventilated; in these situations, heelsticks and airway suctioning are frequent, yet few of these procedures are preceded by any type of analgesia. Repeated handling and acute pain episodes sensitize the neonate to increased reactivity and stress responses to subsequent procedures. Typical stress responses include increases in heart rate, respiratory rate, blood pressure, and intracranial pressure. Cardiac vagal tone, transcutaneous oxygen saturation, carbon dioxide levels, and peripheral blood flow are decreased. Autonomic signs include changes in skin color, vomiting, gagging, hiccupping, diaphoresis, dilated pupils, and palmar and forehead sweating (see Table 93.4).

Untreated pain in the newborn has serious short- and long-term consequences. There has been a shift in most NICUs to more liberal use of opioids. Nonetheless, **morphine**, the traditional gold standard of analgesia for acute pain, may not be effective and may have adverse long-term consequences. No differences have been found in the incidence of severe intraventricular hemorrhage or in the mortality rate when infants receiving morphine are compared with a placebo group, and there are no changes in assessed pain from tracheal suctioning in ventilated infants receiving morphine compared with those receiving a placebo infusion. Morphine may not alleviate acute pain in ventilated preterm neonates, although there are few data on the effects of morphine and fentanyl in nonventilated newborns. The lack of opioid effects for acute pain in neonates may result from immaturity of opioid receptors; acute pain may cause the uncoupling of μ-opioid receptors in the forebrain. Repetitive acute pain may create central neural changes in the newborn that may have long-term consequences for later pain vulnerability, cognitive effects, and opioid tolerance. Most

Table 93.19 World Health Organization Analgesic Ladder for Cancer Pain

STEP 1
Patients who present with mild to moderate pain should be treated with a nonopioid.

STEP 2
Patients who present with moderate to severe pain or for whom the step 1 regimen fails should be treated with an oral opioid for moderate pain combined with a nonopioid analgesic.

STEP 3
Patients who present with very severe pain or for whom the step 2 regimen fails should be treated with an opioid used for severe pain, with or without a nonopioid analgesic.

neonatologists use opioids in painful situations. Sucrose and pacifiers are also being used in the NICU. The effects of 24% **sucrose** (Sweetease) are believed to be opioid mediated because the effect can be reversed with naloxone. Sucrose, with or without a pacifier, may be effective for acute pain and stress control. Other nonpharmacologic strategies for stress and pain control include infant care by an individual primary nurse, tactile-kinesthetic stimuli (massage), "kangaroo care," and soothing sensorial saturation.

Children With Cancer Pain

The World Health Organization (WHO) proposed an analgesic therapy model for cancer pain known as the *analgesic ladder* (Table 93.19). Designed to guide therapy in care systems with limited access to analgesic experts, this ladder consists of a hierarchy of oral pharmacologic interventions intended to treat pain of increasing magnitude. The hierarchy ignores modalities such as the use of nonconventional analgesics and interventional pain procedures, which physicians in developed countries are often able to prescribe. Nevertheless, because oral medications are simple and efficacious, especially for home use, the ladder presents a framework for rationally using them, before applying other drugs and techniques of drug administration.

Oral medications are the first line of analgesic treatment. Because NSAIDs affect platelet adhesiveness, they are typically not used. As noted earlier, celecoxib may be the exception to this rule. Opioid therapy is the preferred approach for moderate or severe pain. Nonopioid analgesics are used for mild pain, a weak opioid is added for moderate pain, and strong opioids are administered for more severe pain. Adjuvant analgesics can be added, and side effects and comorbid symptoms are actively managed. Determining the type and sources of the pain will help develop an effective analgesic plan. Certain treatments, such as the chemotherapeutic agent vincristine, are associated with neuropathic pain. Such pain might require anticonvulsants or TCAs. Stretching pain from tumor growth within an organ might require strong opioids and/or radiation therapy if the tumor is radiosensitive. Organ obstruction, such as intestinal obstruction, should be diagnosed to relieve or bypass the obstruction.

It is important to consider both pharmacologic and nonpharmacologic strategies (e.g., CBT, family/parent support) to treat pain in children with cancer.

Children with Pain Associated with Advanced Disease

Patients with advanced diseases, including cancer, acquired immunodeficiency syndrome (AIDS), neurodegenerative disorders, and cystic fibrosis, need palliative care approaches that focus on optimal quality of life. Nonpharmacologic and pharmacologic management of pain and other distressing symptoms is a key component. *Palliative care* should be offered to all children with serious diseases, whether or not the diseases are potentially curable or long life expectancy is predicted (see Chapter 8). Examples include young children diagnosed with acute lymphoblastic leukemia (>90% posttreatment life expectancy) and children undergoing organ transplantation. Palliative care in pediatrics connotes treatment that focuses on symptom reduction, quality of life, and good family and clinical team communication. It is not only for patients in hospice care or those at the end of life. Differences in the progression of underlying illness, associated distressing symptoms, and common emotional responses in these conditions should shape individual treatment plans. For end-of-life care, >90% of children and adolescents with cancer can be made comfortable by standard escalation of opioids according to the WHO protocol. A small subgroup (5%) requires enormous opioid dose escalation to >100 times the standard morphine or other opiate infusion rate. Most of these patients have spread of solid tumors to the spinal cord, roots, or plexus, and signs of neuropathic pain are evident. **Methadone** given orally is often used in palliative care, not only end-of-life care, because of its long half-life and its targets at both opioid and NMDA receptors.

The type of pain experienced by the patient (neuropathic, myofascial) should determine the need for adjunctive agents. Complementary measures, such as massage, hypnotherapy, and spiritual care, must also be offered in palliative care. Although the oral route of opioid administration should be encouraged, especially to facilitate care at home, if possible, some children are unable to take oral opioids. Transdermal and sublingual routes, as well as IV infusion with PCA, are likely next choices. Small, portable infusion pumps are convenient for home use. If venous access is limited, a useful alternative is to administer opioids (especially morphine or hydromorphone, but not methadone or meperidine) through continuous SC infusion, with or without a bolus option. A small (e.g., 22-gauge) cannula is placed under the skin and secured on the thorax, abdomen, or thigh. Sites may be changed every 3-7 days, as needed. As noted, alternative routes for opioids include the transdermal and oral transmucosal routes. These latter routes are preferred over IV and SC drug delivery when the patient is being treated at home.

CHRONIC AND RECURRENT PAIN SYNDROMES

Chronic pain is defined as recurrent or persistent pain lasting longer than the normal tissue healing time (3-6 months). Children may experience pain related to injury (e.g., burns) or to a chronic or underlying disease process (e.g., cancer, arthritis), or pain can also be the chronic condition itself (e.g., CRPS, fibromyalgia, functional abdominal pain) (see Chapter 212). During childhood, abdominal, musculoskeletal, and headache pain are the most frequently occurring conditions. However, definitions of chronic pain do not take into account standard criteria for assessing particular pain symptoms or for evaluating the intensity or impact of pain and therefore include individuals with varying symptoms and experiences. Consequently, in epidemiologic surveys, prevalence estimates vary widely. Overall prevalence rates for different childhood pains range from 4% to 88%. An average of 13.5–31.8% of adolescents in a community sample reported having weekly abdominal, headache, or musculoskeletal pains. Most epidemiologic studies report prevalence and do not report the *severity* or impact of the pain. Research indicates that only a subset of children and adolescents with chronic pain (approximately 5%) experience moderate to severe disability, and this likely better represents the estimated population for whom help is needed to treat pain and associated problems.

Neuropathic Pain Syndromes

Neuropathic pain is caused by abnormal excitability in the peripheral or central nervous system that may persist after an injury heals or inflammation subsides. The pain, which can be acute or chronic, is typically described as burning or stabbing and may be associated with cutaneous hypersensitivity **(allodynia)**, distortion of sensation **(dysesthesia)**, and amplification of noxious sensations **(hyperalgesia** and **hyperpathia)**. Neuropathic pain conditions may be responsible for >35% of referrals to chronic pain clinics, conditions that typically include posttraumatic and postsurgical peripheral nerve injuries, phantom pain after amputation, pain after spinal cord injury, and pain caused by metabolic neuropathies (see Table 93.18). Patients with neuropathic pain typically respond poorly to opioids. Evidence supports

the efficacy of antidepressants (nortriptyline, amitriptyline, venlafaxine, duloxetine) and anticonvulsants (gabapentin, pregabalin, oxcarbazepine) for treatment of neuropathic pain (see Table 93.16).

Complex regional pain syndrome is well described in the pediatric population (see Chapter 211 and Table 93.17). **CRPS type 1** is a syndrome of neuropathic pain that typically follows an antecedent and usually minor injury or surgery to an extremity without identifiable nerve injury. It is seen after injury such as sprain or fracture or even in instances as minimal as an IV start. The syndrome of CRPS type 1 includes severe spontaneous neuropathic pain, hyperpathia, hyperalgesia, severe cutaneous allodynia to touch and cold, changes in blood flow (typically extremity cyanosis), and increased sweating. In more advanced cases, symptoms include dystrophic changes of the hair, nails, and skin; immobility of the extremity (dystonia); and muscle atrophy. In the most advanced cases, symptoms include ankylosis of the joints of the extremity. Specific causal factors in CRPS type 1 in both children and adults remain elusive, although coincidental events may be noted. **CRPS type 2** clinically appears the same with respect to symptoms but is associated with a known nerve injury.

Treatment of CRPS in children has been extrapolated from that in adults, with some evidence for efficacy of physical therapy, CBT, nerve blocks, antidepressants, AEDs, and other related drugs. All experts in pediatric pain management agree on the value of aggressive physical therapy, including desensitization. Some centers provide aggressive therapy without the use of pharmacologic agents or interventional nerve blocks. Unfortunately, recurrent episodes of CRPS may be seen in up to 25–50% of patients, particularly adolescent females. Physical therapy can be extraordinarily painful for children to endure; it is tolerated only by the most stoic and motivated patients. If children have difficulty enduring the pain, there is a well-established role for pharmacologic agents, with or without peripheral or central neuraxial nerve blocks, to render the affected limb sufficiently analgesic so that physical therapy can be tolerated. Pharmacologic interventions include the use of AEDs such as gabapentin and/or TCAs such as amitriptyline (see Fig. 93.4). Although there is clear evidence of a peripheral inflammatory component of CRPS, with release of cytokines and other inflammatory mediators from the peripheral nervous system in the affected limb, the use of antiinflammatory agents has been disappointing. Common nerve block techniques include IV regional anesthetics, epidural analgesia, and peripheral nerve blocks. In extreme and refractory cases, more invasive strategies have been reported, including surgical sympathectomy and spinal cord stimulation, although these are not generally recommended in the pediatric population

Although an array of treatments has some benefit, the mainstay of treatment remains **physical therapy** emphasizing desensitization, strengthening, and functional improvement. Additionally, pharmacologic agents and psychologic and complementary therapies are important components of a treatment plan. Invasive techniques, although not curative, can be helpful if they permit the performance of frequent and aggressive physical therapy that cannot be carried out otherwise. A good biopsychosocial evaluation will help determine the orientation of the treatment components. There are insufficient data to indicate the superior value of interventional blocks, such as epidural anesthesia, in children with CRPS over physical and psychologic interventions, with or without pharmacologic support.

Myofascial Pain Disorders and Fibromyalgia

Myofascial pain disorders are associated with tender points in the affected muscles and with muscle spasms (tight muscles). Treatment is targeted at relaxing the affected muscles through physical therapy, Iyengar yoga, massage, and acupuncture. Rarely are pharmacologic muscle relaxants helpful other than for creating tiredness at night for sleep. Dry needling or injections of local anesthetic into the tender points has been advocated, but the data do not support this as a standard treatment. Similarly, although botulinum toxin injections may be used, no data support this practice in children. Often, poor body postures, repetitive use of a body part not accustomed to that movement, or carrying heavy backpacks initiates pain. When it becomes widespread, a diagnosis may be made of **juvenile fibromyalgia**, which may or may not continue to subsequently become adult fibromyalgia. Newer guidelines do not use "tender points" in the diagnosis of fibromyalgia. Instead, diagnosis relies on a model that assesses for widespread pain and symptom severity (see Chapter 211). Likely there are different subtypes of widespread pain syndromes, and physical therapy is a key component of treatment. Psychologic interventions may play an important role to assist the child in resuming normal activities and to manage any psychologic comorbidities. Any pain rehabilitation plan should enhance return to full function. Because there is a high incidence of chronic pain in parents of children presenting with a chronic pain condition, especially fibromyalgia, attention to parent and family

Table 93.20 Clinical Features of Human Disorders Caused by Pathologic Variants in Ion-Channel Genes That Lead to Altered Pain Perception and Are Inherited in a Mendelian Manner

	AFFECTED GENE (PROTEIN)	TYPE AND EFFECT OF MUTATION	MAIN PHENOTYPE	ADDITIONAL FEATURES
Inherited erythromelalgia	*SCN9A* ($Na_v1.7$)	Heterozygous, activating	Onset by age 20 yr; episodic pain triggered by warmth; feet affected more frequently than hands	Erythema of feet
Paroxysmal extreme pain disorder	*SCN9A* ($Na_v1.7$)	Heterozygous, activating	Onset at birth; episodic pain; sacral region is affected most frequently, face is affected more often than the limbs; physical triggers include defecation	Erythema of the sacrum; tonic attacks
Small fiber neuropathy	*SCN9A* ($Na_v1.7$)	Heterozygous, activating	Onset at any age but more common in early adulthood; persistent burning pain; feet affected more frequently than hands	Could be autonomic features
Small fiber neuropathy	*SCN10A* ($Na_v1.8$)	Heterozygous, activating	Persistent burning pain	Could be autonomic features
Familial episodic pain syndrome type I	*TRPA1* (TRPA1)	Heterozygous, activating	Onset at birth or in infancy; episodic chest or arm pain; triggers are hunger and cold	—
Familial episodic pain syndrome type III	*SCN11A* ($Na_v1.9$)	Heterozygous, activating	Onset in first decade; episodic hand and foot pain; triggers are intercurrent illness or exercise	—

Na_v, Sodium ion channel.
Modified from Bennett DLH, Woods CG. Painful and painless channelopathies. *Lancet Neurol*. 2014;13:587–599, Table 1, p. 590.

factors is important. Parent training may entail teaching the parent to model more appropriate pain coping behaviors and to recognize the child's independent attempts to manage pain and function adaptively. Parents may also need referrals to obtain appropriate pain management for their own pain condition.

Pregabalin and duloxetine are FDA approved for management of fibromyalgia in adults; duloxetine is also approved for adolescents ages 13-17. However, the best evidence for the treatment of adolescents with fibromyalgia remains a multimodal approach including CBT and physical therapy. This is generally considered superior to solitary use of pharmacologic agents.

Erythromelalgia

Erythromelalgia in children is generally primary, whereas in adults it may be either primary or secondary to malignancy or other hematologic disorders, such as polycythemia vera (see Chapter 211.5). Patients with erythromelalgia exhibit red, warm, hyperperfused distal limbs. The disorder is usually bilateral and may involve either or both the hands and feet. Patients perceive burning pain and typically seek relief by immersing the affected extremities in ice water, sometimes so often and for so long so that skin pathology results. **Primary erythromelalgia** is caused by a gain of function pathogenic variant (autosomal dominant) in the gene for the NaV1.7 neuronal sodium channel on peripheral C nociceptive fibers, resulting in their spontaneous depolarization, and thus continuous burning pain. The most common pathogenic variant identified is in the *SCN9A* gene, although there are several variants that affect the NaV1.7 channel (Table 93.20). Other ion channel pathologic gene variants are associated with rare pain syndromes (see Table 93.20). Another pathogenic variant (loss of function) in the NaV1.7 channel results in a rare but serious genetic condition, the congenital indifference to pain.

Although some similarities to CRPS may be present in erythromelalgia, there are differences to distinguish the two conditions. CRPS in general is a unilateral phenomenon rather than bilateral. CRPS often presents with a cold, cyanotic limb (although "hot" CRPS with a warm, erythematous limb may occur as well). In addition, erythromelalgia is associated with intermittent pain compared with the more continuous nature and symptoms seen in CRPS. In erythromelalgia, ice water immersion is analgesic, the condition is bilateral and symmetric, and it is associated with hyperperfusion of the distal extremity.

The evaluation of hyperperfused limbs with burning pain should include genetic testing for **Fabry disease (alpha-galactosidase deficiency)** and screening for hematologic malignancies, with diagnosis of primary erythromelalgia being one of exclusion. The definitive treatment of Fabry disease includes enzyme replacement (as disease-modifying treatment) and administration of neuropathic pain medications such as gabapentin, although the success of antineuropathic pain drugs in small fiber neuropathies has not been impressive. The treatment of erythromelalgia is much more difficult. Antineuropathic pain medications (AEDs, TCAs) are typically prescribed but rarely helpful (see Fig. 93.4). Although one might predict that sodium channel–blocking AEDs might be effective in this sodium channelopathy, oxcarbazepine has not proved to be a particularly effective modality. The pain responds well to regional anesthetic nerve blocks, but it returns immediately when the effects of the nerve block resolve. In contrast, in other neuropathic syndromes, the analgesia usually (and inexplicably) persists well after the resolution of the pharmacologic nerve block. Aspirin and even nitroprusside infusions have been anecdotally reported to be of benefit with secondary erythromelalgia but have not been reported to be helpful in children with primary erythromelalgia. Case reports in adults and clinical experience in children suggest that periodic treatment with high-dose **capsaicin cream (8%)** may be effective in alleviating the burning pain and disability of erythromelalgia. Capsaicin (essence of chili pepper) cream is a vanilloid receptor (TRPV1) agonist that depletes small fiber peripheral nerve endings of the neurotransmitter substance P, an important neurotransmitter in the generation and transmission of nociceptive impulses. Once depleted, these nerve endings are no longer capable of generating spontaneous pain until the receptors regenerate, a process that takes many months.

Other Chronic Pain Conditions in Children

A variety of genetic and other medical/surgical conditions are often associated with chronic pain. Examples include Fabry disease, Chiari malformation/syringomyelia, epidermolysis bullosa, juvenile idiopathic arthritis, porphyria, mitochondrial disorders, degenerative neurologic diseases, cerebral palsy, ASD, intestinal pseudoobstruction, inflammatory bowel disease, chronic migraine/daily headaches, and irritable bowel disease. In many cases, treating the underlying disease, such as with enzyme replacement in Fabry disease and in other lysosomal disorders, will reduce what otherwise might be progression of symptoms but may not totally reduce pain and suffering, and other modalities will be needed. Pain that persists and is not well treated can lead to central sensitization and widespread pain, such as seen in children with one pain source who then develop fibromyalgia.

MANAGING COMPLEX CHRONIC PAIN PROBLEMS

Some patients with chronic pain have a prolonged course of evaluation in attempts to find what is expected as the singular "cause" of the pain and thus also undergo many failed treatments (see Chapter 212). Parents worry that the doctors have not yet discovered the cause that may be serious and life threatening, and children often feel not believed, that others perceive they are faking their pain or are "crazy." There may be no identifiable or diagnosable condition, and families may seek opinions from multiple treatment facilities to find help for their suffering child. For some children, what may have begun as an acute injury or infectious event may result in a chronic pain syndrome, with changes in the neurobiology of the pain-signaling system.

In the context of disabling chronic pain, it is very important for the pediatrician to avoid overmedication, because this can exacerbate associated disability. In addition, it is important to maintain an open mind and reassess the diagnosis if the clinical presentation changes. It is essential to communicate to the family that pain has a biologic basis (likely related to neural signaling and neurotransmitter dysregulation) and that the pain is naturally distressing to the child and family. All patients and families should receive a simple explanation of pain physiology that helps them understand the importance of (1) functional rehabilitation to normalize pain signaling, (2) the low risk of causing further injury with systematic increases in normal functioning, and (3) the likely failure of treatment if pain is managed as if it were acute. Because it is counterintuitive for most people to move a part of the body that hurts, many patients with chronic pain have atrophy or contractures of a painful extremity from disuse. Associated increases in worry and anxiety may exacerbate pain and leave the body even more vulnerable to further illness, injury, and disability.

Pain can have a significant impact on many areas of normal functioning and routines for children, and school absenteeism and related consequences of missed schooling are often significant problems. Appropriate assessment and evaluation of the child with chronic pain and the family is the critical first step in developing a treatment plan. For example, a high–academically functioning child might have an acute injury that leads to chronic pain and significant school absenteeism. Although many downstream contributors to pain and disability maintenance can accumulate the more school that is missed, often previously unrecognized focal learning disabilities may become the increasing trigger for a downhill cascade of pain, disability, and school absenteeism. Even for the child with outstanding grades, it may be helpful to learn about the amount of time spent on each subject. As certain subjects become more complicated, such as math, the child with a previously unrecognized math learning disability may be spending hours on math homework each night, even with good grades in math. In this case, the acute illness or injury becomes the "final straw" that breaks down the child's coping and turns the acute pain into a chronic problem.

Interdisciplinary pediatric pain programs have become the standard of care for treating complex chronic pain problems in youth. Although available in many parts of the United States, Canada, Europe, Australia, and New Zealand, the overall number of programs is still small. Therefore many children and adolescents with chronic pain will

be unable to receive specialized pain treatment in their local communities. In recognition of the severity and complexity of pain and disability for some children, different settings and treatment delivery models for providing pain care have been explored. One option is inpatient and day hospital treatment programs, which often address barriers to access to outpatient treatment and coordination of care. In addition, these programs provide an intensive treatment option for children who do not make adequate progress in outpatient treatment or who are severely disabled by pain. Early programs developed in the 1990s focused on CRPS treatment through intensive inpatient rehabilitation and exercise-based programs. Later programs expanded to other clinical populations and broadened the treatment focus to incorporate a range of rehabilitation and psychologic therapies delivered both individually and in groups. The typical length of inpatient admissions for children with chronic pain in such programs is 3-4 weeks, and emerging evidence suggests benefit from these programs. A major problem that limits such care for children with complex chronic disabling pain is the long waiting list for entry into these programs, as well as obtaining financial coverage for the treatment. Additional, more widespread models of care are needed.

Another intervention delivery option is *remote management,* referring to pain interventions used outside the clinic/hospital setting to reach children in their homes or communities. Interventions are typically delivered using some form of technology, such as the internet, or may rely on other media, such as telephone counseling or written self-help materials. Typically, remote management of pain includes monitoring, counseling, and delivery of behavioral and CBT interventions. Internet interventions have received the most research attention to date, with published examples of several different pediatric chronic pain conditions with promising findings for pain reduction. *Telemedicine* may offer additional ways to connect experts in pediatric pain with patients in remote communities. Within any community, the pediatrician will need to locate appropriate referral sources for patients with complex chronic pain. However, although psychologic interventions can be delivered through these telemedicine strategies, the pediatrician is still relied on to obtain the needed biopsychosocial history, complete a thorough physical examination, and provide the pharmacologic management as needed. The pediatrician also communicates with the family to help the child and family understand the pain and how the different pharmacologic and nonpharmacologic treatments will enhance function and alter the long-term neural processes underlying pain.

Chapter 94

Poisoning

Jillian L. Theobald and Justin N. Corcoran

Poisoning is the leading cause of injury-related death in the United States, surpassing that from motor vehicle crashes. Most of these deaths are unintentional (i.e., not suicide). In adolescents, poisoning is the second leading cause of injury-related death. Of the more than 2 million human poisoning exposures reported annually to the National Poison Data System (NPDS) of the American Association of Poison Control Centers (AAPCC), approximately 50% occur in children <6 years old, with the highest number of exposures occurring in 1- and 2-year-olds. Almost all these exposures are unintentional and reflect the propensity for young children to put virtually anything in their mouth. Fortunately, children <6 years old account for <2% of all poisoning fatalities reported to NPDS.

More than 90% of toxic exposures in children occur in the home, and most involve a single substance. Ingestion accounts for the majority of exposures, with a minority occurring by the dermal, inhalational, and ophthalmic routes. Approximately 40% of cases involve nondrug substances, such as cosmetics, personal care items, cleaning solutions, plants, and foreign bodies. Pharmaceutical preparations account for the remainder of exposures, and analgesics, topical preparations, vitamins, and antihistamines are most commonly reported.

The majority of poisoning exposures in children <6 years old can be managed without direct medical intervention beyond a call to the regional **poison control center (PCC)**. This is because the product involved is not inherently toxic or the quantity of the material is not sufficient to produce clinically relevant toxic effects. However, a number of substances can be highly toxic to toddlers in small doses (Table 94.1). In 2019, carbon monoxide (CO), batteries, and analgesics (mainly opioids) were the leading identifiable causes of poison-related fatalities in young children (<6 years). In addition, anesthetics, antihistamines, chemicals, cough and cold preparations, tobacco/nicotine/e-cigarette products, and hydrocarbons were significant causes of mortality.

Poison prevention education should be an integral part of all well-child visits, starting at the 6-month visit. Counseling parents and other caregivers about potential poisoning risks, poison-proofing a child's environment, and actions in the event of an ingestion diminish the likelihood of serious morbidity or mortality. Poison prevention education materials are available from the American Academy of Pediatrics (AAP) and regional PCCs. Through a U.S. network of PCCs, anyone at any time can contact a regional poison center by calling the toll-free number **1-800-222-1222**. Parents should be encouraged to share this number with grandparents, relatives, babysitters, and any other caregivers.

Product safety measures, poison prevention education, early recognition of exposures, and around-the-clock access to regionally based PCCs all contribute to the favorable exposure outcomes in young children. Poisoning exposures in children 6-12 years are much less common, involving only approximately 10% of all reported pediatric exposures. A second peak in pediatric exposures occurs in adolescence. Exposures in the adolescent age-group are primarily intentional (suicide or abuse or misuse of substances) and thus often result in more severe toxicity (see Chapter 157). Families should be informed and given anticipatory guidance that nonprescription and prescription medications, and even household products (e.g., inhalants), are common sources of adolescent exposures. Although adolescents (age 13-19 years) account for only about 16% of pediatric exposures, they constitute a larger proportion of deaths. Of the 159 poison-related pediatric deaths in 2021 reported to NPDS, 86 were adolescents (2% of all fatalities called in to poison centers). Pediatricians should be aware of the signs of drug abuse or suicidal ideation in adolescents and should aggressively intervene (see Chapter 40).

PREVENTION

Deaths caused by unintentional poisoning among younger children have decreased dramatically over the past 2 decades, particularly among children <5 years old. In 1970, when the U.S. Poison Packaging Prevention Act was passed, 226 poisoning deaths of children <5 years old occurred, compared with only 25 in 2021. Poisoning prevention demonstrates the effectiveness of passive strategies, including the use of child-resistant packaging and limited doses per container. Difficulty using child-resistant containers by adults is an important cause of poisoning in young children today. In 18.5% of households in which poisoning occurred in children <5 years old, the child-resistant closure was replaced, and 65% of the packaging used did not work properly. Almost 20% of ingestions occur from drugs belonging to grandparents, who have difficulty using traditional child-resistant containers and often put their medications in pill organizers that are not childproof.

Even though there has been success in preventing poisoning in young children, there has been a remarkable rise in adolescent poison-related death over the past 20 years. This has mirrored the increasing rate of antidepressant prescriptions written by healthcare providers and the epidemic increase in opioid-related fatalities.

Table 94.1 Common Agents Potentially Toxic to Young Children (<6 yr) in Small Doses*

SUBSTANCE	TOXICITY
Aliphatic hydrocarbons (e.g., gasoline, kerosene, lamp oil)	Acute lung injury
Antimalarials (chloroquine, quinine)	Seizures, dysrhythmias
Benzocaine	Methemoglobinemia
β-Adrenergic receptor blockers†	Bradycardia, hypotension
Calcium channel blockers	Bradycardia, hypotension, hyperglycemia
Camphor	Seizures
Caustics (pH <2 or >12)	Airway, esophageal and gastric burns
Clonidine	Lethargy, bradycardia, hypotension
Diphenoxylate and atropine (Lomotil)	CNS depression, respiratory depression
Ethylene glycol	Altered mental status, seizures
Hypoglycemics, oral (sulfonylureas and meglitinides)	Hypoglycemia, seizures
Imidazolines (oxymetazoline, tetrahydrozoline)	CNS depression, respiratory depression
Laundry detergent packets (pods)	Airway issues, respiratory distress, altered mental status
Lindane	Seizures
Marijuana (cannabis, THC)	Lethargy, seizures, coma
Monoamine oxidase inhibitors	Hypertension followed by delayed cardiovascular collapse
Methyl salicylate	Tachypnea, metabolic acidosis, seizures
Opioids (especially methadone, buprenorphine)	CNS depression, respiratory depression
Organophosphate pesticides	Cholinergic crisis
Phenothiazines (especially chlorpromazine, thioridazine)	Seizures, dysrhythmias
Sulfonylureas (glipizide, glyburide)	Hypoglycemia
Theophylline	Seizures, dysrhythmias
Tricyclic antidepressants	CNS depression, seizures, dysrhythmias, hypotension

*"Small dose" typically implies one to two pills or 5 mL.
†Lipid-soluble β blockers (e.g., propranolol) are more toxic than water-soluble β blockers (e.g., atenolol).
CNS, Central nervous system.

APPROACH TO THE POISONED PATIENT

The initial approach to the patient with a witnessed or suspected poisoning should be no different than that in any other sick child, starting with stabilization and rapid assessment of the airway, breathing, circulation (pulse, blood pressure), and mental state. In any patient with altered mental status, a serum glucose concentration should be obtained early, and naloxone administration should be considered if there is coma or respiratory depression. A targeted history and physical examination serve as the foundation for a thoughtful differential diagnosis, which can then be further refined through laboratory testing and other diagnostic studies.

History

Obtaining an accurate problem-oriented history is of paramount importance. *Intentional* poisonings (suicide attempts, drug abuse/misuse) are typically more severe than unintentional, exploratory ingestions. In patients without a witnessed exposure, historical features such as age of the child (toddler or adolescent), acute onset of symptoms without prodrome, multisystem organ dysfunction, or high levels of household stress should suggest a possible diagnosis of poisoning. In patients with a witnessed exposure, determining exactly what the child was exposed to and the circumstances surrounding the exposure is crucial to initiating directed therapy quickly. For household and workplace products, names (brand, generic, chemical) and specific ingredients, along with their concentrations, can often be obtained from the labels. PCC specialists can also help to identify possible ingredients and review the potential toxicities of each component. Poison center specialists can also help identify pills based on markings, shape, and color. If referred to the hospital for evaluation, parents should be instructed to bring the products, pills, and/or containers with them to assist with identifying and quantifying the exposure. If a child is found with an unknown pill, a list of all medications in the child's environment, including medications that grandparents, parents, siblings, caregivers, or other visitors might have brought into the house, must be obtained. In the case of an unknown exposure, clarifying where the child was found (e.g., garage, kitchen, laundry room, bathroom, backyard, workplace) can help to generate a list of potential toxins.

Next, it is important to clarify the *timing* of the ingestion and to obtain some estimate of how much of the substance may have been ingested. It is better to overestimate the amount ingested to prepare for the worst-case scenario. Counting pills or measuring the remaining volume of a liquid ingested can sometimes be useful in generating estimates. For inhalational, ocular, or dermal exposures, the concentration of the agent and the length of contact time with the material should be determined, if possible.

Symptoms

Obtaining a description of symptoms experienced after ingestion, including their timing of onset relative to the time of ingestion and their progression, can generate a list of potential toxins and help anticipate the severity of the ingestion. Coupled with physical exam findings, reported symptoms assist practitioners in identifying **toxidromes**, or recognized poisoning syndromes, suggestive of toxicity from specific substances or classes of substances (Tables 94.2 to 94.5).

Past Medical and Developmental History

Underlying diseases can make a child more susceptible to the effects of a toxin. Concurrent drug therapy can also increase toxicity because certain drugs may interact with the toxin. A history of psychiatric illness can make patients more prone to substance abuse, misuse, intentional ingestions, and polypharmacy complications. Pregnancy is a common precipitating factor in adolescent suicide attempts and can influence both evaluation of the patient and subsequent treatment. A developmental history is important to ensure that the exposure history provided is appropriate for the child's developmental stage (e.g., report of 6-month-old picking up a large container of laundry detergent and drinking it should indicate a "red flag").

Social History

Understanding the child's social environment helps to identify potential sources of exposure (caregivers, visitors, grandparents, recent parties or social gatherings) and social circumstances (new baby, parent's illness, financial stress) that might have contributed to the ingestion (suicide or unintentional). Unfortunately, some poisonings occur in the setting of serious neglect or intentional abuse.

Table 94.2 Selected Historical and Physical Findings in Poisoning

SIGN	TOXIN
ODOR	
Bitter almonds	Cyanide
Acetone	Isopropyl alcohol, methanol, paraldehyde, salicylates
Rotten eggs	Hydrogen sulfide, sulfur dioxide, methyl mercaptans (additive to natural gas)
Wintergreen	Methyl salicylate
Garlic	Arsenic, thallium, organophosphates, selenium
Mothballs	Camphor, naphthalene
Freshly mowed hay	Phosgene
Carrots	Water hemlock
Gasoline	Petroleum distillates
OCULAR SIGNS	
Miosis	Opioids (except propoxyphene, meperidine, and pentazocine), organophosphates and other cholinergics, clonidine, phenothiazines (typical antipsychotics), sedative-hypnotics, olanzapine
Mydriasis	Anticholinergics (e.g., antihistamines, TCAs, atropine), sympathomimetics (cocaine, amphetamines, PCP), post–anoxic encephalopathy, opiate withdrawal, cathinones, MDMA
Nystagmus	Anticonvulsants, sedative-hypnotics, alcohols, PCP, ketamine, dextromethorphan
Lacrimation	Organophosphates, irritant gas or vapors
Retinal hyperemia	Methanol
CUTANEOUS SIGNS	
Diaphoresis	Cholinergics (organophosphates), sympathomimetics, salicylates, phencyclidine (PCP), withdrawal syndromes
Alopecia	Thallium, arsenic
Erythema	Boric acid, elemental mercury, cyanide, carbon monoxide, disulfiram, scombroid, anticholinergics, vancomycin
Cyanosis (unresponsive to oxygen)	Methemoglobinemia (e.g., benzocaine, dapsone, nitrites, phenazopyridine), amiodarone, silver
Bullae/blisters	Barbiturates, mustard gas, xylazine, snake, spiders
ORAL SIGNS	
Salivation	Organophosphates, salicylates, corrosives, ketamine, PCP, strychnine
Oral burns	Corrosives, oxalate-containing plants
Gum lines	Lead, mercury, arsenic, bismuth
GASTROINTESTINAL SIGNS	
Diarrhea	Antimicrobials, arsenic, iron, boric acid, cholinergics, colchicine, opioid withdrawal
Hematemesis	Arsenic, iron, caustics, NSAIDs, salicylates
Constipation	Lead
CARDIAC SIGNS	
Tachycardia	Sympathomimetics, anticholinergics, antidepressants, antipsychotics, methylxanthines (theophylline, caffeine), salicylates, cellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide), withdrawal (ethanol, sedatives, clonidine, opioids), serotonin syndrome, neuroleptic malignant syndrome, MDMA, cathinones
Bradycardia	β Blockers, calcium channel blockers, digoxin, clonidine, organophosphates, opioids, sedative-hypnotics xylazine
Hypertension	Sympathomimetics, anticholinergics, monoamine oxidase inhibitors, serotonin syndrome, nicotine, caffeine, neuroleptic malignant syndrome, clonidine withdrawal
Hypotension	β Blockers, calcium channel blockers, cyclic antidepressants, iron, antipsychotics, barbiturates, clonidine, opioids, arsenic, amatoxin mushrooms, cellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide), snake envenomation, xylazine
RESPIRATORY SIGNS	
Depressed respirations	Opioids, sedative-hypnotics, alcohol, clonidine, marijuana, barbiturates, xylazine
Tachypnea	Salicylates, sympathomimetics, caffeine, metabolic acidosis, carbon monoxide, hydrocarbon aspiration
CENTRAL NERVOUS SYSTEM SIGNS	
Ataxia	Alcohols, anticonvulsants, sedative-hypnotics, lithium, dextromethorphan, carbon monoxide, inhalants
Coma	Opioids, sedative-hypnotics, anticonvulsants, antidepressants, antipsychotics, ethanol, anticholinergics, clonidine, GHB, alcohols, salicylates, barbiturates, hypoglycemics, lead, arsenic, rohypnol, carbon monoxide
Seizures	Sympathomimetics, anticholinergics, antidepressants (especially TCAs, bupropion, venlafaxine), cholinergics (organophosphates), isoniazid, camphor, lindane, salicylates, lead, nicotine, tramadol, water hemlock, withdrawal (especially ethanol), strychnine, cocaine
Delirium/psychosis	Sympathomimetics, anticholinergics, LSD, PCP, hallucinogens, lithium, dextromethorphan, steroids, withdrawal, MDMA, cathinones
Peripheral neuropathy	Lead, arsenic, mercury, organophosphates, nicotine
Hypothermia	Carbon monoxide, opioids, oral hypoglycemics, liquor, sedative-hypnotics
Hyperthermia	Antihistamines, amphetamines, salicylates, antidepressants (TCAs), antipsychotics, serotonin syndrome, neuroleptic malignant syndrome, withdrawal (alcohol, baclofen)

GHB, γ-Hydroxybutyrate; LSD, lysergic acid diethylamide; MDMA, 3,4-methylenedioxymethamphetamine (ecstasy); NSAIDs, nonsteroidal antiinflammatory drugs; PCP, phencyclidine; TCAs, tricyclic antidepressants.

Table 94.3 Recognizable Poison Syndromes ("Toxidromes")

	SIGNS						
TOXIDROME	**VITAL SIGNS**	**MENTAL STATUS**	**PUPILS**	**SKIN**	**BOWEL SOUNDS**	**OTHER**	**POSSIBLE TOXINS**
Sympathomimetic	Hypertension, tachycardia, hyperthermia	Agitation, psychosis, delirium, violence	Dilated	Diaphoretic, flushed	Normal to increased		Amphetamines, cocaine, PCP, bath salts (cathinones), ADHD medication
Anticholinergic	Hypertension, tachycardia, hyperthermia	Agitated, delirium, coma, seizures	Dilated	Dry, hot, flushed	Diminished	Ileus, urinary retention	Antihistamines, TCAs, atropine, jimsonweed
Cholinergic	Bradycardia, BP and temp typically normal	Confusion, coma, fasciculations	Small	Diaphoretic	Hyperactive	Diarrhea, urination, bronchorrhea, bronchospasm, emesis, lacrimation, salivation	Organophosphates (insecticides, nerve agents), carbamates (physostigmine, neostigmine, pyridostigmine) Alzheimer medications, myasthenia treatments
Opioids	Respiratory depression, bradycardia, hypotension, hypothermia	Depression, coma, euphoria	Pinpoint	Normal	Normal to decreased		Methadone, buprenorphine, morphine, oxycodone, heroin, etc.
Sedative-hypnotics	Respiratory depression, HR normal to decreased, BP normal to decreased, temp normal to decreased	Somnolence, coma	Small or normal	Normal	Normal		Barbiturates, benzodiazepines, ethanol xylazine
Serotonin syndrome (similar findings with neuroleptic malignant syndrome)	Hyperthermia, tachycardia, hypertension or hypotension (autonomic instability)	Agitation, confusion, coma	Dilated	Diaphoretic	Increased	Neuromuscular hyperexcitability: clonus, hyperreflexia (lower > upper extremities)	SSRIs, lithium, MAOIs, linezolid, tramadol, meperidine, dextromethorphan
Salicylates	Tachypnea, hyperpnea, tachycardia, hyperthermia	Agitation, confusion, coma	Normal	Diaphoretic	Normal	Nausea, vomiting, tinnitus, ABGs with primary respiratory alkalosis and primary metabolic acidosis; tinnitus or difficulty hearing	Aspirin and aspirin-containing products, methyl salicylate
Withdrawal (sedative-hypnotic)	Tachycardia, tachypnea, hyperthermia	Agitation, tremor, seizure, hallucinosis, delirium tremens	Dilated	Diaphoretic	Increased		Lack of access to ethanol, benzodiazepines, barbiturates, GHB, or excessive use of flumazenil
Withdrawal (opioid)	Tachycardia	Restlessness, anxiety	Dilated	Diaphoretic	Hyperactive	Nausea, vomiting, diarrhea	Lack of access to opioids or excessive use of naloxone

ABGs, Arterial blood gases; ADHD, attention-deficit/hyperactivity disorder; BP, blood pressure; GHB, γ-hydroxybutyrate; HR, heart rate; MAOIs, monoamine oxidase inhibitors; PCP, phencyclidine; SSRIs, selective serotonin reuptake inhibitors; temp, temperature; TCAs, tricyclic antidepressants.

Table 94.4 Mini-Toxidromes

TOXIDROME	SYMPTOMS AND SIGNS	EXAMPLES
α_1-Adrenergic receptor antagonists	CNS depression, tachycardia, miosis	Chlorpromazine, quetiapine, clozapine, olanzapine, risperidone
α_2-Adrenergic receptor agonist	CNS depression, bradycardia, hypertension (early), hypotension (late), miosis	Clonidine, oxymetazoline, tetrahydrozoline, tizanidine, dexmedetomidine
Clonus/myoclonus	CNS depression, myoclonic jerks, clonus, hyperreflexia	Carisoprodol, lithium, serotonergic agents, bismuth, organic lead, organic mercury, serotonin or neuroleptic malignant syndrome
Sodium channel blockers	CNS toxicity, wide QRS	Cyclic antidepressants and structurally related agents, propoxyphene, quinidine/quinine, amantadine, antihistamines, bupropion, cocaine
Potassium channel blockers	CNS toxicity, long QT interval	Antipsychotics, methadone, phenothiazines
Cathinones, synthetic cannabinoids	Hyperthermia, tachycardia, delirium, agitation, mydriases	See Chapter 157.

CNS, Central nervous system.
From Ruha AM, Levine M. Central nervous system toxicity. *Emerg Med Clin North Am.* 2015;32(1):205–221, p. 208.

Table 94.5 Predicting Toxicity from Vital Signs

BRADYCARDIA (PACED)
Propranolol (β blockers), poppies (opioids), propoxyphene, physostigmine
Anticholinesterase drugs, antiarrhythmics
Clonidine, calcium channel blockers
Ethanol or other alcohols
Digoxin, digitalis

TACHYCARDIA (FAST)
Free base or other forms of cocaine, Freon
Anticholinergics, antihistamines, antipsychotics amphetamines, alcohol withdrawal
Sympathomimetics (cocaine, caffeine, amphetamines, phencyclidine [PCP]), solvent abuse, strychnine
Theophylline, tricyclic antidepressants (TCAs), thyroid hormones

HYPOTHERMIA (COOLS)
Carbon monoxide
Opioids
Oral hypoglycemics, insulin
Liquor (alcohols)
Sedative-hypnotics

HYPERTHERMIA (NASA)
Neuroleptic malignant syndrome (NMS), nicotine
Antihistamines, alcohol withdrawal
Salicylates, sympathomimetics, serotonin syndrome
Anticholinergics, antidepressants, antipsychotics

HYPOTENSION (CRASH)
Clonidine, calcium channel blockers
Rodenticides (containing arsenic, cyanide)
Antidepressants, aminophylline, antihypertensives
Sedative-hypnotics (xylazine)
Heroin or other opioids

HYPERTENSION (CT SCAN)
Cocaine
Thyroid supplements
Sympathomimetics
Caffeine
Anticholinergics, amphetamines
Nicotine

RAPID RESPIRATION (PANT)
PCP, paraquat, pneumonitis, phosgene
Acetylsalicylic acid (ASA) and other salicylates
Noncardiogenic pulmonary edema, nerve agents
Toxin-induced metabolic acidosis

SLOW RESPIRATION (SLOW)
Sedative-hypnotics (barbiturates, benzodiazepines, xylazine)
Liquor (alcohols)
Opioids
Weed (marijuana)

From Meehan TJ. Approach to the poisoned patient. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. *Rosen's Emergency Medicine*, 9th ed. Philadelphia: Elsevier; 2018, Box 139.6, p. 1816.

Physical Examination

A targeted physical examination is important to identifying the potential toxin and assessing the severity of the exposure. Initial efforts should be directed toward assessing and stabilizing the airway, breathing, circulation, and mental status. Once the airway is secure and the patient is stable from a cardiopulmonary standpoint, a more extensive physical exam can help to identify characteristic findings of specific toxins or classes of toxins.

In the poisoned patient, key features of the physical exam are vital signs, mental status, pupils (size, reactivity), nystagmus, skin, bowel sounds, and muscle tone. These findings might suggest a toxidrome, which can then guide the differential diagnosis and management.

Laboratory Evaluation

A basic chemistry panel (electrolytes, renal function, glucose) is necessary for all poisoned or potentially poisoned patients. Any patient with acidosis (low serum bicarbonate level on serum chemistry panel) must have an anion gap calculated because of the more specific differential diagnoses associated with an elevated **anion gap metabolic acidosis** (Table 94.6). Patients with a known overdose of acetaminophen should have liver transaminases (alanine transaminase [ALT], aspartate transaminase [AST]) and international normalized ratio (INR) assessed. A serum creatinine kinase level is indicated on any patient with a prolonged "down time" to evaluate for **rhabdomyolysis**. A urine pregnancy test is mandatory for all postpubertal female patients. Based

Table 94.6 Laboratory Clues in Toxicologic Diagnosis

ANION GAP METABOLIC ACIDOSIS (MNEMONIC = MUDPILES CAT)
Methanol, metformin
Uremia
Diabetic ketoacidosis
Propylene glycol
Isoniazid, iron, massive ibuprofen
Lactic acidosis
Ethylene glycol
Salicylates
Cellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide)
Alcoholic ketoacidosis
Tylenol (clinical significance depends upon presence or absence of liver injury), toluene

ELEVATED OSMOLAR GAP
Alcohols: ethanol, isopropyl, methanol, ethylene glycol

HYPOGLYCEMIA (MNEMONIC = HOBBIES)
Hypoglycemics, oral: sulfonylureas, meglitinides
Other: quinine, unripe ackee fruit
Beta Blockers
Insulin
Ethanol
Salicylates (late)

HYPERGLYCEMIA
Salicylates (early)
Calcium channel blockers
Caffeine

HYPOCALCEMIA
Ethylene glycol
Fluoride

RHABDOMYOLYSIS
Neuroleptic malignant syndrome, serotonin syndrome
Statins
Mushrooms (Tricholoma equestre)
Any toxin causing prolonged immobilization (e.g., opioids, antipsychotics) or excessive muscle activity or seizures (e.g., sympathomimetics)

RADIOPAQUE SUBSTANCE ON KUB (MNEMONIC = CHIPPED)
Chloral hydrate, calcium carbonate
Heavy metals (lead, zinc, barium, arsenic, lithium, bismuth)
Iron
Phenothiazines
Play-Doh, potassium chloride
Enteric-coated pills
Dental amalgam, drug packets

KUB, Kidney-ureter-bladder radiograph.

on the clinical presentation and the presumed poison, additional laboratory tests may also be helpful. Acetaminophen is a widely available medication and a commonly detected co-ingestant with the potential for severe toxicity. There is an effective antidote to acetaminophen poisoning that is time dependent. Given that patients might initially be asymptomatic and might not report or be aware of acetaminophen ingestion, an acetaminophen level should be checked in all patients who present after an intentional exposure or ingestion.

For select intoxications (e.g., salicylates, some anticonvulsants, acetaminophen, iron, digoxin, methanol, ethanol, lithium, ethylene glycol, theophylline, CO, lead), **quantitative blood concentrations** are integral to confirming the diagnosis and formulating a treatment plan. However, for most other exposures, quantitative measurement is not readily available and is not likely to alter management. All intoxicant levels must be interpreted in conjunction with the history. For example, a methanol level of 20 mg/dL 1 hour after ingestion may be nontoxic, whereas a similar level 24 hours after ingestion implies a significant poisoning. In general, patients with multiple or chronic exposures to a drug or other chemical will be more symptomatic at lower drug levels than those with a single acute exposure.

Both the rapid urine drug-of-abuse screens and the more comprehensive drug screens vary widely in their ability to detect toxins and generally add little information to the clinical assessment. This is particularly true if the agent is known and the patient's symptoms are consistent with that agent. If a drug screen is ordered, it is important to know that the components screened for, and the lower limits of detection, vary from laboratory to laboratory. In addition, the interpretation of most drug screens is hampered by many false-positive and false-negative results. Many opiate toxicology screens poorly detect hydrocodone and do not detect the fully synthetic opioids at all (e.g., meperidine, methadone, buprenorphine, fentanyl, carfentanil, furanylfentanyl, tramadol). Several common benzodiazepines (e.g., alprazolam and clonazepam) may not be detected; synthetic cannabinoids or "bath salts" may also be missed. The amphetamine screen, on the other hand, is typically overly sensitive and often is triggered by prescription amphetamines and some over-the-counter cold preparations. As such, the urine drug-of-abuse screen is typically of limited utility for the poisoned patient but may serve a useful function for other providers, including psychiatrists, in their evaluation of the adolescent patient. Urine drug-of-abuse screens are potentially helpful in patients with altered mental status of unknown etiology, persistent unexplained tachycardia, and acute myocardial ischemia or stroke at a young age. These screens can also be useful in the assessment of a neglected or abused child. Consultation with a medical toxicologist can be helpful in interpreting drug screens and directing which specific drug levels or other laboratory analyses might aid in patient management.

In the case of a neglected or allegedly abused child, a positive toxicology screen can add substantial weight to a claim of abuse or neglect. In these cases, and any case with medicolegal implications, any positive screen *must* be followed by confirmatory testing (most commonly via gas chromatography/mass spectroscopy), which is considered the gold-standard measurement for legal purposes.

Additional Diagnostic Testing

An electrocardiogram (ECG) is a quick and noninvasive bedside test that can yield important clues to diagnosis and prognosis. Particular attention should be paid to the ECG intervals (Table 94.7). A widened QRS interval, putting the patient at risk for monomorphic ventricular tachycardia, suggests blockade of fast sodium channels. A widened QTc interval suggests effects at the potassium rectifier channels and portends a risk of torsades de pointes (polymorphic ventricular tachycardia).

Further diagnostic testing is based on the differential diagnosis and pattern of presentation. For example, adjunctive chest radiography may reveal signs of pneumonitis (e.g., hydrocarbon aspiration), noncardiogenic pulmonary edema (e.g., salicylate toxicity), or a foreign body. Abdominal radiography is most helpful in screening for the presence of lead paint chips or other foreign bodies. It may detect a *bezoar* (concretion), demonstrate radiopaque tablets, or reveal drug packets in a "body packer."

PRINCIPLES OF MANAGEMENT

The principles of management of the poisoned patient are supportive care, decontamination, directed therapy, and enhanced elimination. Few patients meet criteria for all these interventions, although clinicians should consider each option in every poisoned patient so as not to miss a potentially lifesaving intervention. Antidotes are available for relatively few poisons (Tables 94.8 and 94.9), thus emphasizing the importance of meticulous supportive care and close clinical monitoring.

Poison control center personnel are specifically trained to provide expertise in the management of poisoning exposures. Parents should be instructed to call the poison control center **(1-800-222-1222)** for any concerning exposure. PCC specialists can assist parents in assessing the potential toxicity and severity of the exposure. They can further determine which children can be safely monitored at home and which children should be referred to the emergency department for further evaluation and care. Although up to one third of calls to PCCs involve hospitalized patients, 86% of PCC calls for exposures in children <6 years old are managed at home. The AAPCC has generated consensus statements for out-of-hospital management of common ingestions (e.g., acetaminophen, iron, calcium channel blockers [CCBs]) that serve to guide poison center recommendations.

Supportive Care

Careful attention is paid first to the "ABCs" of airway, breathing, and circulation; there should be a low threshold to aggressively manage the airway of a poisoned patient because of the patient's propensity to quickly become comatose. Endotracheal intubation is often the only significant intervention needed in many poisoned patients. An important caveat is the tachypneic patient with a clear lung examination and normal oxygen saturation. This should alert the clinician to the likelihood that the patient is compensating for an acidemia. Paralyzing such a patient and underventilating might prove fatal. If intubation is necessary for airway protection or a tiring patient, a good rule of thumb is to match the ventilatory settings to the patient's preintubation minute ventilation.

Hypotensive poisoned patients often are not hypovolemic, and aggressive fluid resuscitation may lead to fluid overload. If hypotension persists after one to two standard boluses of crystalloid, infusion of a direct-acting vasopressor, such as norepinephrine or epinephrine, is preferred. Dysrhythmias are typically managed in the standard manner. The exceptions are for dysrhythmias caused by agents that block fast sodium channels of the heart, for which boluses of sodium bicarbonate are given; dysrhythmias caused by hydrocarbons, which should be treated with β blockers; and an overall avoidance of amiodarone for toxicologic-induced arrythmias.

Seizures should primarily be managed with agents that potentiate the γ-aminobutyric acid (GABA) complex, such as benzodiazepines or barbiturates. Using sodium channel blockers such as phenytoin is likely to be ineffective and potentially harmful. The goal of supportive therapy is to support the patient's vital functions until the patient can eliminate the toxin. Patients with an elevated creatine phosphokinase (CPK) should be aggressively hydrated with crystalloid, with a goal urine output of 1-2 mL/kg/hr and close monitoring of CPK trend.

Decontamination

Most poisonings in children are from ingestion, although exposures can also occur by inhalational, dermal, and ocular routes (Table 94.10). The goal of decontamination is to minimize absorption of the toxic substance. The specific method employed depends on the properties of the toxin itself and the route of exposure. Regardless of the decontamination method used, the efficacy of the intervention decreases with increasing time since exposure. *Decontamination should not be routinely employed for every poisoned patient.* Instead, careful decisions regarding the utility of decontamination should be made for each patient and should include consideration of the toxicity and pharmacologic properties of the exposure, route of the exposure, time since the exposure, and risks vs benefits of the decontamination method.

Dermal and ocular decontamination begins with removal of any contaminated clothing and particulate matter, followed by flushing of the affected area with tepid water or normal saline (NS). Treating clinicians should wear proper protective gear when performing irrigation. Flushing for a minimum of 10-20 minutes is recommended for most exposures, although some chemicals (e.g., alkaline corrosives) require much longer periods of flushing. Dermal decontamination, especially after exposure to adherent or lipophilic (e.g., organophosphates) agents, should include thorough cleansing with soap and water. Water should *not* be used for decontamination after exposure to highly reactive agents, such as elemental sodium, phosphorus, calcium oxide, and titanium tetrachloride. After an inhalational exposure, decontamination involves moving the patient to fresh air and administering supplemental oxygen if indicated.

Gastrointestinal (GI) decontamination strategies are most likely to be effective in the 1-2 hours after an acute ingestion. GI absorption may be delayed after ingestion of agents that slow GI motility (anticholinergic medications, opioids), massive amounts of pills, sustained-release (SR) preparations, and agents that can form pharmacologic bezoars (e.g., enteric-coated salicylates). GI decontamination more than 2 hours after ingestion may be considered in patients who ingest toxic substances with these properties. However, even rapid institution of GI decontamination with activated charcoal will bind only approximately 30% of the ingested substance. GI decontamination should never supplant excellent supportive care and should not be employed in an unstable or persistently vomiting patient. Methods of GI decontamination include induced emesis with ipecac, gastric lavage, cathartics, activated charcoal, and whole-bowel irrigation (WBI). *Of these, only activated charcoal and WBI are of potential benefit.*

Table 94.8 Common Antidotes for Poisoning

POISON	ANTIDOTE	DOSAGE	ROUTE	ADVERSE EFFECTS, WARNINGS, COMMENTS
Acetaminophen	*N*-Acetylcysteine (Mucomyst)	140 mg/kg loading, followed by 70 mg/kg q4h for 17 additional doses (total of 72 hr)	PO	Vomiting (patient-tailored regimens are the norm)
	N-Acetylcysteine (Acetadote)	150 mg/kg over 1 hr, followed by 50 mg/kg over 4 hr, followed by 100 mg/kg over 16 hr	IV	Anaphylactoid reactions (most commonly seen with loading dose) Higher doses of the infusion are often recommended depending on acetaminophen level or degree of injury
Anticholinergics	Physostigmine	0.02 mg/kg over 5 min; may repeat q5-10 min to 2 mg max	IV/IM	Bradycardia, seizures, bronchospasm *Note:* Relatively contraindicated if conduction delays on ECG.
Benzodiazepines	Flumazenil	0.2 mg over 30 sec; if response is inadequate, repeat q1min to 1 mg max	IV	Agitation, seizures from precipitated withdrawal (doses over 1 mg) **Relatively contraindicated for unknown or polypharmacy ingestions**
β Blockers	Glucagon	0.15 mg/kg bolus followed by infusion of 0.05-0.15 mg/kg/hr	IV	Vomiting, relative lack of efficacy
Calcium channel blockers	Insulin	1 unit/kg bolus followed by infusion of 1-10 units/kg/hr	IV	Hypoglycemia Follow serum potassium and glucose closely.
	Calcium salts	Dose depends on the specific calcium salt	IV	
Carbon monoxide	Oxygen	100% FIO_2 by non-rebreather mask (or ETT if intubated)	Inhalation	Some patients may benefit from hyperbaric oxygen (see text).
Cyanide	Hydroxocobalamin (Cyanokit)	70 mg/kg (adults: 5 g) given over 15 min	IV	Flushing/erythema, nausea, rash, chromaturia, hypertension, headache
Digitalis	Digoxin-specific Fab antibodies (Digibind, DigiFab)	1 vial binds 0.6 mg of digitalis glycoside; #vials = digitalis level × weight in kg/100	IV	Allergic reactions (rare), return of condition being treated with digitalis glycoside
Ethylene glycol, methanol	Fomepizole	15 mg/kg load; 10 mg/kg q12h × 4 doses; 15 mg/kg q12h until ethylene glycol level is <20 mg/dL	IV	Infuse slowly over 30 min If fomepizole is not available, can treat with oral ethanol (80 proof)
Iron	Deferoxamine	Infusion of 15 mg/kg/hr (max: 6 g/24 hr)	IV	Hypotension (minimized by titrating dose up slowly)
Isoniazid (INH)	Pyridoxine	Empirical dosing: 70 mg/kg (max dose = 5 g) If ingested dose is known: 1 g per gram of INH	IV	May also be used for *Gyromitra* mushroom ingestions
Lead and other heavy metals (e.g., arsenic, inorganic mercury)	BAL (dimercaprol)	3-5 mg/kg/dose q4h, for the first day; subsequent dosing depends on the toxin	Deep IM	Local injection site pain and sterile abscess, vomiting, fever, salivation, nephrotoxicity *Caution:* Prepared in peanut oil; contraindicated in patients with peanut allergy
	Calcium disodium EDTA	35-50 mg/kg/day × 5 days; may be given as a continuous infusion or 2 divided doses/day	IV	Vomiting, fever, hypertension, arthralgias, allergic reactions, local inflammation, nephrotoxicity (maintain adequate hydration; follow UA and renal function)
	Dimercaptosuccinic acid (succimer, DMSA, Chemet)	10 mg/kg/dose q8h × 5 days, then 10 mg/kg q12h × 14 days	PO	Vomiting, hepatic transaminase elevation, rash
Methemoglobinemia	Methylene blue, 1% solution	0.1-0.2 mL/kg (1-2 mg/kg) over 5-10 min; may be repeated q30-60 min	IV	Vomiting, headache, dizziness, blue discoloration of urine
Opioids	Naloxone	1 mg if patient not likely to be addicted 0.04-0.4 mg if possibly addicted; repeated as needed; may need continuous infusion; higher and prolonged dosing is required for novel potent opioid overdose	IV, intranasal, IO, IM, nebulized	Acute withdrawal symptoms if given to addicted patients May also be useful for clonidine ingestions (typically at higher doses)

Table 94.8 Common Antidotes for Poisoning—cont'd

POISON	ANTIDOTE	DOSAGE	ROUTE	ADVERSE EFFECTS, WARNINGS, COMMENTS
Organophosphates	Atropine	0.05-0.1 mg/kg repeated q5-10 min as needed	IV/ET	Tachycardia, dry mouth, blurred vision, urinary retention
	Pralidoxime (2-PAM)	25-50 mg/kg over 5-10 min (max: 200 mg/min); can be repeated after 1-2 hr, then q10-12h as needed	IV/IM	Nausea, dizziness, headache, tachycardia, muscle rigidity, bronchospasm (rapid administration)
Salicylates	Sodium bicarbonate	Bolus 1-2 mEq/kg followed by continuous infusion	IV	Follow potassium closely and replace as necessary. Goal urine pH: 7.5-8.0
Sulfonylureas	Octreotide and dextrose	1-2 µg/kg/dose (adults 50-100 µg) q6-8h	IV/SC	
Tricyclic antidepressants	Sodium bicarbonate	Bolus 1-2 mEq/kg; repeated bolus dosing as needed to keep QRS <110 msec	IV	Indications: QRS widening (≥110 msec), hemodynamic instability; follow potassium.

BAL, British antilewisite; DMSA, dimercaptosuccinic acid; ECG, electrocardiogram; F_{IO_2}, fraction of inspired oxygen; EDTA, ethylenediaminetetraacetic acid; ET, endotracheal tube; IO, intraosseous; max, maximum; UA, urinalysis.

Table 94.9 Other Antidotes

ANTIDOTES	TOXIN OR POISON
Latrodectus antivenin	Black widow spider
Botulinum antitoxin	Botulinum toxin
Diphenhydramine and/or benztropine	Dystonic reactions
Calcium salts	Fluoride, calcium channel blockers
Intravenous lipid emulsion (ILE)	Local anesthetics; consider for bupropion, calcium channel blockers, β blockers, and type I antidysrhythmics
Protamine	Heparin
Folinic acid	Methotrexate, trimethoprim, pyrimethamine, methanol
Crotalidae-specific Fab antibodies	Rattlesnake envenomation
Sodium bicarbonate	Sodium channel blockade (tricyclic antidepressants, type 1 antiarrhythmics)

Table 94.10 Toxins Associated with Systemic Toxicity After Dermal Absorption

Syrup of Ipecac

Syrup of ipecac contains two emetic alkaloids that work in both the central nervous system (CNS) and locally in the GI tract to produce vomiting. Many studies have failed to document a significant clinical impact from the use of ipecac and have documented multiple adverse events from its use. The AAP, the American Academy of Clinical Toxicology (AACT), and the AAPCC have all published statements in favor of *abandoning the use of ipecac.*

Gastric Lavage

Gastric lavage involves placing a large tube orally into the stomach to aspirate contents, followed by flushing with aliquots of fluid, usually water or NS. Although gastric lavage was used routinely for many years, objective data do not document or support clinically relevant efficacy. This is particularly true in children, in whom only small-bore tubes can be used. Lavage is time-consuming and painful and can induce bradycardia through a vagal response to tube placement. It can delay administration of more definitive treatment (activated charcoal) and under the best circumstances, only removes a fraction of gastric contents. *Thus, in most clinical scenarios, the use of gastric lavage is no longer recommended.*

Single-Dose Activated Charcoal

Activated charcoal is a potentially useful method of GI decontamination. Charcoal is "activated" by heating to extreme temperatures, creating an extensive network of pores that provides a very large adsorptive surface area that many (but not all) toxins will bind to, preventing absorption from the GI tract. Charged molecules (i.e., heavy metals, lithium, iron) and liquids do not bind well to activated charcoal (Table 94.11). Administration should also be avoided after ingestion of a caustic substance, as it can impede subsequent endoscopic evaluation. *Charcoal is most likely to be effective when given within 1 hour of ingestion.* A repeat dose of activated charcoal may be warranted in the cases of ingestion of an extended-release product or, more frequently, with significant salicylate poisoning as a result of its delayed and erratic absorption pattern.

The dose of activated charcoal, with or without sorbitol, is 1g/kg in children or 50-100 g in adolescents and adults. Before administering charcoal, one *must* ensure that the patient's airway is intact or protected and that the patient has a benign abdominal examination. In the awake, uncooperative adolescent or child who refuses to drink the activated charcoal, there is little utility and potential morbidity associated

with forcing activated charcoal down a nasogastric (NG) tube, and such practice should be avoided. In young children, practitioners can attempt to improve palatability by adding flavorings (chocolate or cherry syrup) or giving the mixture over ice cream. Approximately 20% of children vomit after receiving a dose of charcoal, emphasizing the importance of an intact airway and avoiding administration of charcoal after ingestion of substances that are particularly toxic when aspirated (e.g., hydrocarbons). If charcoal is given through a gastric tube in an intubated patient, placement of the tube should be confirmed before activated charcoal is given. Instillation of charcoal directly into the lungs can have disastrous effects. Constipation is another common side effect of activated charcoal, and in rare cases, bowel perforation has been reported.

Cathartics (sorbitol, magnesium sulfate, magnesium citrate) have been used in conjunction with activated charcoal to prevent constipation and accelerate evacuation of the charcoal-toxin complex. There are no data demonstrating their value and numerous reports of adverse effects from cathartics, such as dehydration and electrolyte imbalance.

Whole-Bowel Irrigation

WBI involves instilling large volumes (25 mL/kg/hr in children or 1-2 L/hr in adolescents) of a polyethylene glycol electrolyte solution (e.g., GoLYTELY) to "wash out" the entire GI tract. This technique may have some success for the ingestion of SR preparations, substances not well adsorbed by charcoal (e.g., lithium, iron), transdermal patches, foreign bodies, and drug packets. WBI is most frequently administered to decontaminate the gut of a child whose abdominal radiograph demonstrates multiple lead paint chips. Careful attention should be paid to assessment of the airway and abdominal exam before initiating WBI. WBI should never be given to a patient with signs of obstruction or ileus or with a compromised airway. Given the rate of administration and volume needed to flush the system, WBI is typically administered by NG tube. WBI is continued until the rectal effluent is clear. If the WBI is for a child with ingested paint chips, the end-point will be clearing of the chips from the bowel based on repeat radiographs. Complications of WBI include vomiting, abdominal pain, and abdominal distention. Bezoar formation might respond to WBI but may also require endoscopy or surgery.

Directed Therapy

Antidotal Therapy

Antidotes are available for relatively few toxins (see Tables 94.8 and 94.9), but early and appropriate use of an antidote is a key element in managing the poisoned patient.

Intravenous Lipid Emulsion Therapy

Intravenous lipid emulsion (ILE) therapy is a potentially lifesaving intervention. ILE therapy sequesters fat-soluble drugs, decreasing their impact at target organs; this is known as a "lipid sink." It also enhances cardiac function by supplying an alternative energy source to a depressed myocardium and acting on calcium channels in the heart, increasing myocardial calcium and thus cardiac function. ILE is most effective as a reversal agent for toxicity from inadvertent intravenous (IV) injection of bupivacaine. Using the same 20% lipid solution used for total parenteral nutrition (TPN), a bolus dose of 1.5 mL/kg is given over 3 minutes, followed by an infusion of 0.25 mL/kg/min until recovery or until a total of 10 mL/kg has been infused. *Lipophilic drugs,* those in which the logarithm of the coefficient describing the partition between two solvents (hydrophobic phase and hydrophilic phase) is >2, have the most potential to be bound by ILE. These include but are not limited to CCBs (verapamil, diltiazem), bupropion, tricyclic antidepressants, and refractory β-blocker overdose. Complications associated with ILE include significant lipemia that interferes with serum laboratory tests, pancreatitis, and acute respiratory distress syndrome (ARDS).

Enhanced Elimination

Enhancing elimination results in increased clearance of a poison that has already been absorbed. It is only useful for a few toxins and in these cases is a potentially lifesaving intervention. Methods of enhanced elimination include urinary alkalinization, hemodialysis, and multidose activated charcoal.

Urinary Alkalinization

Urinary alkalinization enhances the elimination of drugs that are weak acids by forming charged molecules, which then become trapped in the renal tubules. Charged molecules, being polar and hydrophilic, do not easily cross cellular membranes; thus they remain in the renal tubules and are excreted. Urinary alkalinization is accomplished by a continuous infusion of sodium bicarbonate–containing IV fluids, with a goal urine pH of 7.5-8. Alkalinization of the urine is most useful in managing salicylate and methotrexate toxicity. Complications of urinary alkalinization include electrolyte derangements (e.g., hypokalemia, hypocalcemia), fluid overload, and excessive serum alkalinization. Serum pH should be closely monitored and not exceed a pH >7.55. Patients typically unable to tolerate the volumes required for alkalinization are those with heart failure, kidney failure, pulmonary edema, or cerebral edema.

Hemodialysis

Few drugs or toxins are removed by dialysis in amounts sufficient to justify the risks and difficulty of dialysis. Toxins amenable to dialysis have the following properties: low volume of distribution (<1 L/kg) with a high degree of water solubility, low molecular weight, and low degree of protein binding. Hemodialysis may be useful for toxicity from methanol, ethylene glycol, salicylates, theophylline, bromide, lithium, and valproic acid. Hemodialysis is also used to correct severe electrolyte disturbances and acid-base derangements resulting from the ingestion (e.g., severe metformin-associated lactic acidosis).

Multidose Activated Charcoal

Whereas single-dose activated charcoal is used as a method of decontamination, multidose activated charcoal (**MDAC**) can help to enhance the elimination of certain toxins. MDAC is typically given as 0.5 g/kg every 4-6 hr (for four doses). MDAC enhances elimination by two proposed mechanisms: interruption of enterohepatic recirculation and "GI dialysis." The concept of GI dialysis involves using the intestinal mucosa as a dialysis membrane and pulling toxins from the bloodstream back into the intraluminal space, where they are adsorbed to the charcoal. The AACT/European Association of Poisons Centres and Clinical Toxicologists position statement recommends MDAC in managing significant ingestions of carbamazepine, dapsone, phenobarbital, quinine, and theophylline. As with single-dose activated charcoal, contraindications to the use of MDAC include an unprotected airway and a concerning abdominal examination (e.g., ileus, distention, peritoneal signs). Thus the airway and abdominal exam *should be assessed before each dose.* A cathartic (e.g., sorbitol) may be given with the first dose, but it should not be used with subsequent doses because of the risk of dehydration and electrolyte derangements. Although MDAC reduces the serum level of an intoxicant quicker than without MDAC, it has not been shown to have a significant impact on outcome.

SELECT COMPOUNDS IN PEDIATRIC POISONING

See other chapters for drug use (Chapter 157) and environmental health hazards (Chapters 757-763).

Pharmaceuticals

Analgesics

Acetaminophen. Acetaminophen (APAP) is the most widely used analgesic and antipyretic in pediatrics, available in multiple formulations, strengths, and combinations. Consequently, APAP is commonly available in the home, where it can be unintentionally ingested by young children, taken in an intentional overdose by adolescents and adults, or inappropriately dosed in all ages. In the United States, APAP toxicity remains the most common cause of acute liver failure and one of the leading causes of death from oral poisonings.

Pathophysiology. APAP toxicity results from the formation of a highly reactive intermediate metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI). In therapeutic use, only a small percentage of a dose (approximately 5%) is metabolized by the hepatic cytochrome P450 enzyme CYP2E1 to NAPQI, which is then immediately conjugated with glutathione to form a nontoxic mercapturic acid conjugate. In overdose, glutathione stores are overwhelmed, and free NAPQI is able to combine with hepatic macromolecules to produce hepatocellular necrosis. The single acute toxic dose of APAP is generally considered to be >200 mg/kg in children and >7.5-10 g in adolescents and adults. Repeated administration of APAP at supratherapeutic doses (>90 mg/kg/day for consecutive days) can lead to hepatic injury or failure in some children, especially in the setting of fever, dehydration, poor nutrition, and other conditions that serve to reduce glutathione stores.

Any child with a history of acute ingestion of >200 mg/kg (unusual in children <6 years) or with an acute intentional ingestion of any amount should be referred to a healthcare facility for clinical assessment and measurement of a serum APAP level.

Clinical and Laboratory Manifestations. Classically, four general stages of APAP toxicity have been described (Table 94.12). In the first 24 hours after ingestion, patients are most frequently asymptomatic, although they may have nonspecific symptoms such as nausea/vomiting. Thus the diagnosis of APAP toxicity cannot be based on clinical symptoms alone, but instead requires consideration of the combination of the patient's history, symptoms, and laboratory findings.

If a toxic ingestion is suspected, a serum APAP level should be measured 4 hours after the reported time of ingestion. For patients who present to medical care more than 4 hours after ingestion, a stat APAP level should be obtained. *APAP levels obtained <4 hours after ingestion, unless "nondetectable," are difficult to interpret and cannot be used to estimate the potential for toxicity.* Other important baseline laboratory tests include hepatic transaminases, bilirubin, renal function tests, and coagulation parameters.

Table 94.12 Classic Stages in Clinical Course of Acetaminophen Toxicity

STAGE	TIME AFTER INGESTION	CHARACTERISTICS
I	0-24 hr	Anorexia, vomiting, malaise Laboratory tests typically normal, except for acetaminophen level
II	24-48 hr	Resolution of earlier symptoms; right upper quadrant abdominal pain and tenderness; elevated hepatic transaminases (aspartate > alanine), INR
III	3-5 days	Peak transaminase elevations; development of liver failure, multiorgan system failure, death *or* recovery begins
IV	4 days to 2 wk	Resolution of liver function abnormalities Clinical recovery precedes histologic recovery

Treatment. When considering the treatment of a patient poisoned or potentially poisoned with APAP, and after assessment of the ABCs, it is helpful to place the patient into one of the following four categories:

1. Prophylactic. These patients have a normal AST. If the APAP level is known and the ingestion is within 24 hours of the level being drawn, treatment decisions are based on where the level falls on the Rumack-Matthew nomogram (Fig. 94.1). Any patient with a serum APAP level in the possible or probable hepatotoxicity range per the nomogram should be treated with *N*-acetylcysteine (NAC). This nomogram is only intended for use in patients who present within 24 hours of a single *acute* APAP ingestion with a known time of ingestion. If treatment is recommended, they should receive NAC. Food and Drug Administration (FDA)–approved treatment regimens include a 21-hour protocol for IV administration and a 72-hour protocol for oral administration. Several shorter dosing regimens have been described and may be considered in consultation with a toxicologist. Regardless of treatment duration, serial transaminases and APAP level should be monitored. If the AST becomes elevated while receiving NAC, the patient moves into the next category of treatment (hepatic injury, see later). If AST remains normal but APAP is still present, NAC should be continued until the level is nondetectable. In the case of a patient with a documented APAP level, normal AST, and an unknown time of ingestion, treatment should ensue until the level is undetectable, with normal transaminases.

The importance of instituting therapy with either IV or oral NAC *no later than 8 hours from the time of ingestion* cannot be overemphasized.

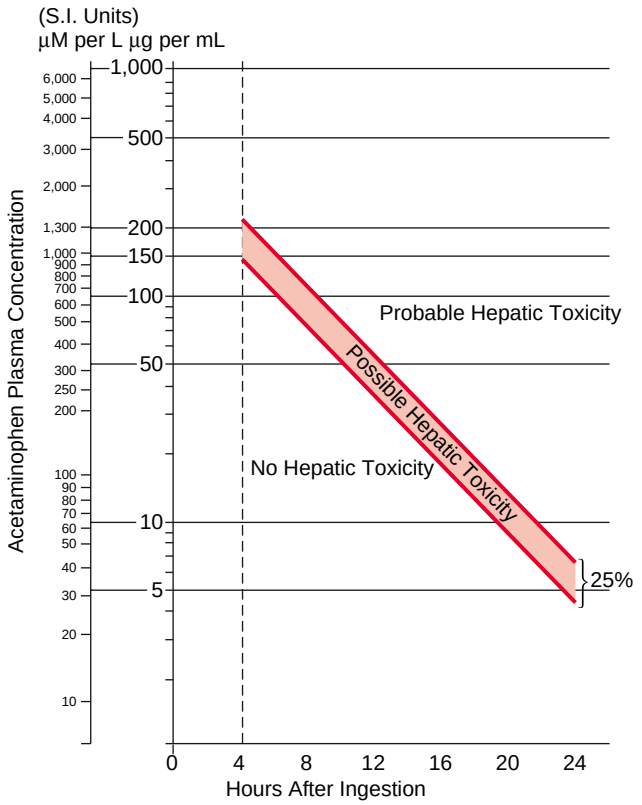

Fig. 94.1 Rumack-Matthew nomogram for acetaminophen poisoning, a semilogarithmic plot of plasma acetaminophen concentrations vs time. *Cautions for the use of this chart:* The time coordinates refer to time after ingestion; serum concentrations obtained before 4 hours are not interpretable, and the graph should be used only in relation to a single acute ingestion with a known time of ingestion. This nomogram is not useful for chronic exposures or unknown time of ingestion and should be used with caution in the setting of co-ingestants that slow gastrointestinal motility. The *lower solid line* is typically used in the United States to define toxicity and direct treatment, whereas the *upper line* is generally used in Europe. *(From Rumack BH, Hess AJ, eds.* Poisindex, *Denver: Micromedix; 1995. Adapted from Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. Pediatrics.1975;55:871–876.)*

No patient, regardless of the size of the ingestion, who receives NAC within 8 hours of overdose should die from liver failure. The longer from the 8 hour-mark that the initiation of therapy is delayed, the greater the risk of acute liver failure. Any patient presenting close to or beyond the 8-hour mark after an APAP overdose should be empirically started on NAC pending laboratory results.

2. Hepatic Injury. These patients exhibit evidence of hepatocellular necrosis, manifested first as elevated liver transaminases (usually AST first, then ALT), followed by a rise in the INR. Any patient in this category requires therapy with NAC (IV or oral). When to discontinue therapy in the clinically well-appearing patient remains controversial, but in general NAC can be discontinued when the transaminases and INR have peaked and are declining significantly (they do not need to be normal). Most patients' liver enzymes will peak 3-4 days after their ingestion.

3. Acute Liver Failure. The King's College criteria are used to determine which patients should be referred for consideration of liver transplant. These criteria are met when a patient exhibits either acidemia (serum pH <7.3) after adequate fluid resuscitation or all three of the following: coagulopathy (INR >6.5), renal dysfunction (creatinine >3.4 mg/dL), and grade III or IV hepatic encephalopathy (see Chapter 412). A serum lactic acid >3 mmol/L (after IV fluids) adds to both sensitivity and specificity of the criteria to predict death without liver transplant. The degree of transaminase elevation does not factor into this decision-making process.

4. Repeated Supratherapeutic Ingestion. APAP is particularly prone to unintentional overdose through the ingestion of multiple medications containing the drug or simply because people assume it to be safe at any dose. Ingestion of amounts significantly greater than the recommended daily dose for several days or more puts one at risk for liver injury. Because the Rumack-Matthew nomogram is not helpful in this scenario, a conservative approach is taken. In the asymptomatic patient, if the AST is normal and the APAP is <10 μg/mL, no therapy is indicated. A normal AST and an elevated APAP warrant NAC dosing for at least long enough for the drug to metabolize while the AST remains normal. An elevated AST puts the patient in the "hepatic injury" category previously described. A patient presenting with symptoms (i.e., right upper quadrant pain, vomiting, jaundice) should be empirically started on NAC pending laboratory results.

NAC is available in oral and IV forms, and both are considered equally efficacious (see Table 94.8 for the dosing regimens of the oral and IV form). The IV form is used in patients with intractable vomiting, those with evidence of hepatic failure, and pregnant patients. Oral NAC has an unpleasant taste and smell and can be mixed in a soft drink or fruit juice or given by NG tube to improve tolerability of the oral regimen. Administration of IV NAC (as a standard 3% solution to avoid administering excess free water, typically in 5% dextrose), especially the initial loading dose, is associated in some patients with the development of anaphylactoid reactions (non–immunoglobulin E mediated). These reactions are typically managed by stopping the infusion; treating with diphenhydramine, albuterol, and/or epinephrine as indicated; and restarting the infusion at a slower rate once symptoms have resolved. IV NAC is also associated with mild elevation in measured INR (range: 1.2-1.5) because of laboratory interference. IV dosing, however, delivers less medication to the liver compared with the oral regimen. As a result, many toxicologists now recommend higher doses of the IV formulation in patients with large overdoses. Transaminases, synthetic function, and renal function should be followed at least daily while the patient is being treated with NAC. Patients with worsening hepatic function or clinical status might benefit from more frequent laboratory monitoring. A patient-tailored approach is now the norm for when to stop NAC therapy, for deciding whom to refer for transplantation evaluation, and often for the dose of IV NAC in patients with either very high APAP levels or signs of injury. Consultation with the regional PCC and medical toxicologist can help streamline the care of these patients, ultimately shortening their length of stay with potentially improved outcomes.

Adjunctive Therapies

Although activated charcoal binds acetaminophen, risks of vomiting associated with large APAP overdoses as well as the likelihood of co-ingestion that may affect mental status must be considered. Activated charcoal may be considered in the first 1-2 hours after ingestion in an alert patient, but its use should not have bearing on the need for NAC. Similarly, hemodialysis is not routinely used in APAP overdose but may be indicated in massive ingestions in consultation with a toxicologist.

Salicylates. The incidence of salicylate poisoning in young children has declined dramatically since APAP and ibuprofen replaced aspirin as commonly used analgesics and antipyretics in pediatrics. However, salicylates remain widely available not only in aspirin-containing products but also in antidiarrheal medications, topical agents (e.g., keratolytics, sports creams), oil of wintergreen, and some herbal products. Oil of wintergreen contains 5 g of salicylate in 5 mL, meaning ingestion of very small volumes of this product has the potential to cause severe toxicity.

Pathophysiology. Salicylates lead to toxicity by interacting with a wide array of physiologic processes, including direct stimulation of the respiratory center, uncoupling of oxidative phosphorylation, inhibition of the tricarboxylic acid cycle, and stimulation of glycolysis and gluconeogenesis. The acute toxic dose of salicylates is generally considered to be >150 mg/kg. More significant toxicity is seen after ingestions of >300 mg/kg, and severe, potentially fatal, toxicity is described after ingestions of >500 mg/kg.

Clinical and Laboratory Manifestations. Salicylate ingestions are classified as acute or chronic, and acute toxicity is much more common in pediatric patients. Early signs of **acute salicylism** include nausea, vomiting, diaphoresis, and tinnitus. Moderate salicylate toxicity can manifest as tachypnea and hyperpnea, tachycardia, and altered mental status. The tachycardia largely results from marked insensible losses from vomiting, tachypnea, diaphoresis, and uncoupling of oxidative phosphorylation. Thus careful attention should be paid to volume status and early volume resuscitation in the significantly poisoned patient. Signs of severe salicylate toxicity include mild hyperthermia, coma, and seizures. **Chronic salicylism** can have a more insidious presentation, and patients can show marked toxicity (e.g., altered mental status, noncardiogenic pulmonary edema, acidemia) at significantly lower salicylate levels than in acute toxicity.

Classically, laboratory values from a patient poisoned with salicylates reveal a primary respiratory alkalosis and a primary, elevated anion gap metabolic acidosis. Early in the course of acute salicylism, respiratory alkalosis dominates and the patient is alkalemic. As the respiratory stimulation diminishes, the patient will move toward acidemia. Hyperglycemia (early) and hypoglycemia (late) have been described. Abnormal coagulation studies and acute kidney injury may be seen but are not common.

Serial serum salicylate levels should be closely monitored (every 2-4 hours initially) until they are consistently downtrending (three consecutive levels <30 mg/dL and decreasing by at least 10–20% on each subsequent measurement). Salicylate absorption in overdose is unpredictable and erratic, especially with an enteric-coated product, and levels can rapidly increase into the highly toxic range, even many hours after the ingestion. The Done nomogram is of poor value and should not be used. Serum and urine pH and electrolytes should be followed closely. An APAP level should be checked in any patient who intentionally overdoses on salicylates, because APAP is a common co-ingestant, and people often confuse or combine their nonprescription analgesic medications. Salicylate toxicity can cause a noncardiogenic pulmonary edema, especially in chronic overdose; consequently, a chest radiograph is recommended in any patient in respiratory distress.

Treatment. For the patient who presents soon after an acute ingestion, initial treatment should include gastric decontamination with activated charcoal. Salicylate pills occasionally form bezoars, which should be suspected if serum salicylate concentrations continue to rise many hours after ingestion or are persistently elevated despite appropriate management. Gastric decontamination is typically not useful after chronic exposure.

Initial therapy focuses on aggressive volume resuscitation and prompt initiation of sodium bicarbonate therapy in the symptomatic patient, even before obtaining serum salicylate levels. Therapeutic salicylate levels are 10-20 mg/dL, and levels >30 mg/dL warrant treatment.

The primary mode of therapy for salicylate toxicity is **urinary alkalinization**. Urinary alkalinization enhances the elimination of salicylates by converting salicylate to its ionized form, "trapping" it in the renal tubules. In addition, maintaining an alkalemic serum pH decreases CNS penetration of salicylates because charged particles are less able to cross the blood-brain barrier. Alkalinization is achieved by administration of a sodium bicarbonate infusion at approximately two times maintenance fluid rates. *The goals of therapy include a urine pH of 7.5-8, a serum pH of 7.45-7.55, and decreasing serum salicylate levels.* In general, the lower the patient's serum pH, the greater the relative amount of salicylate in the uncharged, nonpolar form and the greater amount of salicylate penetration of the blood-brain barrier. Salicylate penetration of the brain leads to severe consequences such as cerebral edema; therefore maintaining alkalemia is imperative. Careful attention should also be paid to serial potassium levels in any patient on a bicarbonate infusion, because potassium will be driven intracellularly, and hypokalemia impairs alkalinization of the urine. For these reasons, potassium is often added to the bicarbonate drip. Repeat doses of charcoal may be beneficial because of the often delayed and erratic absorption of aspirin. Parenteral glucose should be provided to any salicylate-poisoned patients with altered mental status because they may have CNS hypoglycemia (i.e., neuroglycopenia) not seen in a peripheral serum glucose test.

In patients with severe toxicity, hemodialysis may be required. Indications for dialysis include severe acid-base abnormalities (specifically severe acidosis and acidemia), a rising salicylate level (despite adequate decontamination and properly alkalinized urine), pulmonary edema or respiratory failure, cerebral edema, seizures, hepatic failure, and renal failure. Serum salicylate concentrations alone are not a clear indicator of the need for dialysis and should always be interpreted along with the clinical status of the patient.

Ibuprofen and Other Nonsteroidal Antiinflammatory Drugs (NSAIDs). Ibuprofen and other NSAIDs are often involved in unintentional and intentional overdoses because of their widespread availability and common use as analgesics and antipyretics. Fortunately, serious effects after acute NSAID overdose are rare because of their wide therapeutic index.

Pathophysiology. NSAIDs inhibit prostaglandin synthesis by reversibly inhibiting the activity of cyclooxygenase (COX), the primary enzyme responsible for the biosynthesis of prostaglandins. In therapeutic use, side effects include GI irritation, reduced renal blood flow, and platelet dysfunction. To minimize these side effects, NSAID analogs have been developed that are more specific for the inducible form of COX (the COX-2 isoform) than the constitutive form (COX-1). However, overdose of the more selective COX-2 inhibitors (e.g., celecoxib [Celebrex]) is treated the same as overdose of nonspecific COX inhibitors (e.g., ibuprofen) because at higher doses, COX-2–selective agents lose their COX inhibitory selectivity.

Ibuprofen, the primary NSAID used in pediatrics, is well tolerated, even in overdose. In children, acute doses of <200 mg/kg rarely cause toxicity, but ingestions of >400 mg/kg can produce more serious effects, including altered mental status and metabolic acidosis.

Clinical and Laboratory Manifestations. Symptoms usually develop within 4-6 hours of ingestion and resolve within 24 hours. If toxicity does develop, it is typically manifested as nausea, vomiting, and abdominal pain. Although GI bleeding and ulcers have been described with chronic use, they are rare in the setting of acute ingestion. After massive ingestions, patients can develop marked CNS depression, anion gap metabolic acidosis, renal insufficiency, and (rarely) respiratory depression. Seizures have also been described, especially after overdose of mefenamic acid. Specific drug levels are not readily available, nor do they inform management decisions. Renal function studies, acid-base balance, complete blood count (CBC), and coagulation parameters should be monitored after very large ingestions. Co-ingestants, especially APAP, should be ruled out after any intentional ingestion.

Treatment. Supportive care, including use of antiemetics and acid blockade as indicated, is the primary therapy for NSAID toxicity. Decontamination with activated charcoal should be considered if a patient presents within 1-2 hours of a potentially toxic ingestion. There is no specific antidote for this class of drugs. Given the high degree of protein binding and excretion pattern of NSAIDs, none of the modalities used to enhance elimination is particularly useful in managing these overdoses. Unlike in patients with salicylate toxicity, urinary alkalinization is not helpful for NSAID toxicity. Patients who develop significant clinical signs of toxicity should be admitted to the hospital for ongoing supportive care and monitoring. Patients who remain asymptomatic for 4-6 hours after ingestion do not require further medical care but may need psychiatric assessment if their ingestion was intentional.

Prescription Opioids. Opioids are a frequently abused class of medications in both IV and oral forms. The opioid epidemic gripping the United States and other countries is discussed in Chapter 157. Two specific oral opioids, buprenorphine and methadone, merit mention because of potential life-threatening toxicity in toddlers with ingestion of even one pill. Both agents are used in managing opioid use disorder, although **buprenorphine** is the drug of choice. **Methadone** is also widely used in the treatment of chronic pain, meaning multiday prescriptions can be filled. Other agents commonly available in the home include morphine, oxycodone, and hydrocodone, as they are frequently prescribed to patients after injuries or surgical procedures. All of these drugs are also readily available for illicit purchase and potential abuse. Opioids are of great potential toxicity to small children if not dosed appropriately, especially buprenorphine because of its long half-life and high potency.

Pathophysiology. Opioids are well absorbed via multiple routes, including the GI tract, which is the most common route of accidental overdose in young children. At therapeutic dosing, opioids are typically absorbed within a few hours, but absorption may be slowed and symptoms prolonged in overdose. Individual opioids cross the blood-brain barrier to varying degrees. Opioids all undergo hepatic metabolism with renal excretion.

Methadone is a lipophilic synthetic opioid with potent agonist effects at μ-opioid receptors, leading to both its desired analgesic effects and undesired side effects, including sedation, respiratory depression, and impaired GI motility. Methadone is thought to cause QTc interval prolongation through interactions with the human ether-a-go-go–related gene (hERG)–encoded potassium rectifier channel. Its duration of effect for pain control averages only about 8 hours, whereas the dangerous side effects can occur up to 24 hours from the last dose and longer after overdose. Methadone has an average half-life >25 hours, which may be extended to >50 hours in overdose.

Suboxone is a combination of buprenorphine, a potent opioid with partial agonism at μ-opioid receptors and weak antagonism at κ-opioid receptors, and naloxone. Naloxone has poor oral bioavailability but is included in the formulation to discourage diversion for IV use, during which it can precipitate withdrawal. Suboxone is formulated for buccal or sublingual administration; consequently, toddlers can absorb significant amounts of drug even by sucking on a tablet. Buprenorphine has an average half-life of 37 hours.

Clinical and Laboratory Manifestations. In children, opioid ingestions can manifest with the classic toxidrome of respiratory depression, sedation, and miosis. Signs of more severe toxicity can include bradycardia, hypotension, and hypothermia. Many opioids have clinical features that are unique to their chemical structure (Table 94.13). Even in therapeutic use, methadone is associated with a prolonged QTc interval and risk of torsades de pointes. Accordingly, an ECG should be part of the initial evaluation after ingestion of methadone or any unknown opioid. Many prescription opioids, including methadone and buprenorphine, are not detected on routine urine opiate screens, although some centers have added a separate urine methadone screen. Levels of many drugs can be measured, although this is rarely done clinically and is seldom helpful in the acute setting. An exception may be in the cases involving concerns about neglect or abuse, at which point urine for gas chromatography/mass spectroscopy, the legal gold standard, should be sent to confirm and document the presence of the drug.

Treatment. Patients with significant respiratory depression or CNS depression should be treated with the opioid antidote **naloxone**

Table 94.13 Clinical Properties of Select Prescription Opioids

CLINICAL EFFECT	OPIOID
QRS widening, sodium channel blockade	Propoxyphene
QT widening, potassium channel blockade	Methadone
Seizures	Propoxyphene, meperidine
Serotonin syndrome	Meperidine, methadone, tramadol
Hearing loss, ototoxicity	Methadone, hydrocodone

Modified from Nikolaides JK, Thompson TM. Opioids. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. *Rosen's Emergency Medicine*, 9th ed. Philadelphia: Elsevier; 2018, Table 156.2, p. 1944.

(see Table 94.8). In pediatric patients who are not chronically taking opioids, the full reversal dose of 1-2 mg should be used. In contrast, opioid-dependent patients should be treated with smaller initial doses (0.04-0.4 mg), which can then be repeated as needed to achieve the desired clinical response, avoiding abrupt induction of withdrawal. Because the half-life of many opioids is much longer than that of naloxone, patients can require multiple doses of naloxone. These patients may benefit from a continuous infusion of naloxone, typically started at two thirds of the reversal dose per hour and titrated to maintain an adequate respiratory rate and level of consciousness. Patients who have ingested methadone should be placed on a cardiac monitor and have serial ECGs to monitor for the development of a prolonged QTc interval. If a patient does develop a prolonged QTc, management includes close cardiac monitoring, repletion of electrolytes (potassium, calcium, and magnesium), and having a defibrillator readily available should the patient develop torsades de pointes.

Given the potential for clinically significant and prolonged toxicity, any toddler who has ingested methadone, even if asymptomatic, should be admitted to the hospital for at least 24 hours of monitoring. Duration of observation after ingestion of other opioids depends on the half-life and dose of the agent ingested. All such cases should be discussed with a PCC or medical toxicologist before determining disposition.

Cardiovascular Medications

β-Adrenergic Receptor Blockers. β Blockers competitively inhibit the action of catecholamines at the β-adrenergic receptor. Therapeutically, β blockers are used for a variety of conditions, including hypertension, coronary artery disease, tachydysrhythmias, anxiety disorders, migraines, essential tremor, and hyperthyroidism. Because of its lipophilicity and blockade of fast sodium channels, **propranolol** is considered to be the most toxic member of the β-blocker class. Overdoses of water-soluble β blockers (e.g., atenolol) are associated with milder symptoms.

Pathophysiology. In overdose, β blockers decrease chronotropy and inotropy in addition to slowing conduction through atrioventricular (AV) nodal tissue. Clinically, these effects are manifested as bradycardia, hypotension, and heart block. Patients with reactive airway disease can experience bronchospasm as a result of blockade of β_2-mediated bronchodilation. β_2 Blockers interfere with glycogenolysis and gluconeogenesis, which can sometimes lead to hypoglycemia, especially in patients with poor glycogen stores (e.g., toddlers).

Clinical and Laboratory Manifestations. Toxicity typically develops within 6 hours of ingestion, although it may be delayed after ingestion of sotalol or SR preparations. The most common features of severe poisoning are bradycardia and hypotension. Lipophilic agents, including propranolol, can enter the CNS and cause altered mental status, coma, and seizures. Overdose of β blockers with sodium channel–blocking properties (e.g., propranolol) can cause QRS interval widening and ventricular dysrhythmias.

Evaluation after β-blocker overdose should include an ECG, frequent reassessments of hemodynamic status, and blood glucose. Serum levels of β blockers are not readily available for routine clinical use and are not useful in management of the poisoned patient.

Treatment. In addition to supportive care and GI decontamination as indicated, **glucagon** is theoretically the preferred antidote of choice for β-blocker toxicity (see Table 94.8). Glucagon stimulates adenylate cyclase and increases levels of cyclic adenosine monophosphate (cAMP) independent of the β-receptor. Glucagon is typically given as a bolus and, if this is effective, followed by a continuous infusion. In practice, glucagon is often only marginally effective, limited by its proemetic effects, especially at the high doses typically required. Other useful interventions include calcium, vasopressors, and high-dose insulin. Seizures are managed with benzodiazepines, and QRS widening should be treated with sodium bicarbonate. Lipid emulsion therapy (discussed earlier) may be considered in patients with signs of shock who do not respond to conventional treatments. Children who ingest one or two water-soluble β blockers are unlikely to develop toxicity and can typically be discharged to home if they remain asymptomatic over a 6-hour observation period. Children who ingest SR products, highly lipid-soluble agents, and sotalol require longer periods of observation before safe discharge. Any symptomatic child should be admitted for ongoing monitoring and directed therapy.

Calcium Channel Blockers. CCBs are used for a variety of therapeutic indications and have the potential to cause severe toxicity, even after exploratory ingestions. Specific agents include verapamil, diltiazem, and the dihydropyridines (e.g., amlodipine, nifedipine). Of these, diltiazem and verapamil are the most dangerous in overdose because of their higher lipophilicity and direct cardiac suppressant effects.

Pathophysiology. CCBs antagonize L-type calcium channels, inhibiting calcium influx into myocardial and vascular smooth muscle cells. Verapamil works primarily by slowing inotropy and chronotropy and in therapeutic dosing has no effect on systemic vascular resistance (SVR). Diltiazem has effects both on the heart and the peripheral vasculature. The dihydropyridines exclusively diminish SVR. Verapamil and diltiazem can significantly diminish myocardial contractility and conduction, with diltiazem also lowering SVR. By contrast, dihydropyridines will decrease the SVR, leading to vasodilation and reflex tachycardia, although this receptor selectivity may be lost after a large overdose. Because the same L-type calcium channels blocked by CCBs are also on the pancreatic islet cells, any patient significantly poisoned with a CCB may develop hyperglycemia.

Clinical and Laboratory Manifestations. Overdoses of CCBs lead to hypotension, accompanied by bradycardia, normal heart rate, or even tachycardia, depending on the agent. Other rhythm disturbances, including AV block, bundle branch blocks, QT prolongation, and junctional rhythms, may also be seen. A common feature of CCB overdose is the patient exhibiting profound hypotension with preserved consciousness.

Initial evaluation should include an ECG, continuous and careful hemodynamic monitoring, and rapid measurement of serum glucose levels. Both the absolute degree of hyperglycemia and the percentage increase in serum glucose have been correlated with the severity of CCB toxicity in adults. The development of hyperglycemia can even precede the development of hemodynamic instability. Blood levels of CCBs are not readily available and are not useful in guiding therapy.

Treatment. Once initial supportive care has been instituted, GI decontamination should begin with activated charcoal as appropriate. WBI may be beneficial in a stable patient after ingestion of an SR product. Calcium channel blockade in the smooth muscles of the GI tract can lead to greatly diminished motility; thus any form of GI decontamination should be undertaken with careful attention to serial abdominal exams.

Calcium salts, administered through a peripheral IV line as calcium gluconate or a central line as calcium chloride, help to overcome blocked calcium channels. **High-dose insulin euglycemia therapy** is considered the antidote of choice for CCB toxicity. An initial bolus of 1 unit/kg of regular insulin is followed by an infusion at 1-10 units/kg/hr (see Table 94.8). The main mechanism of high-dose insulin euglycemia

is to improve the metabolic efficiency of a poisoned heart that needs carbohydrates for energy (instead of the usual free fatty acids) but has minimal circulating insulin. Blood glucose and serum potassium levels should be closely monitored, and supplemental dextrose may be necessary to maintain euglycemia. Mild hypokalemia may be tolerated, as this reflects intracellular shifting of potassium rather than whole-body potassium depletion; severe hypokalemia (e.g., K <2.8 mEq/L) is treated with IV potassium supplementation.

Additional therapies include judicious IV fluid boluses and vasopressors (often in very high doses). Cardiac pacing is rarely of value. Lipid emulsion therapy (discussed earlier) is a potentially lifesaving intervention, especially for patients poisoned with the more lipid-soluble CCBs, verapamil and diltiazem. In extreme cases an intraaortic balloon pump or extracorporeal membrane oxygenation (ECMO) are potential treatments. Given the potential for profound and sometimes delayed toxicity in toddlers after ingestion of one or two CCB tablets, hospital admission and 12-24 hours of monitoring for all of these patients is strongly recommended.

α_2-Adrenergic Agonists. Although originally intended for use as antihypertensives, the number of **clonidine** and **guanfacine** prescriptions in the pediatric population has greatly increased because of its reported efficacy in the management of attention-deficit/hyperactivity disorder (ADHD), tic disorders, and other behavioral disorders. With this increased use has come a significant rise in pediatric ingestions and therapeutic misadventures. Clonidine is available in pill and transdermal patch forms, while guanfacine is available in pill form.

Pathophysiology. Clonidine, along with the closely related agent guanfacine, is a centrally acting α_2-adrenergic receptor agonist with a very narrow therapeutic index. Agonism at central α_2 receptors decreases sympathetic outflow, producing lethargy, bradycardia, hypotension, and apnea. Toxicity can develop after ingestion of only one pill or after sucking on or swallowing a discarded transdermal patch. Even a "used" transdermal patch might contain as much as one third to one half the original amount of drug.

Clinical and Laboratory Manifestations. The most common clinical manifestations of toxicity are lethargy, miosis, and bradycardia. Hypotension, respiratory depression, and apnea may be seen in severe cases. Very early after ingestion, patients may be hypertensive in the setting of agonism at peripheral α-receptors and resulting vasoconstriction. Symptoms develop relatively soon after ingestion and typically resolve within 24 hours. Serum clonidine concentrations are not readily available and are of no clinical value in the acute setting. Although signs of clinical toxicity are common after clonidine or guanfacine overdose, death is extremely unusual.

Treatment. Given the potential for significant toxicity, most young children warrant referral to a healthcare facility for evaluation after unintentional ingestions of α_2-adrenergic agonists. Gastric decontamination is of minimal value because of the small quantities ingested and the rapid onset of serious symptoms. Aggressive supportive care is imperative and is the cornerstone of management. Naloxone, often in high doses (i.e., 10 mg IV), has shown variable efficacy in treating clonidine toxicity. Other potentially useful therapies include atropine, IV fluid boluses, and vasopressors. Symptomatic children should be admitted to the hospital for close cardiovascular and neurologic monitoring. Also, in a patient receiving chronic clonidine or guanfacine therapy, rapid discontinuation of the drug, or even missing one or two doses, could lead to potentially dangerous elevations in blood pressure.

Digoxin. Digoxin is a cardiac glycoside extracted from the leaves of *Digitalis lanata*. Other natural sources of cardiac glycosides include *Digitalis purpura* (foxglove), *Nerium oleander* (oleander), *Convallaria majalis* (lily of the valley), Siberian ginseng, and the *Bufo marinus* toad. Therapeutically, digoxin is used in the management of heart failure and some supraventricular tachydysrhythmias. Acute overdose can occur in the setting of dosing errors (especially in younger children), unintentional or intentional medication ingestion, or exposure to plant material containing digitalis glycosides. Regarding exposure to such plants, toxicity is unusual unless the poison is concentrated in the form of a tea. Chronic toxicity can result from alteration of the digoxin dose, alteration in digoxin clearance as a result of renal impairment, or drug interactions.

Pathophysiology. Digoxin blocks the sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) pump, leading to intracellular loss of K^+ and gain of Na^+ and calcium (Ca^{2+}). This resulting rise in Ca^{2+} available to the contractile myocardium improves inotropy. An increase in myocardial automaticity leads to subsequent atrial, nodal, and ventricular ectopy. Digoxin also affects nodal conduction, leading to a prolonged refractory period, decreased sinus node firing, and slowed conduction through the AV node. Impaired Na^+/K^+ exchange can lead to elevated serum K^+. Overall, digoxin overdose manifests as a combination of slowed or blocked conduction and increased ectopy.

Clinical and Laboratory Manifestations. Nausea and vomiting are common initial symptoms of acute digoxin toxicity, manifesting within 6 hours of overdose. Cardiovascular manifestations include bradycardia, heart block, and a wide variety of dysrhythmias. CNS manifestations consist of lethargy, confusion, and weakness. Chronic toxicity (which is rare in children) is more insidious and may also manifest as altered mental status and visual disturbances.

Initial assessment should include an ECG, serum digoxin level, serum potassium, and kidney function tests. The serum digoxin level should be assessed at least 6 hours after ingestion and carefully interpreted in the setting of clinical symptoms, because the digoxin level alone does not entirely reflect the severity of intoxication. In acute ingestions, serum potassium is an independent marker of morbidity and mortality, with levels >5 mEq/L predicting poor outcomes. In chronic toxicity, serum K^+ concentration is less useful as a prognostic marker and may be altered from concomitant use of diuretics or renal dysfunction.

Digoxin has a very narrow therapeutic index. Therapeutic plasma digoxin concentrations are 0.5-2 ng/mL; a level >2 ng/mL is considered toxic, and >6 ng/mL is considered potentially fatal (in chronic poisonings). As with all serum levels of intoxicants, one must be careful to interpret the number in the context of the scenario of the poisoning and the status of the patient. An acutely poisoned patient may have a very high serum level and minimal to no symptoms, whereas a patient with a chronic or acute-on-chronic poisoning will usually be sicker with a lower serum level.

Numerous drug interactions affect plasma digoxin concentrations. Medications known to increase serum digoxin concentrations include the macrolides, erythromycin and clarithromycin, spironolactone, verapamil, amiodarone, and itraconazole.

Treatment. Initial treatment includes good general supportive care and gastric decontamination with activated charcoal if the ingestion was recent. An antidote for digoxin, digoxin-specific antibody fragments (Fab: Digibind or DigiFab) is available (see Table 94.8). Fab fragments bind free digoxin in both the intravascular and the interstitial spaces to form a pharmacologically inactive complex that is subsequently eliminated renally. Indications for administration of Fab fragments in children are listed in Table 94.14. Atropine is potentially useful in managing symptomatic bradycardia. Although dogma states that patients on digoxin with severe hyperkalemia and QRS widening on the ECG should not receive calcium salts, this has not been supported in the literature. Once stabilized, consultation with a cardiologist is recommended in the management of patients receiving chronic digoxin therapy, because administration of Fab fragments can lead to recurrence of the patient's underlying dysrhythmias or dysfunction.

Iron. Historically, iron was a common cause of childhood poisoning deaths. However, preventive measures such as childproof packaging have significantly decreased the rates of serious iron toxicity in young children. Iron-containing products remain widely available, with the most potentially toxic being adult iron preparations and prenatal vitamins. The severity of an exposure is related to the amount of *elemental iron* ingested. Ferrous sulfate contains 20% elemental iron, ferrous gluconate 12%, and ferrous fumarate 33%. Multivitamin preparations and children's vitamins rarely contain enough elemental iron to cause significant toxicity. Furthermore, nonionic forms of iron, carbonyl iron and iron polysaccharide, also do not cause significant toxicity.

Pathophysiology. Iron is directly corrosive to the GI mucosa, leading to hematemesis, melena, ulceration, and potential perforation.

Table. 94.14 Indications for Administration of Digoxin Antibody Fragments in Children

Ingestion of >0.1-0.3 mg/kg *or* steady-state digoxin concentration >5 ng/mL *PLUS* one of the following: • Rapidly progressive symptoms • Signs of cardioactive steroid intoxication • Potentially life-threatening dysrhythmias or conduction blocks • Serum potassium concentration >5 mEq/L
Co-ingestion of other cardiotoxic drugs with additive or synergistic toxicity
Ingestion of plant known to contain cardioactive steroids *plus* severe dysrhythmias

Modified from Cole JB. Cardiovascular drugs. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. *Rosen's Emergency Medicine*, 9th ed. Philadelphia: Elsevier; 2018, Box 147.4, p. 1879.

Table 94.15 Clinical Manifestations of Iron Toxicity After Acute Overdose

PHASE	CLINICAL FEATURES
1. Gastrointestinal (6 hr)	Vomiting Diarrhea Hematemesis Hematochezia
2. Latent (6-24 hr)	Resolution of GI symptoms Tachycardia Acidosis Depressed mental status
3. Systemic (12-24 hr)	Return of GI symptoms Acidosis Leukocytosis Coagulopathy Renal failure Lethargy or coma Cardiovascular collapse
4. Hepatic (2-5 days)	Fulminant liver failure Coagulopathy
5. Obstructive (3-6 wk)	Pyloric or bowel scarring Obstruction

GI, Gastrointestinal.
Modified from Theobald JL, Mycyk MB. Iron and heavy metals. In: Walls RM, Hockberger RS, Gausche-Hill M, et al., eds. *Rosen's Emergency Medicine*, 9th ed. Philadelphia: Elsevier; 2018, Table 151.2, p. 1913.

Early iron-induced hypotension is caused by massive volume losses, increased permeability of capillary membranes, and vasodilation mediated by free iron. Iron accumulates in tissues, including the Kupffer cells of the liver and myocardial cells, leading to hepatotoxicity, coagulopathy, and cardiac dysfunction. Metabolic acidosis develops in the setting of hypotension, hypovolemia, and iron's direct interference with oxidative phosphorylation and the Krebs cycle. Pediatric patients who ingest >40 mg/kg of elemental iron should be referred to medical care for evaluation, although moderate to severe toxicity is typically seen with ingestions >60 mg/kg.

Clinical and Laboratory Manifestations. Iron toxicity is described in five often-overlapping stages (Table 94.15). Patients who do not develop GI symptoms within 6 hours of ingestion are unlikely to develop serious toxicity. Symptomatic patients and patients with a large exposure by history should have serum iron levels drawn 4-6 hours after ingestion. Serum iron concentrations of <350 µg/dL 4-8 hours after ingestion suggest a low risk of significant toxicity, concentrations of 350-500 µg/dL suggest moderate toxicity, and concentrations of >500 µg/dL indicate that significant toxicity is likely. Additional laboratory evaluation in the ill patient should include arterial or venous blood gas, lactate, CBC, serum glucose level, liver transaminases, and coagulation parameters. Careful attention should be paid to the patient's hemodynamic status. An abdominal radiograph may reveal the presence of iron tablets, although not all formulations of iron are radiopaque.

Treatment. Close clinical monitoring, combined with aggressive supportive and symptomatic care, is essential to the management of iron poisoning. Activated charcoal does not adsorb iron, and WBI remains the decontamination strategy of choice. **Deferoxamine**, a specific chelator of iron, is the antidote for moderate to severe iron intoxication (see Table 94.8). Indications for deferoxamine treatment include a serum iron concentration >500 µg/dL or moderate to severe symptoms of toxicity (e.g., acidosis), regardless of serum iron concentration. Deferoxamine is preferably given by continuous IV infusion at 15 mg/kg/hr. Hypotension is a common side effect of deferoxamine infusion and is managed by slowing the rate of the infusion and administering fluids and vasopressors as needed. Prolonged deferoxamine infusion (>24 hours) has been associated with pulmonary toxicity (ARDS) and *Yersinia* sepsis. The deferoxamine-iron complex can color the urine reddish ("vin rosé"), although the degree of this coloration should not guide therapy. Deferoxamine is typically continued until clinical symptoms and acidosis resolve. Consultation with a PCC or medical toxicologist can yield guidelines for discontinuing deferoxamine.

Oral Hypoglycemics

Oral medications used in the management of type 2 diabetes include sulfonylureas, biguanides (e.g., metformin), thiazolidinediones, and meglitinides. Of these, only the sulfonylureas and meglitinides have the potential to cause profound hypoglycemia in both diabetic and nondiabetic patients. These classes of medications are widely prescribed and thus readily available. In toddlers, unintentional ingestion of a single sulfonylurea tablet can lead to significant toxicity.

Pathophysiology. Sulfonylureas work primarily by enhancing endogenous insulin secretion. In binding to the sulfonylurea receptor, these drugs induce closure of K^+ channels, leading to membrane depolarization, opening of Ca^{2+} channels, and stimulation of Ca^{2+}-mediated insulin release. Even in therapeutic use, the duration of hypoglycemic action can last up to 24 hours.

Clinical and Laboratory Manifestations. Hypoglycemia and symptoms associated with hypoglycemia are the primary clinical manifestations of sulfonylurea toxicity. These signs and symptoms can include diaphoresis, tachycardia, lethargy, irritability, coma, seizures, and even focal neurologic findings. As with other hyperinsulinemic states, sulfonylurea overdoses are associated with a nonketotic hypoglycemia. In the majority of patients, hypoglycemia develops within 6 hours of ingestion but can be delayed up to 16-18 hours after ingestion. Toddlers are particularly susceptible to hypoglycemia during an overnight fast.

Treatment. Patients with symptomatic hypoglycemia should be promptly treated with dextrose. In patients with mild symptoms, oral dextrose may be sufficient. However, patients with severe symptoms or profound hypoglycemia should be treated with a bolus of IV dextrose. Continuous dextrose infusions and repeated IV dextrose boluses should be avoided, if possible, because this can stimulate further insulin release and lead to recurrent and prolonged hypoglycemia. Instead, the preferred antidote for persistent (i.e., requiring ≥2 doses of IV dextrose) sulfonylurea toxicity is **octreotide** (see Table 94.8). Octreotide is a somatostatin analog that inhibits insulin release. Octreotide is given IV or subcutaneously (SC), typically in doses of 1-2 µg/kg (50-100 µg in teens or adults) every 6-8 hours.

Given the potential for significant hypoglycemia, toddlers with witnessed or suspected sulfonylurea ingestions should be admitted to the hospital for serial glucose measurements for at least 12 hours, including an overnight fast. Patients of any age who develop hypoglycemia are also candidates for admission, given the prolonged duration of hypoglycemic activity with these medications. Prophylactic IV dextrose infusions are not recommended because they can mask the symptoms of toxicity and stimulate further insulin secretion. Patients who require IV dextrose and/or octreotide should be monitored until they can demonstrate euglycemia for at least 8 hours off all therapy.

With the increasing numbers of adolescents with type 2 diabetes, pediatricians should be familiar with the toxic effects of **metformin** as well. Although metformin does not cause hypoglycemia, its association with lactic acidosis is well documented (metformin-associated lactic acidosis [MALA]). This state typically arises after a large overdose in which the agent interferes with the liver's ability to clear lactic acid. Dangerously high serum lactate levels can result, leading to hemodynamic instability. Hemodialysis is usually the best option for patients with severe MALA.

Psychiatric Medications: Antidepressants

Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram) are the most commonly prescribed class of antidepressants. This trend largely results from their wide therapeutic index and more favorable side effect profile compared with older agents such as tricyclic antidepressants (TCAs; amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, imipramine) and monoamine oxidase inhibitors (MAOIs). Other agents include the serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) and atypical antidepressants (e.g., bupropion).

Tricyclic Antidepressants. Although now prescribed less often for depression, TCAs remain in use for a variety of other conditions, including chronic pain syndromes, enuresis, ADHD, and obsessive-compulsive disorder. TCAs can cause significant toxicity in children, even with ingestion of one or two pills (10-20 mg/kg).

Pathophysiology. TCAs achieve their desired antidepressant effects primarily through blockade of norepinephrine and serotonin reuptake. TCAs have complex interactions with other receptor types. Antagonism at muscarinic acetylcholine receptors leads to clinical features of the anticholinergic toxidrome. Antagonism at peripheral α-receptors leads to hypotension and syncope. Key to the toxicity of TCAs is their ability to block fast sodium channels, leading to impaired cardiac conduction and arrhythmias.

Clinical and Laboratory Manifestations. Cardiovascular and CNS symptoms dominate the clinical presentation of TCA toxicity. Symptoms typically develop within 1-2 hours of ingestion, and serious toxicity usually manifests within 6 hours of ingestion. Patients can have an extremely rapid progression from mild symptoms to life-threatening dysrhythmias. Patients often develop features of **anticholinergic toxidrome**, including delirium, mydriasis, dry mucous membranes, tachycardia, hyperthermia, urinary retention, and slow GI motility. CNS toxicity can include lethargy, coma, myoclonic jerks, and seizures. Sinus tachycardia is the most common cardiovascular manifestation of toxicity; however, patients can also develop widening of the QRS complex, premature ventricular contractions, and ventricular dysrhythmias. Refractory hypotension is a poor prognostic indicator and is the most common cause of death in TCA overdose.

An ECG can help determine the diagnosis and prognosis of the TCA-poisoned patient (Fig. 94.2; see Table 94.7). A QRS duration >100 msec identifies patients who are at risk for seizures and cardiac arrhythmias. An R wave in lead aVR of ≥3 mm is also an independent predictor of toxicity. Both ECG parameters are superior to measured serum TCA concentrations for identifying patients at risk for serious toxicity, and obtaining levels is rarely helpful in management of the acutely ill patient.

Treatment. Initial attention should be directed to supporting vital functions, including airway and ventilation as needed. Gastric decontamination can be accomplished with activated charcoal in patients who are alert and cooperative without clinical signs of toxicity. Treating clinicians should obtain an ECG as soon as possible and follow serial ECGs to monitor for progression of toxicity. The four primary effects described next may be seen at the bedside.

1. Altered Mental State. TCA-poisoned patients can become deeply comatose relatively quickly, so careful and prompt attention to the airway and placement of an endotracheal tube is of paramount importance.

2. Widened QRS on ECG. TCAs, as well as other agents (e.g., diphenhydramine, cocaine), block the fast Na^+ channels on the myocardial cells, slowing the upstroke of the QRS complex. Because the effect on Na^+ channels is greatest within the first 6 hours, frequent ECGs (i.e., every 20-30 minutes) during this period are important. As the QRS approaches 160 msec, the risk of the patient developing monomorphic ventricular tachycardia rises to 30%. Sodium, usually in the form of sodium bicarbonate, is the antidote of choice. *Indications for sodium bicarbonate include a QRS duration ≥100 msec, ventricular dysrhythmias, and hypotension.* Multiple bolus doses of sodium bicarbonate, 1-2 mEq/kg each, may be needed to narrow the QRS to <100 msec. Some prefer then to place the patient on an infusion of sodium bicarbonate, but this may not be necessary if the QRS is carefully monitored after the initial doses and repeat bolus dosing is provided as needed during the first 6-12 hours. Hypertonic (3%) saline and/or lipid emulsion therapy may be beneficial in refractory cases.

3. Hypotension. A direct-acting vasopressor such as norepinephrine or epinephrine is the agent of choice. Boluses of IV crystalloid fluids should be used with caution to prevent fluid overload.

4. Seizures. Seizures are relatively common and likely the result of multiple factors, including increased synaptic monoamines, sodium channel inhibition, and GABA receptor antagonism. Seizures are typically brief and should be treated with agents targeting the GABA-receptor complex in the brain. Benzodiazepines are the agent of choice.

Asymptomatic children should receive appropriate decontamination and have continuous cardiac monitoring and serial ECGs for at least 6 hours after exposure. If any manifestations of toxicity develop, the child should be admitted to a monitored setting. Children who remain

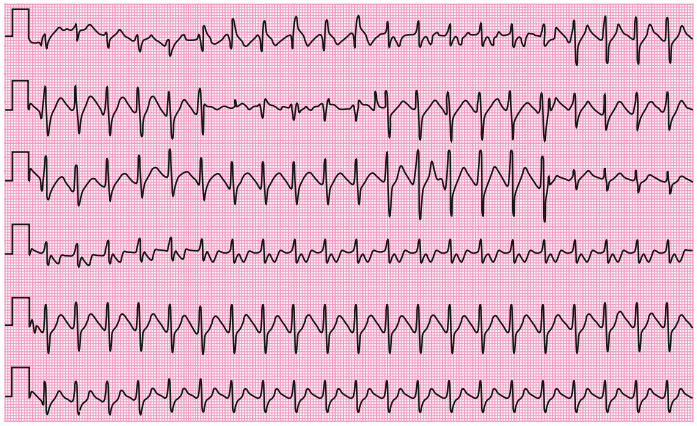

Fig. 94.2 Electrocardiographic findings in tricyclic antidepressant toxicity. Note the tachycardia, widened QRS interval (144 msec), and prominent R wave in lead aVR. These findings are consistent with blockade of fast sodium channels.

completely asymptomatic with normal serial ECGs may be candidates for discharge after that monitoring period.

Selective Serotonin Reuptake Inhibitors. In overdose, SSRIs are considerably less toxic than TCAs. SSRIs are unlikely to cause significant toxicity in exploratory ingestions. Some data suggest that initiating SSRI therapy is associated with an increased risk of suicidal ideation and behavior (see Chapter 40).

Pathophysiology. SSRIs selectively block the reuptake of serotonin in the CNS. In contrast to TCAs and atypical antidepressants, SSRIs do not directly interact with other receptors.

Clinical and Laboratory Manifestations. Although seen more often after therapeutic use or overdose of several serotonergic agents in combination, **serotonin syndrome** has also been described in ingestion of SSRIs alone (Table 94.16). Clinically, serotonin syndrome describes a spectrum of altered mental status, autonomic instability, fever, and neuromuscular hyperactivity (hyperreflexia, tremors, clonus in lower extremities > upper extremities) (Table 94.17). One or all of these signs may be present to varying degrees.

In overdose, the principal clinical manifestations of toxicity are sedation and tachycardia. Cardiac conduction abnormalities (primarily QTc prolongation) and seizures have been described in significant overdoses, especially after ingestions of citalopram. An ECG should be part of the initial assessment after SSRI ingestion. Serum creatine kinase (CK) levels are almost always elevated in a patient with clinically significant serotonin syndrome. The differential diagnosis includes neuroleptic malignant syndrome and malignant hyperthermia (Table 94.18).

Table 94.16 Drugs Associated with Serotonin Syndrome

DRUG TYPE	DRUGS
Selective serotonin reuptake inhibitors	Sertraline, fluoxetine, fluvoxamine, paroxetine, citalopram, escitalopram
Antidepressant drugs	Trazodone, nefazodone, buspirone, clomipramine, venlafaxine, amitriptyline, nortriptyline
Monoamine oxidase inhibitors	Phenelzine, moclobemide, clorgyline, isocarboxazid
Anticonvulsants	Valproate
Analgesics	Meperidine, fentanyl, tramadol, pentazocine
Antiemetic agents	Ondansetron, granisetron, metoclopramide
Antimigraine drugs	Sumatriptan
Bariatric medications	Sibutramine
Antibiotics	Linezolid (a monoamine oxidase inhibitor), ritonavir (through inhibition of cytochrome P450 enzyme isoform 3A4)
Nonprescription cough and cold remedies	Dextromethorphan
Drugs of abuse	Methylenedioxymethamphetamine (MDMA, "ecstasy"), lysergic acid diethylamide (LSD), 5-methoxydiisopropyltryptamine ("foxy methoxy"), Syrian rue (contains harmine and harmaline, both monoamine oxidase inhibitors)
Dietary supplements and herbal products	Tryptophan, *Hypericum perforatum* (St. John's wort), *Panax ginseng* (ginseng)
Other	Lithium

From Boyer EW, Shannon M. The serotonin syndrome. *N Engl J Med.* 2005;352:1112–1120.

Treatment. Initial management includes a careful assessment for signs and symptoms of serotonin syndrome and an ECG. Most patients simply require supportive care and observation until their mental status improves and tachycardia, if present, resolves. Management of serotonin syndrome is directed by the severity of symptoms; possible therapeutic interventions include benzodiazepines in mild cases and intubation, sedation, and paralysis in patients with severe manifestations (e.g., significant hyperthermia). Because agonism at the 5-HT_{2A} serotonin receptor is thought to be primarily responsible for the development of serotonin syndrome, use of the 5-HT_{2A} receptor antagonist cyproheptadine has been considered a possible antidote; the efficacy of cyproheptadine in managing serotonin syndrome is not well-supported by the available literature. Furthermore, cyproheptadine should be used with caution when the diagnosis is unclear, as it can worsen anticholinergic toxicity.

Atypical Antidepressants. The atypical antidepressant class includes agents such as venlafaxine and duloxetine (SNRIs), bupropion (dopamine, norepinephrine, and some serotonin reuptake blockade), and trazodone (serotonin reuptake blockade and peripheral α-receptor antagonism). The variable receptor affinities of these agents lead to some distinctions in their clinical manifestations and management.

Clinical and Laboratory Manifestations. In overdose, **venlafaxine** and other SNRIs have been associated with cardiac conduction defects, including QRS and QTc prolongation, and seizures (typically within a few hours of ingestion). **Bupropion** warrants special consideration because it is one of the most common etiologies of toxicant-induced seizures in the United States. After ingestion of SR or extended-release (ER) preparations of bupropion, seizures can occur as late as 18-20 hours after ingestion. In addition, bupropion can cause tachycardia, agitation, and QRS and QTc prolongation. These cardiac effects are thought to result from a reduction in cardiac intracellular coupling caused by inhibition at gap junctions in the heart. Mortality results from not only status epilepticus but also the cardiac conduction disturbances causing ventricular tachycardia and dysrhythmias. In addition to sedation and signs of serotonin excess, trazodone overdose may be associated with hypotension from blockade of peripheral α-receptors.

Treatment. Management is directed at clinical signs and symptoms. QRS and QTc interval prolongation after bupropion poisoning is typically resistant to the standard treatments of sodium bicarbonate and magnesium. Seizures are often brief and self-limited but can be treated with benzodiazepines if necessary. A patient poisoned with bupropion who shows unstable hemodynamics with prolonged ECG intervals or persistent seizure activity after the appropriate therapies should be discussed with a toxicologist for possible lipid emulsion therapy. Because of the potential for delayed seizures, asymptomatic patients who have ingested an SR preparation of bupropion should be admitted to a monitored setting for at least 20-24 hours. Trazodone-associated hypotension typically responds to fluids, though it can require vasopressors in extreme cases.

Monoamine Oxidase Inhibitors. Although now rarely used therapeutically, MAOIs remain important agents given their potential for serious and delayed toxicity. Ingestions of only one or two pills (6 mg/kg) are associated with toxicity in children. Clinical manifestations initially include hypertension, hyperthermia, tachycardia, muscle rigidity, and seizures, followed up to 24 hours later by hemodynamic instability and cardiovascular collapse. *Any child who ingests a MAOI should be admitted to a monitored setting for at least 24 hours, regardless of symptoms.* Management includes blood pressure control, cooling and benzodiazepines for hyperthermia, serial monitoring of CK and renal function, and fluid and vasopressor therapy for hemodynamic instability.

Psychiatric Medications: Antipsychotics

Clinicians are increasingly prescribing antipsychotic medications in the pediatric population. Antipsychotics are usually classified as either typical or atypical. In general, typical agents are associated with more side effects and toxicity than the atypical agents.

Table 94.17 Spectrum of Symptoms of Serotonergic Toxicity

SEVERITY	NEUROMUSCULAR EXCITATION	ALTERED MENTAL STATUS	AUTONOMIC DYSFUNCTION
Mild	Hyperreflexia Tremor Myoclonus	Anxiety Restlessness Insomnia	Diaphoresis Mydriasis Tachycardia
Moderate	Opsoclonus Spontaneous or inducible clonus	Agitation	Hypertension Hyperthermia (<40°C [<104°F]) Hyperactive bowel sounds Diarrhea, nausea, vomiting
Severe	Rigidity Respiratory failure Tonic-clonic seizure	Coma Delirium Confusion	Severe hyperthermia (≥40°C [≥104°F]) Dynamic blood pressure

Adapted from Wang RZ, Vashistha V, Kaur S, Houchens NW. Serotonin syndrome: Preventing, recognizing, and treating it. *Clev Clinic J Med*. 2016;83(11):810–817, Table 2, p. 812.

Table 94.18 Signs and Symptoms of Neuroleptic Malignant Syndrome (NMS)/Serotonin Syndrome/Malignant Hyperthermia

CLINICAL FEATURES	NMS	SEROTONIN SYNDROME	MALIGNANT HYPERTHERMIA
Triggering agent	Neuroleptic	Proserotonergic agent	Succinylcholine or inhaled anesthetic
Onset	Slow (hours to days)	Fast (minutes to hours)	Very fast to fast (minutes to hours)
Duration	Long (days to weeks)	Short (1-2 days)	Short (1-3 days)
Agitation	Sometimes	Yes	No
Confusion	Yes	Sometimes	Unusual
Hyperactivity	No	Yes	No
Bradykinesia/stupor	Yes	No	Unusual
Myoclonus	No	Yes	No
Shivering	No	Yes/sometimes	No
Tremor	Sometimes	Yes	No
Pupils	Mid-sized	Large	Not specific
Hyperreflexia	No	Yes (especially lower extremities)	No
Rigidity	Severe	Sometimes	Severe
Rigidity type	Extrapyramidal (lead pipe)	Pyramidal (clasp-knife)	Generalized
Hyperpyrexia	Yes	Yes	Severe
Tachypnea	Yes	Yes	Yes
Tachycardia	Yes	Yes	Yes (severe)
Hypertension	Sometimes	Yes	Sometimes
Leukocytosis	Yes	Uncommon	Not typical
Elevated creatine phosphokinase	Severe	Mild	Severe

Adapted from Gillman PK. The serotonin syndrome and its treatment. *J Psychopharmacol* 1999;13:100–109; Gillman K; Serotonin toxicity www.psychotropical.com/serotonin-toxicity; and Wappler F, Fiege M, Schulte am Esch J. Pathophysiological role of the serotonin system in malignant hyperthermia. *Br J Anaesth*. 2001;87(5):794–798.

Pathophysiology. *Typical,* or "traditional," antipsychotics (haloperidol, droperidol, thioridazine, chlorpromazine, fluphenazine) are characterized by their antagonism at D_2 dopamine receptors. In therapeutic use, these agents are associated with extrapyramidal symptoms, tardive dyskinesia, and, rarely, development of **neuroleptic malignant syndrome (NMS)** (see Table 94.18). The *atypical* agents (aripiprazole, clozapine, quetiapine, risperidone, ziprasidone) were developed with relatively less dopamine (D_2-receptor) antagonism in the nigrostriatum to avoid these side effects and improve their efficacy in managing the "negative" symptoms of schizophrenia. Instead, these agents have complex and varied interactions with multiple receptor types, including α-receptors, serotonin receptors, muscarinic acetylcholine receptors, and histamine receptors.

Clinical and Laboratory Manifestations. Typical antipsychotic toxicity usually includes sedation, tachycardia, and QTc prolongation. Patients can present with acute dystonia, akathisia, and NMS, although these are seen less frequently in acute overdoses than in therapeutic use. The phenothiazines (e.g., thioridazine) can cause widening of the QRS interval from blockade of fast sodium channels. Clinically, NMS can be difficult to distinguish from serotonin syndrome.

Although the presentation of atypical antipsychotic toxicity can vary based on the receptor affinities of the specific agent, sedation, tachycardia, and QTc prolongation are common. Peripheral α-receptor blockade (e.g., with quetiapine) is associated with hypotension. In therapeutic use, clozapine is associated with agranulocytosis. Atypical antipsychotics that antagonize muscarinic acetylcholine receptors (e.g., olanzapine, quetiapine) may cause symptoms of anticholinergic toxidrome.

Diagnostic testing should include an ECG. Patients with hyperthermia or muscle rigidity should have a serum CK level sent to monitor

for possible rhabdomyolysis. CBC is indicated in patients with fever to evaluate for neutropenia. Antipsychotic levels are not readily available and are not helpful in managing acute poisoning.

Management. Initial management involves assessing and supporting vital functions. In some patients, CNS depression may be so profound as to require intubation for airway control. Acute dystonia is treated with diphenhydramine and benztropine. Management of NMS includes aggressive supportive care, IV fluids, active cooling, benzodiazepines, and bromocriptine or dantrolene in severe cases. QTc prolongation is managed with repletion of electrolytes (especially calcium, magnesium, and potassium), continuous cardiac monitoring, prevention of bradycardia (overdrive pacing, isoproterenol, atropine), and defibrillation if the patient develops torsades de pointes. Delirium associated with anticholinergic toxicity may be managed with benzodiazepines, and a specific antidote (physostigmine) can be considered in consultation with a medical toxicologist (see Table 94.8). Seizures typically are well controlled with benzodiazepines. Hypotension usually responds to boluses of IV fluids, although vasopressor therapy is necessary in some patients.

Household Products

Caustics

Caustics include acids and alkalis as well as a few common oxidizing agents (see Chapter 373). Strong acids and alkalis can produce severe injury even in small-volume ingestions.

Pathophysiology. **Alkalis** produce a *liquefaction necrosis,* allowing further tissue penetration of the toxin and setting the stage for possible perforation. **Acids** produce a *coagulative necrosis,* which limits further tissue penetration, although perforation can still occur. The severity of the corrosive injury depends on the pH and concentration of the product and the length of contact time with the product. Agents with a pH of <2 or >12 are most likely to produce significant injury.

Clinical Manifestations. Ingestion of caustic materials can produce injury to the oral mucosa, posterior pharynx, vocal cords, esophagus, and stomach. Patients can have significant esophageal injury even in the absence of visible oral burns. Symptoms include pain, drooling, vomiting, abdominal pain, and difficulty swallowing or refusal to swallow. Laryngeal injury can manifest as stridor and respiratory distress, necessitating intubation. In the most severe cases, patients can present in shock after perforation of a hollow viscus. Circumferential burns of the esophagus are likely to cause strictures when they heal, which can require repeated dilation or surgical correction and long-term follow-up for neoplastic changes in adulthood. Caustic exposures on the skin or in the eye can cause significant tissue damage.

Treatment. Initial treatment of caustic exposures includes thorough removal of the product from the skin or eye by flushing with water. *Emesis and lavage are contraindicated.* Activated charcoal should not be used because it does not bind these agents, interferes with endoscopy, and can predispose the patient to vomiting and subsequent aspiration. Stridor or other signs of respiratory distress should alert the provider to the need for a thorough evaluation of the airway for potential intubation or surgical airway management. Endoscopy can be performed within 12-24 hours of ingestion in *symptomatic* patients or those with suspected injury based on history and known characteristics of the ingested product. The role of endoscopy is purely diagnostic and is contraindicated in patients with severe oropharyngeal injury with edema and necrosis, evidence of perforation, respiratory distress, or hemodynamic instability, as these patients instead require immediate surgical consultation. Expectant management with a period of nothing by mouth (NPO) and proton pump inhibitor therapy is likely appropriate for most *asymptomatic* patients. Corticosteroids or prophylactic antibiotics are not beneficial.

Pesticides

Cholinesterase-Inhibiting Insecticides. The most commonly used insecticides in agriculture are **organophosphates** and **carbamates**; both are inhibitors of cholinesterase enzymes: acetylcholinesterase (AChE), pseudocholinesterase, and erythrocyte AChE. Most pediatric poisonings occur as the result of unintentional exposure to insecticides in and around the home or farm. The chemical warfare weapons known as "nerve agents" are also organophosphate compounds with a similar mechanism of action but much greater potency.

Pathophysiology. Organophosphates and carbamates produce toxicity by binding to and inhibiting AChE, preventing the degradation of acetylcholine (ACh) and resulting in its accumulation at nerve synapses. If left untreated, organophosphates form an irreversible bond to AChE, permanently inactivating the enzyme. This process, called *aging,* occurs over a variable period, depending on the characteristics of the specific organophosphate. A period of weeks to months is required to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond with the enzymes, typically allowing reactivation of AChE within 24 hours.

Clinical and Laboratory Manifestations. Clinical manifestations of organophosphate and carbamate toxicity relate to ACh accumulation at peripheral nicotinic and muscarinic synapses and in the CNS. Symptoms of carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used mnemonic for the symptoms of cholinergic excess at muscarinic receptors is **DUMBBELS**: diarrhea/defecation, urination, miosis, bronchorrhea/bronchospasm, bradycardia, emesis, lacrimation, and salivation. Nicotinic signs and symptoms include muscle weakness, fasciculation, tremors, hypoventilation (diaphragm weakness), hypertension, tachycardia, and dysrhythmias. Severe manifestations include coma, seizures, shock, arrhythmias, and respiratory failure.

Diagnosis of poisoning is based primarily on history and physical exam findings. Red blood cell cholinesterase and pseudocholinesterase activity levels can be measured in the laboratory. These are only helpful when compared with the patient's known baseline. As such, these assessments are typically limited to farmworkers undergoing ongoing occupational surveillance.

Treatment. Basic decontamination should be performed, including washing all exposed skin with soap and water and immediately removing all clothing. Activated charcoal is unlikely to be of benefit because these are liquids that are rapidly absorbed. Basic supportive care should be provided, including fluid and electrolyte replacement, intubation, and ventilation if necessary. The use of succinylcholine for rapid sequence intubation should be avoided because the same cholinesterase enzymes that are poisoned metabolize this neuromuscular blocking agent, leading to prolonged paralysis.

Two antidotes are useful in treating cholinesterase inhibitor poisoning: atropine and pralidoxime (see Table 94.8). **Atropine**, which antagonizes the muscarinic ACh receptor, is useful for both organophosphate and carbamate intoxication. Often, large doses of atropine must be administered by intermittent bolus or continuous infusion to control symptoms. Atropine dosing is primarily targeted to drying the respiratory secretions. **Pralidoxime** breaks the bond between the organophosphate and the enzyme, reactivating AChE. Pralidoxime is only effective if it is used before the bond ages and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously.

Without treatment, symptoms of organophosphate poisoning can persist for weeks, requiring continuous supportive care. Even with treatment, some patients develop a delayed polyneuropathy and a range of chronic neuropsychiatric symptoms.

Pyrethrins and Pyrethroids. Pyrethrins are derived from the chrysanthemum flower and, along with synthetic derivatives, pyrethroids, are the most used pesticides in the home. Although >1,000 pyrethrins and pyrethroids exist, <20 are available in the United States, with **permethrin** being the most common. Exposure to these compounds occurs by inhalation, dermal absorption, or ingestion. Ingestion is the predominant route and typically occurs by eating contaminated foods. Permethrin is also a prescribed medication for the treatment of scabies and lice.

Pathophysiology. Pyrethrins and pyrethroids prolong the open state of the voltage-gated Na^+ channel conduction, which is the main mechanism resulting in its pesticide activity. Pyrethrins have minimal toxicity in mammals because of rapid metabolism, higher affinity for the insect Na^+ channel, and decreased activity at higher temperatures

seen in warm-blooded animals. Because pyrethroids were specifically manufactured to be more stable in the environment, they have a higher likelihood of toxicity.

Clinical and Laboratory Manifestations. Pyrethrin exposures can lead to allergic reactions ranging from dermatitis to urticaria to anaphylaxis. Acute pyrethroid exposure can result in headache, nausea, dizziness, tremors, ataxia, choreoathetosis, loss of consciousness, and seizures. The severity of the symptoms depends on the magnitude of the exposure. Reports of acute lung injury have also occurred after pyrethroid exposures, although this is likely from the other components of the insecticide, such as surfactants and solvents. Paresthesias limited to the cutaneous exposure area can also occur after a dermal exposure. Chronic exposures have not been shown to result in any clinical manifestations. Although one can test for urinary pyrethroid metabolites, this is only useful for monitoring occupational exposure and has no role in the acute exposure.

Treatment. Initial treatment should focus on decontamination, which involves removing all clothing and irrigation of exposed areas. Allergic reactions are treated with oral antihistamines and topical corticosteroids. Systemic toxicity should be treated with excellent supportive care, using benzodiazepines for tremors and seizures.

Hydrocarbons

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Specific characteristics of each product determine whether exposure will produce systemic toxicity, local toxicity, both, or neither. Nevertheless, aspiration of even small amounts of certain hydrocarbons can lead to serious, potentially life-threatening toxicity.

Pathophysiology. The most important manifestation of hydrocarbon toxicity is *aspiration pneumonitis* through inactivation of the type II pneumocytes and resulting in surfactant deficiency (see Chapter 446). Aspiration usually occurs during coughing and gagging at the time of ingestion or vomiting after the attempted ingestion of an aliphatic hydrocarbon. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity and directly proportional to its volatility. Compounds with low viscosity and high volatility, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1 mL) of such chemicals need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration. Gasoline and kerosene are poorly absorbed, but they often cause considerable irritation of the GI mucosa as they pass through the intestines.

Certain hydrocarbons have unique toxicities and can cause symptoms after ingestion, inhalation, or dermal exposures. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. **Methylene chloride**, found in some paint removers, is metabolized to carbon monoxide. **Benzene** is known to cause cancer, most often acute myelogenous leukemia, after long-term exposure. Nitrobenzene, aniline, and related compounds can produce methemoglobinemia. A number of **volatile** hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are frequently abused by inhalation. Some of these substances, principally the **halogenated** hydrocarbons (which contain a chlorine, bromine, or fluorine), can sensitize the myocardium to the effects of endogenous catecholamines. This can result in dysrhythmias and "sudden sniffing death." Chronic abuse of these agents can lead to cerebral atrophy, neuropsychologic changes, peripheral neuropathy, and kidney disease (see Chapter 157).

Clinical and Laboratory Manifestations. Transient, mild CNS depression is common after hydrocarbon ingestion or inhalation. Aspiration is characterized by coughing, which usually is the first clinical finding. Chest radiographs may initially be normal, but they often show abnormalities within 6 hours of exposure in patients who have aspirated. Respiratory symptoms can remain mild or progress rapidly to ARDS and respiratory failure. Fever and leukocytosis are common accompanying signs in patients with pneumonitis and do not necessarily imply bacterial superinfection. Chest radiographs can remain abnormal long after the patient returns to their clinical baseline. Pneumatoceles can appear on the chest radiograph 2-3 weeks after exposure.

After inhalational exposures to halogenated hydrocarbons, patients can present with ventricular dysrhythmias, often refractory to conventional management. Recurrent inhalation of the aromatic hydrocarbon **toluene** can lead to a type IV renal tubular acidosis.

Treatment. *Emesis and lavage are contraindicated given the risk of aspiration*. Activated charcoal is not useful because it does not bind the common hydrocarbons and can also induce vomiting. If hydrocarbon-induced pneumonitis develops, respiratory treatment is supportive (see Chapter 446). Neither corticosteroids nor prophylactic antibiotics have shown any clear benefit. Standard mechanical ventilation, high-frequency ventilation, and ECMO have all been used to manage the respiratory failure and ARDS associated with severe hydrocarbon-induced pneumonitis.

Patients with dysrhythmias in the setting of halogenated hydrocarbon inhalation should be treated with β blockers (usually esmolol) to block the effects of endogenous catecholamines on the sensitized myocardium.

Toxic Alcohols

Methanol is found in windshield washer fluids, deicers, paint removers, fuel additives, liquid fuel canisters, and industrial solvents. **Ethylene glycol** is found in antifreeze. Unintentional ingestion is the most common exposure in children, and small-volume ingestions of concentrated products can theoretically cause toxicity. The pathophysiology, acid-base derangements, and treatment of both chemicals are similar, although they differ in their primary end-organ toxicity. In both cases the metabolites of the parent compounds are responsible for the serious clinical effects that can follow exposure.

Isopropyl alcohol (rubbing alcohol), found in hand sanitizers, causes intoxication similar to that associated with ethanol but can also cause a hemorrhagic gastritis and myocardial depression in massive ingestions. Unlike ethylene glycol and methanol, isopropyl alcohol is metabolized to a ketone and does not cause a metabolic acidosis. Management is similar to that of ethanol ingestions (see Chapter 157) and is not further discussed here.

Methanol

Pathophysiology. Methanol is oxidized in the liver by alcohol dehydrogenase to formaldehyde, which is further oxidized to formic acid by aldehyde dehydrogenase. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration.

Clinical and Laboratory Manifestations. Drowsiness, mild inebriation, nausea, and vomiting develop early after methanol ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is often delayed up to 12-24 hours as methanol undergoes metabolism to its toxic metabolites. This metabolism is further slowed if *ethanol* has also been ingested, because the liver will preferentially metabolize ethanol. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the "feeling of being in a snowstorm" and appear only after acidosis is well established. These visual defects may be reversible if treated early, but untreated can lead to permanent blindness. On examination, dilated pupils, retinal edema, and optic disc hyperemia may be noted. Initially, patients have an elevated osmolar gap, then develop an anion gap metabolic acidosis as the parent compound is metabolized to formic acid.

In young children, determining if a significant exposure has occurred is usually difficult based on history. Methanol blood levels are available at some laboratories and should be sent after a concerning exposure. If methanol blood levels are not readily available, estimation of an osmolar gap may be used as a surrogate marker, but a normal osmolar gap does not rule out ingestion of any alcohol. Serum osmolality is measured by the freezing-point depression method and compared with a calculated serum osmolarity.

Treatment. Treatment is as discussed for ethylene glycol toxicity.

Ethylene Glycol

Pathophysiology. Ethylene glycol is oxidized by alcohol dehydrogenase in the liver to glycolaldehyde, which is further converted to

glycolic acid by aldehyde dehydrogenase. Glycolic acid is responsible for the metabolic acidosis and is further metabolized to glyoxylic and then to oxalic acid. Oxalic acid combines with serum and tissue calcium, forming calcium oxalate crystals that deposit throughout the body, especially in the renal parenchyma, leading to acute tubular necrosis.

Clinical and Laboratory Manifestations. Early symptoms include nausea, vomiting, CNS depression, and inebriation. Delayed manifestations include an anion gap metabolic acidosis, hypocalcemia, and acute kidney injury. Even later, patients can develop cranial nerve palsies.

Both ethylene glycol and methanol can produce profound, life-threatening metabolic acidosis and acidemia, with measured serum bicarbonates that may even be nondetectable. The onset of the acidosis is delayed up to 4-12 hours after ethylene glycol ingestion and may be delayed further with any concomitant ingestion of ethanol. Ethylene glycol blood concentrations are technically difficult to perform and are available only at some larger reference laboratories. In the absence of readily available ethylene glycol concentrations, calculation of the osmolar gap may be helpful as a surrogate marker.

Examination of the urine with a Wood lamp is neither sensitive nor specific for ethylene glycol ingestion. The earliest sign on a urinalysis of ethylene glycol poisoning is usually hematuria. Calcium oxalate crystals can be seen on urine microscopy but might not be evident early after exposure. Electrolytes (including calcium), acid-base status, kidney function, and ECG should be closely monitored in poisoned patients.

Treatment. Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is generally not of value. The classic antidote for methanol and ethylene glycol poisoning was ethanol, a preferential substrate for alcohol dehydrogenase, thus preventing the metabolism of parent compounds to toxic metabolites. **Fomepizole**, a potent competitive inhibitor of alcohol dehydrogenase, has almost entirely replaced ethanol because of its ease of administration, lack of CNS and metabolic effects, and overall excellent patient tolerability profile (see Table 94.8). A serum concentration must be interpreted along with the time removed from exposure. A patient with a methanol level of 20 mg/dL 24 hours after exposure had a much larger dose than a patient with the same level only 1 hour after ingestion. Indications for fomepizole include ethylene glycol or methanol level >20 mg/dL (assuming no ethanol is present), history of potentially toxic ingestion (e.g., any intentional overdose), or history of ingestion with evidence of acidosis. There are few disadvantages to giving the initial dose of fomepizole to patients with a concerning history of ingestion or laboratory findings. Given the dosing schedule of fomepizole (every 12 hours), this strategy buys the clinician time to confirm or exclude the diagnosis before giving a second dose. Adjunctive therapy includes folate (methanol toxicity), pyridoxine (ethylene glycol toxicity), and sodium bicarbonate infusion (if acidemic). If a child has had an unintentional exposure and the toxic alcohol level cannot be obtained, a reasonable approach is to follow serum chemistries every 4 hours until 12 hours after the exposure. If the bicarbonate level on the chemistry panel does not fall in that period, a toxic exposure is unlikely (assuming no ethanol is present).

Hemodialysis effectively removes ethylene glycol, methanol, and their metabolites (except calcium oxalate) and corrects acid-base and electrolyte disturbances. Fomepizole should be given both before and immediately after dialysis. Indications for dialysis include a methanol or ethylene glycol level >50 mg/dL, acidosis, severe electrolyte disturbances, renal failure, and hemodynamic instability. However, in the absence of acidosis and kidney failure, even massive ethylene glycol ingestions have been managed without dialysis. Methanol, however, because its elimination in the setting of alcohol dehydrogenase inhibition is prolonged, often warrants dialysis to remove the parent compound. Therapy (fomepizole and/or dialysis) should be continued until ethylene glycol and methanol levels are <20 mg/dL. Although the visual effects from methanol poisoning are usually permanent, the kidney injury from ethylene glycol injury is not. Patients requiring hemodialysis after ethylene glycol poisoning will almost always recover complete renal function within 2-6 weeks. Consultation with a PCC, medical toxicologist, and nephrologist may be helpful in managing toxic alcohol ingestions.

Plants

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, most ingestions of plant parts (leaves, seeds, flowers) result in either no toxicity or mild, self-limiting effects. However, ingestion of certain plants can lead to serious toxicity (Table 94.19).

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, growing conditions, and the route of exposure. Assessment of the potential severity after an exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, which can vary among communities. PCCs have access to professionals who can assist in properly identifying plants. They also are well versed in the common poisonous plants in their service area and the seasons when they are more abundant. For these reasons, consultation with the local PCC may be very helpful in the management of these ingestions.

For potentially toxic plant ingestions, consider decontamination with activated charcoal in patients who present within 1-2 hours of ingestion; otherwise, treatment is primarily supportive and based on symptoms. The most common manifestation of toxicity after plant ingestion is GI upset, which can be managed with antiemetics and fluid and electrolyte support. Table 94.19 outlines management strategies for a few specific toxicities.

Herbal Remedies

Herbal remedies represent a relatively common exposure in children; despite this, reports of life-threatening toxicity are rare.

There are several mechanisms by which herbal remedies may be poisonous. Many herbal remedies are inherently toxic; it is either the dose used or specific processing of the remedy that renders them safe for use. For example, oil of wintergreen used as a liniment contains a high concentration of methyl salicylate, a concerning source of salicylate poisoning in small children. A remedy intended to contain one compound may accidentally contain another; reports exist of contamination of skin creams with mercury, herbal remedies contaminated with lead, and weight loss supplements contaminated with cardioactive steroids. Herbal remedies may interfere with the metabolism of pharmaceuticals; an example is St. John's wort, which by induction of the cytochrome oxidase system (specifically, CYP3A4) may render certain medications less effective.

Management of toxicity associated with herbal remedies remains largely the same as for other organic compounds. Decontamination with activated charcoal should be considered for patients arriving within 1-2 hours of an ingestion. Signs and symptoms should be treated as outlined previously in this chapter, with excellent supportive care and therapy directed toward the suspected toxin. In the rare case of concern for contamination with a heavy metal, specific assays may be obtained for confirmation of exposure. A list of herbal remedies and their associated toxicities are provided in Table 94.20.

In limited cases, specific antidotes are suggested based on the pathophysiologic mechanism. Several plant and animal species contain cardioactive steroids with digoxin-like toxicity. Although digoxin-specific immune fragments are only evidence based for the management of yellow oleander *(Thevetia peruviana)* toxicity, it is reasonable to use this therapy in a critically ill patient who has developed cardiac toxicity or hyperkalemia after ingestion of lily of the valley, squill, or oleander. Several essential oils (pennyroyal oil, clove oil) deplete glutathione as part of their toxic mechanism, and thus treatment with NAC may be of benefit. Gingko causes a depletion of active pyridoxine stores, and thus pyridoxine administration may be helpful in the setting of benzodiazepine-refractory seizures.

Table 94.19 Commonly Ingested Plants with Significant Toxic Potential

PLANT	SYMPTOMS	MANAGEMENT
Autumn crocus (Colchicum autumnale)	Vomiting Diarrhea Initial leukocytosis followed by bone marrow failure Multisystem organ failure	Activated charcoal decontamination Aggressive fluid resuscitation and supportive care
Belladonna alkaloids: jimsonweed (Datura stramonium) Belladonna ("deadly nightshade"; Atropa belladonna)	Anticholinergic toxidrome Seizures	Supportive care, benzodiazepines Consider physostigmine; only use if no conduction delays on ECG
Cardiac glycoside–containing plants (e.g., foxglove, lily of the valley, oleander, yellow oleander)	Nausea Vomiting Bradycardia Dysrhythmias (AV block, ventricular ectopy) Hyperkalemia	Digoxin-specific Fab fragments
Jequirity bean and other abrin-containing species (e.g., rosary pea, precatory bean)	Oral pain Vomiting Diarrhea Shock Hemolysis Renal failure	Supportive care, including aggressive volume resuscitation and correction of electrolyte abnormalities
Monkshood (Aconitum species)	Numbness and tingling of lips/tongue Vomiting Bradycardia	Atropine for bradycardia Supportive care
Oxalate-containing plants: Philodendron, Dieffenbachia, Colocasia ("elephant ear")	Local tissue injury Oral pain Vomiting	Supportive care, pain control
Poison hemlock (Conium maculatum)	Vomiting Agitation followed by CNS depression Paralysis Respiratory failure	Supportive care
Pokeweed	Hemorrhagic gastroenteritis Burning of mouth and throat	Supportive care
Rhododendron	Vomiting Diarrhea Bradycardia	Atropine for symptomatic bradycardia Supportive care
Tobacco	Vomiting Agitation Diaphoresis Fasciculations Seizures	Supportive care
Water hemlock (Cicuta species)	Abdominal pain Vomiting Delirium Seizures	Supportive care, including benzodiazepines for seizures
Yew (Taxus species)	GI symptoms QRS widening Hypotension CV collapse	Supportive care Atropine for bradycardia Sodium bicarbonate does not appear to be effective

AV, Atrioventricular; CNS, central nervous system; CV, cardiovascular; ECG, electrocardiogram; Fab, fragment, antigen binding; GI, gastrointestinal.

Toxic Gases

Carbon Monoxide

Although many industrial and naturally occurring gases pose a health risk by inhalation, the most common gas involved in pediatric exposures is CO. CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel; the less efficient the combustion, the greater the amount of CO produced. Wood-burning stoves, kerosene heaters, old furnaces, hot-water heaters, closed-space fires, and automobiles are a few of the potential sources of CO.

Pathophysiology. CO binds to hemoglobin with an affinity >200 times that of oxygen, forming carboxyhemoglobin (HbCO). In doing so, CO displaces oxygen and creates a conformational change in hemoglobin that impairs the delivery of oxygen to the tissues, leading to tissue hypoxia. HbCO levels are not well correlated with clinical signs of toxicity, likely because CO interacts with multiple proteins in addition to hemoglobin. CO binds to cytochrome oxidase, disrupting cellular respiration. CO displaces nitric oxide (NO) from proteins, allowing NO to bind with free radicals to form the toxic metabolite peroxynitrite, leading to lipid peroxidation and cellular damage. NO is also a potent vasodilator, in part responsible for clinical symptoms such as headache, syncope, and hypotension.

Table 94.20 Clinical Toxicity of Selected Herbs

COMMON NAME	BOTANICAL NAME	THERAPEUTIC USES	POTENTIAL TOXICITY
Aconite (monkshood, wolfsbane)	*Aconitum* spp.	Sedative, analgesic, antihypertensive	Cardiac arrhythmias
Aloe	*Aloe* spp.	Burns, skin diseases	Nephritis, GI upset
Betel nut	*Areca catechu*	Mood elevation	Bronchoconstriction, oral cancers
Bloodroot	*Sanguinaria canadensis*	Emetic, cathartic, eczema	GI upset, vertigo, visual disturbances
Chaparral (greasewood)	*Larrea tridentata*	Aging, free radical scavenging	Hepatitis
Compound Q	*Trichosanthes kirilowii*	Anthelmintic, cathartic	Diarrhea, hypoglycemia, CNS toxicity
Dandelion	*Taraxacum officinale*	Diuretic, heartburn remedy	Anaphylaxis
Figwort (xuan shen)	*Scrophularia* spp.	Antiinflammatory, antibacterial	Cardiac stimulation
Ginseng	*Panax quinquefolium*	Antihypertensive, aphrodisiac, stimulant, mood elevation, digestive aid	Ginseng abuse syndrome
Goldenseal	*Hydrastis canadensis*	Digestive aid, mucolytic, antiinfective	Uterine, cardiac stimulation; GI upset, leukopenia
Hellebore	*Veratrum* spp.	Antihypertensive	Vomiting, bradycardia, hypotension
Hyssop	*Hyssopus officinalis*	Asthma, mucolytic	Seizures
Juniper	*Juniperus communis*	Hallucinogen	GI upset, seizures, renal injury, hypotension, bradycardia
Kava	*Piper methysticum*	Sedative	Inebriation
Kombucha		Stimulant	Metabolic acidosis, hepatotoxicity, death
Licorice	*Glycyrrhiza* spp.	Indigestion	Mineralocorticoid effects
Lily of the valley	*Convallaria* spp.	Cardiotonic	GI (nausea, vomiting), cardiac arrhythmias
Linn (willow)	*Salix caprea*	Purgative	Hemolysis with glucose-6-phosphate dehydrogenase deficiency
Lobelia (Indian tobacco)	*Lobelia* spp.	Stimulant	Nicotine intoxication
Ma Huang	*Ephedra sinica*	Stimulant	Sympathetic crisis, especially with monoamine oxidase inhibitors
Mandrake	*Mandragora officinarum*	Hallucinogen	Anticholinergic syndrome
Mormon tea	*Ephedra nevadensis*	Stimulant, asthma, antipyretic	Hypertension, sympathomimetic
Nutmeg	*Myristica fragrans*	Hallucinogen, abortifacient	Hallucinations, GI upset
Oleander	*Nerium oleander*	Cardiac stimulant	Cardiac arrhythmias
Passionflower	*Passiflora caeruliea*	Hallucinogen	Hallucinations, seizures, hypotension
Periwinkle	*Vinca* spp.	Antiinflammatory, diabetes	Alopecia, seizures, hepatotoxicity
Pokeweed	*Phytolacca* spp.	Arthritis, chronic pain	GI upset, seizures, death
Sabah	*Sauropus androgynus*	Weight loss, vision	Pulmonary injury
Sage	*Salvia* spp.	CNS stimulant	Seizures
Snakeroot	*Rauwolfia serpentina*	Sedative, antihypertensive	Bradycardia, coma
Squill	*Urginea maritima*	Arthritis, cardiac stimulant	Seizures, arrhythmias, death
Thorn apple (jimsonweed)	*Datura stramonium*	Hallucinations	Anticholinergic
Tonka bean	*Dipteryx odorata*	Anticoagulant	Bleeding diathesis
Valerian root	*Valeriana* spp.	Sedative	Sedation, obtundation
Wild (squirting) cucumber	*Ecballium elaterium*	Constipation, antiinflammatory, rheumatic disease	Airway obstruction
Wormwood (mugwort)	*Artemisia* spp.	Stimulant, hallucinogen	Hallucinations, seizures, uterine stimulation
Yohimbine	*Corynanthe yohimbe*	Aphrodisiac, stimulant	Hypertension, sympathetic crisis

CNS, Central nervous system; GI, gastrointestinal.

From Kingston RL, Foley C. Herbal, traditional, and alternative medicines. In: Shannon MW, Borron SW, Burns MJ, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*, 4th ed. Philadelphia: Saunders; 2007, Table 68.1, p. 1081.

Clinical and Laboratory Manifestations. Early symptoms are nonspecific and include headache, malaise, nausea, and vomiting. These symptoms are often misdiagnosed as indicating flu or food poisoning. At higher exposure levels, patients can develop mental status changes, confusion, ataxia, syncope, tachycardia, and tachypnea. Severe poisoning is manifested by coma, seizures, myocardial ischemia, acidosis, cardiovascular collapse, and potentially death. Physical examination should focus on the cardiovascular and neurologic systems because these are the most detrimentally affected by CO. Emergency department evaluation should include arterial or venous blood gas analysis with HbCO determined by CO-oximetry, CK level in severely poisoned patients, pregnancy test, and ECG and troponin in any patient with cardiac symptoms.

Treatment. Prevention of CO poisoning is paramount and should involve educational initiatives and the use of home CO detectors. Treatment of CO poisoning focuses on the administration of 100% oxygen to enhance elimination of CO. In ambient air the average half-life of HbCO is 4-6 hours. This is dramatically reduced to 60-90 minutes by providing 100% oxygen at normal atmospheric pressures by non-rebreather face mask. Severely poisoned patients might benefit from **hyperbaric oxygen (HBO)**, which decreases the half-life of HbCO to 20-30 minutes and is thought also to decrease the risk of delayed neurologic sequelae. Although the clinical benefits and referral guidelines for HBO therapy remain controversial, frequently cited indications include syncope, coma, seizure, altered mental status, evidence of myocardial ischemia, HbCO level >25% (or >15% in pregnancy), and abnormal cerebellar examination. Consultation with a PCC, medical toxicologist, or HBO facility can assist clinicians in determining which patients could benefit from HBO therapy. Sequelae of CO poisoning include persistent and delayed cognitive and cerebellar effects. HBO advocates believe that the risk of such sequelae is minimized through the delivery of 100% oxygen at 3 atm of pressure. Patients typically receive oxygen, by non-rebreather mask or hyperbaric chamber, for 6 hours.

Hydrogen Cyanide

Pathophysiology. Cyanide inhibits cytochrome-*c* oxidase, part of the electron transport chain, interrupting cellular respiration and leading to profound tissue hypoxia. Patients may be exposed to hydrogen cyanide (HCN) gas in the workplace (manufacturing of synthetic fibers, nitriles, and plastics) by smoke inhalation in a closed-space fire or by ingestion of cassava flour.

Clinical and Laboratory Manifestations. Onset of symptoms is rapid after significant exposure. Clinical manifestations of toxicity include headache, agitation/confusion, sudden loss of consciousness, tachycardia, cardiac dysrhythmias, and metabolic acidosis. Cyanide levels can be measured in whole blood but are not readily available at most institutions. A severe lactic acidosis (lactate >10 mmol/L) in fire victims suggests cyanide toxicity. Impaired oxygen extraction by tissues is implied by elevated mixed-venous oxyhemoglobin saturation, another laboratory finding suggesting cyanide toxicity.

Treatment. Treatment includes removal from the source of exposure, rapid administration of high concentrations of oxygen, and antidotal therapy.

Hydroxocobalamin is the preferred agent for use in known or suspected cyanide poisoning (see Table 94.8). This antidote reacts with cyanide to form the nontoxic cyanocobalamin (vitamin B_{12}), which is then excreted in urine. Side effects of hydroxocobalamin include red discoloration of the skin and urine, transient hypertension, and interference with colorimetric laboratory assays. Other FDA-approved treatments for cyanide poisoning include sodium nitrite and sodium thiosulfate, either alone or in combination. Sodium nitrite induces methemoglobinemia, which may exacerbate symptoms of carboxyhemoglobinemia and thus should be avoided in patients with smoke inhalation.

Miscellaneous Toxic Agents Found in the Home

Nicotine-Containing Products

Nicotine poisoning has become increasingly common with the recent advent of vaporizer ("vaping") and e-cigarette devices (see Chapter 157). Although there are many nicotine-containing products (patches, gums, snuff, chewing tobacco, sprays, lozenges), tobacco cigarettes remain the main source of exposure. Prescription medications (varenicline and cytisine) are available that are partial nicotine receptor agonists. For children, some of the most concerning exposures are from the bottles of liquid nicotine used to refill vaping and e-cigarette devices. These bottles typically do not have childproof caps and contain a large amount of concentrated nicotine.

Pathophysiology. Nicotine acts on nicotinic ACh receptors in the nervous system, neuromuscular junctions, and adrenal medulla, stimulating neurotransmitter release. Nicotine's effects on the dopaminergic reward pathway play a significant role in its addictive properties. The effects of nicotine are dose dependent; at lower doses it primarily acts on the brain, causing stimulation. At higher doses, nicotine overstimulates receptors, leading to inhibition and resulting in neuromuscular and nervous system blockade.

Clinical and Laboratory Manifestations. Clinical effects of nicotine also depend on the dose. At low doses typically achieved through smoking, nicotine results in cognitive and mood enhancement, increased energy, and appetite suppression. Shortness of breath, cough, and fever may be seen with e-cigarette use–associated lung injury (EVALI), an inflammatory response in the lungs triggered by vaping. At higher doses, significant toxicity follows a biphasic pattern, where cholinergic stimulation symptoms predominate and are later followed by inhibition. The first signs of nicotine poisoning are nausea, vomiting, diarrhea, and often muscle fasciculations. Tachycardia and hypertension occur initially, although in severe poisoning these progress to bradycardia, hypotension, coma, and respiratory muscle failure, which typically leads to death if not treated. Serum and urinary levels of nicotine and its metabolite cotinine can be obtained, but these rarely are available in real time and therefore have little effect on diagnosis and management.

Treatment. Treatment of nicotine poisoning focuses on maximizing symptomatic and supportive care. Aggressive airway management should be the priority, especially in severe poisonings, because death usually occurs from respiratory muscle paralysis. IV fluids with escalation to vasopressors should be used for hypotension. Seizures should be managed with benzodiazepines, barbiturates, or propofol.

Single-Use Detergent Sacs

Commonly known as laundry "pods" for clothing, these products resemble candy to many children. When bitten into, a relatively large dose of concentrated detergent is expelled under pressure onto the posterior pharynx and vocal cords. This can lead to stridor and other signs of respiratory distress. Occasionally, and for unknown reasons, these children may also develop altered mental status. Supportive care with attention to any airway and breathing issues is warranted. Admission to the hospital is often indicated. Importantly, these are not considered caustic ingestions; the pH of these products is in the neutral zone. Upper GI endoscopy is rarely indicated. Curiously, laundry detergent ingested from a bottle is rarely of significant concern.

Electric Dishwasher Detergent

Especially when in the form of crystals, these products are highly alkaline (pH >13), and exposure by ingestion can cause significant burns to the vocal cords and GI tract. Admission for expectant management or upper GI endoscopy is usually indicated.

Magnets

Most foreign body ingestions pass through the GI tract once known to have passed into the stomach. However, ingestion of ≥2 magnets (unless very weak refrigerator-style magnets) cause concern for bowel obstruction and perforation (see Chapter 380). Admission for attempted retrieval by endoscopy or clearance by WBI should be considered.

Batteries

Any disk or button-style battery lodged in the esophagus or airway should be considered a true emergency warranting immediate referral

to an endoscopist for removal (see Chapter 373). These batteries can cause necrosis of the tissues in which they are lodged by continued electrical discharge and leaking of their contents (the former is likely the primary method of injury). Mucosal contact for even 2 hours might induce necrosis. Once past the lower esophageal sphincter, button or even larger batteries (e.g., AA, AAA) can usually be allowed to pass through the GI tract with close follow-up.

Human Genetics

PART VIII

Chapter 95

Genetics in Pediatric Medicine

Daryl A. Scott and Brendan Lee

Since the completion of the Human Genome Project, there has been an unprecedented expansion in the understanding of how human health is impacted by variations in genomic sequence and epigenetic, non-sequence-based changes that affect gene expression. There has also been the development and implementation of accurate clinical tests that makes it easier for physicians to detect pathogenic variant changes. In addition, there has been a dramatic increase in the availability of information about the genetic aspects of pediatric diseases, particularly on the internet (Table 95.1).

THE BURDEN OF GENETIC DISORDERS IN CHILDHOOD

Medical problems associated with genetic disorders can appear at any age, with the most obvious and serious problems typically manifesting in childhood. It has been estimated that 53/1,000 children and young adults can be expected to have diseases with an important genetic component. If congenital anomalies are included, the rate increases to 79/1,000. In 1978 just over half of admissions to pediatric hospitals were for a genetic condition. By 1996, because of changes in healthcare delivery and a greater understanding of the genetic basis of many disorders, that percentage increased to 71% in one large pediatric hospital in the United States, with 96% of chronic disorders leading to admission having an obvious genetic component or influenced by genetic susceptibility.

Major categories of genetic disorders include single-gene, genomic, chromosomal, and multifactorial conditions.

Individually, each **single-gene disorder** is rare, but collectively they represent an important contribution to childhood disease. The hallmark of a single-gene disorder is that the phenotype is overwhelmingly determined by changes that affect an individual gene. The character and severity of a phenotype associated with some single-gene disorders can vary from one patient to another. In some cases, this may be due to differences in the severity of the change affecting the gene. In other cases, variability is seen in individuals who carry the same pathogenic variant or variants. This is termed **variable expressivity**; the same pathogenic variants in *GJB2* can cause mild, moderate, severe, or profound sensorineural hearing loss in different individuals. This variability may be due to differences in other genetic, epigenetic, environmental, and/or stochastic factors. If this variability results in some individuals being completely unaffected, we say that the disorder shows **incomplete penetrance**. Some single-gene disorders are associated with phenotypes that affect different organ systems or biologic functions that may appear unrelated. Pendred syndrome is caused by pathogenic variants in *SLC26A4* and is characterized by both hearing loss and thyroid enlargement (goiter). This feature of some genetic diseases is referred to as **pleiotropy**.

Common single-gene disorders include sickle cell anemia and cystic fibrosis. Some identifiable syndromes and diseases can be caused by more than one gene. Noonan syndrome can be caused by pathogenic variants in at least 12 different genes. In addition, pathogenic variants

affecting a single gene may cause more than one disorder. Variants in *SCN5A* can cause Brugada syndrome type 1, long QT syndrome type 3, dilated cardiomyopathy type 1E, familial atrial fibrillation type 10, familial ventricular fibrillation type 1, progressive heart block type 1A, nonprogressive heart block, and sick sinus syndrome type 1.

Single-gene disorders tend to occur when changes in a gene have a profound effect on the *quantity* of the gene product produced, either too much or too little, or the *function* of the gene product, either a loss of function or a harmful gain of function. Single-gene disorders can be caused by de novo sequence changes that are not found in the unaffected parents of the affected individual, or they may be caused by inheriting the affected gene. When a single-gene disorder is known to be caused by changes in only one gene, or a small number of individual genes, searching for deleterious changes is classically performed by directly sequencing that gene and, in some cases, looking for small deletions and/or duplications in that gene. When multiple genes can cause a particular disorder, it is sometimes more efficient and cost-effective to screen large numbers of disease-causing genes using a disease-specific panel, which takes advantage of massively parallel or next-generation sequencing technology, rather than screening genes individually. When such panels are not available, or when the diagnosis is in question, physicians may consider screening the protein-coding regions of all genes by **exome sequencing (ES),** also termed whole exome sequencing (WES), on a clinical basis. In many circumstances, ES is less expensive than sequencing multiple individual genes. **Whole genome sequencing (WGS)**, in which an individual's entire genome is sequenced, is another clinical option (see Chapter 98; Table 95.2).

The risk of having a child with a particular single-gene disorder can vary from one population to another. This may be the result of a **founder effect**, in which a specific change affecting a disease-causing gene becomes relatively common in a population derived from a small number of founder individuals. This high frequency is maintained when there is relatively little interbreeding with persons outside that population because of social, religious, or physical barriers. This is the case for Tay-Sachs disease in Ashkenazi Jews and French Canadians. Other changes may be subject to **positive selection** when found in the heterozygous carrier state. In this case, individuals who carry a single copy of a genetic change **(heterozygotes)** have a survival advantage over noncarriers. This can occur even when individuals who inherit two copies of the change **(homozygotes)** have severe medical problems. This type of positive selection is evident among individuals in sub-Saharan Africa who carry a single copy of a hemoglobin pathogenic variant that confers relative resistance to malaria but causes sickle cell anemia in homozygotes.

Genomic disorders are a group of diseases caused by alterations in the genome, including **deletions** (copy number loss), **duplications** (copy number gain), **inversions** (altered orientation of a genomic region), and **chromosomal rearrangements** (altered location of a genomic region). **Contiguous gene disorders** are caused by changes that affect two or more genes that contribute to the clinical phenotype and are located near one an other on a chromosome. DiGeorge syndrome, which is caused by deletions of genes located on chromosome 22q11, is a common example. Some genomic disorders are associated with distinctive phenotypes whose patterns can be recognized clinically. Other genomic disorders do not have a distinctive pattern of anomalies but can cause developmental delay, cognitive impairment, structural birth defects, abnormal growth patterns, and changes in physical appearance.

Fluorescent in situ hybridization (FISH) can provide information about the copy number and location of a specific genomic region. **Array-based copy number detection assays**, sometimes referred to as chromosomal microarray analyses, can be used to screen for chromosomal deletions and duplications (large and small) across the genome but do not provide information about the orientation or location of genomic regions. A **chromosome analysis (karyotype)** can detect relatively large chromosomal deletions and duplications and can also be useful in identifying inversions and chromosomal rearrangements even when they are **copy number neutral** changes that do not result in a deletion or duplication of genomic material (e.g., balanced translocations).

Table 95.2 Indications for Single Gene, Gene Panel, Exome, and Genome Sequencing

INDICATIONS	EXAMPLES
SINGLE GENE	
Minimal locus heterogeneity (only one or a small number of genes known to cause the condition)	*CFTR* for cystic fibrosis
Distinctive clinical findings that clearly point to specific gene	*PAH* for phenylketonuria
GENE PANEL	
Locus heterogeneity (multiple genes are known to cause the same or similar conditions)	Muscular dystrophy panel
Disorders with overlapping phenotypes	Cardiomyopathy panel
Disorders that share one manifestation but can have very different presentations	Epilepsy panel
Disorders associated with genes from a common pathway or structure	*RAS*opathy panel
EXOME	
Extreme heterogeneity and de novo mutations common	Autism, intellectual disability
Two or more unrelated phenotypes in one patient	Oculocutaneous albinism and neutropenia
No distinctive phenotypic feature present	Kabuki syndrome
Phenotype indistinct and underlying cause not clear	Congenital diarrhea, Zellweger syndrome
GENOME	
As above for Exome, plus:	
Noncoding variation is suspected as a cause	Hypertrophic cardiomyopathy
Structural variation is suspected as a cause	DiGeorge syndrome
Exome sequencing already performed and was nondiagnostic	Undiagnosed Diseases Network
Rapid generation of sequencing data needed for patients who are critically ill	Neonates and children in intensive care
Suspected mitochondrial disorder: multisystem (heart, brain, muscle, liver) disorder	Whole genome and/or mitochondrial DNA (tissue) sequencing

From Manolio TA, Rowley R, Williams MS, et al. Opportunities, resources, and techniques for implementing genomics in clinical care. *Lancet*. 2019;394:511–520. Table 2.

Deletions, duplications, and chromosomal rearrangements that affect whole chromosomes, or large portions of a chromosome, are typically referred to as **chromosomal disorders**. One of the most common chromosomal disorders is Down syndrome, which is most often associated with the presence of an extra copy, or **trisomy**, of an entire chromosome 21. When all or part of a chromosome is missing, the disorder is referred to as **monosomy**. **Translocations** are a type of chromosomal rearrangement in which a genomic region from one chromosome is transferred to a different location on the same chromosome or on a different (nonhomologous) chromosome. Translocations can be *balanced*, meaning that no genetic material has been lost or gained, or they can be *unbalanced*, in which some genetic material has been deleted or duplicated.

In some cases, only a portion of cells that make up a person's body are affected by a single-gene defect, a genomic disorder, or a chromosomal defect. This is referred to as **mosaicism** and indicates that the individual's body is made up of two or more distinct cell populations. Through use of technologies with high sensitivity, it has become

evident that there can be significant low-level mosaicism in *somatic* tissues.

Polygenic disorders are caused by the cumulative effects of variations in more than one gene. **Multifactorial** disorders are caused by the cumulative effects of variations in multiple genes or the combined effects of genetic, epigenetic, and/or environmental factors. Spina bifida and isolated cleft lip or palate are common birth defects that display multifactorial inheritance patterns. Multifactorial inheritance is seen in many common pediatric disorders, such as asthma and diabetes mellitus. These traits can cluster in families but do not have a mendelian pattern of inheritance (see Chapter 97). In these cases, the genetic changes or variations that are contributing to a particular disorder are often unknown, and genetic counseling is based on empirical data and estimates.

THE CHANGING PARADIGM OF GENETICS IN MEDICINE

Genetic testing is increasingly available for a wide variety of both rare and relatively common genetic disorders. Genetic testing is typically used in pediatric medicine to resolve uncertainty regarding the underlying etiology of a child's medical problems. Identifying a molecular cause often provides the basis for improved genetic counseling, may alter medical management, and may suggest that a specific therapy should be employed. Even in cases where a specific treatment is not available, identifying a genetic cause can aid physicians in providing individuals and families with accurate prognostic and recurrence risk information, can often help to relieve unfounded feelings of guilt, and may stem the tide of misdirected blame.

Genetic tests are influencing an increasing number of medical decisions and are becoming a seamless part of routine medical care. Although most genetic testing is presently aimed at identifying or confirming a diagnosis, in the future genetic testing may find wider application as a means of determining whether an individual is predisposed to develop a particular disease. Another area in which genetic testing could make a significant impact is on individualized drug treatment (pharmacogenetics). It has long been known that genetic variation in the enzymes involved in drug metabolism underlies differences in the therapeutic effect and toxicity of some drugs. When the genetic changes that underlie these variations are identified, new genetic tests can be developed that allow physicians to tailor treatments based on individual variations in drug metabolism, responsiveness, and susceptibility to toxicity. It is likely that the expansion of such testing will depend, at least in part, on the extent to which such tests can be linked to strategies to prevent disease or improve outcome (see Chapter 98).

Long-standing and highly successful carrier screening programs have existed for disorders such as Tay-Sachs disease and many other rare, single-gene disorders that are prevalent in specific populations. Couples are usually offered screening for a variety of conditions based, in part, on ancestry (Tay-Sachs disease, hemoglobinopathies, cystic fibrosis). Couples found to be at increased risk for such disorders can be offered preconception or prenatal testing aimed at detecting specific disease-causing variants.

Prenatal screening is routinely offered for chromosomal disorders such as trisomy 13, trisomy 18, and Down syndrome. Pregnancies affected by these, and possibly other genetic disorders, are being recognized by noninvasive screening tests targeting **fetal cell-free DNA** in maternal blood and by fetal ultrasound. When genetic disorders are suspected, chorionic villus sampling at 10-12 weeks of gestation or amniocentesis at 16-18 weeks of gestation can provide material for genetic testing. When a couple are at risk for a specific genetic defect, **preimplantation genetic diagnosis** can sometimes be used to select unaffected early embryos, which are then implanted as part of an in vitro fertilization procedure.

Although prenatally obtained genetic material can be used to identify single-gene disorders, genomic disorders, and chromosomal anomalies, the information obtained on any pregnancy depends on the tests that are ordered. It is important that physicians select the most appropriate prenatal tests and that couples understand the limitations of these tests. No amount of genetic testing can guarantee the birth of a healthy child.

Specific treatments are not available for most genetic disorders, although some important exceptions exist (see Chapter 98). **Inborn errors of metabolism** were the first genetic disorders to be recognized, and many are amenable to treatment by dietary manipulation (see Chapter 104). These conditions result from genetically determined deficiency of specific enzymes, leading to the buildup of toxic substrates and/or deficiency of critical end products.

Individual metabolic disorders tend to be very rare, but their combined impact on the pediatric population is significant. Tandem mass spectrometry has made it relatively inexpensive to screen for a large number of these disorders in the newborn period. Use of this technology not only dramatically increases the number of metabolic disorders identified within a population but also allows treatment to be initiated at a much earlier stage in development. Broader screening in the postnatal period, in the form of metabolomic screening, has increased the potential for identifying an increasing list of rare inborn errors of metabolism, especially when combined with exome or genome sequencing.

Progress in genetic therapies has improved the treatment of some **lysosomal storage disorders** (see Chapter 106.4). These metabolic diseases are caused by defects in lysosomal function. Lysosomes are cellular organelles that contain specific digestive enzymes. Some of these disorders that were characterized by early lethal or intractable chronic illness can now be treated using specially modified enzymes administered by intravenous infusion. These enzymes are taken up by cells and incorporated into lysosomes. Conditions such as Gaucher disease and Fabry disease are routinely treated using **enzyme replacement**; similar therapies are being developed for other lysosomal disorders.

Therapeutic advances are also being made in the treatment of nonmetabolic genetic disorders. Improvements in surgical techniques and intensive care medicine are extending the survival of children with life-threatening birth defects such as congenital diaphragmatic hernia and severe cardiac defects. In many cases, the life expectancy of children with debilitating genetic disorders is also increasing. Improvements in nutrition and the management of chronic pulmonary disease in patients with cystic fibrosis allow an increasing percentage of affected patients to survive into adulthood, creating a need to transition care from pediatric to adult providers.

Gene replacement therapies are being used in the treatment of a variety of genetic disorders (see Chapter 98). Stem cell–based therapies have also been employed as a potential treatment for a number of intractable disorders.

DIRECT-TO-CONSUMER GENETIC TESTING

In most cases, healthcare providers order genetic tests, interpret the results, communicate these results to their patients, and then document these finding in the medical record. The costs of these tests are often covered completely or in part by a health insurance company. In contrast, some companies are offering direct-to-consumer genetic tests in which individuals order their own tests and receive test results directly from the company. The individual usually pays for these tests, and the results are not recorded in their medical record unless the individual chooses to share this information with their healthcare providers. Some direct-to-consumer genetic tests only provide information about common traits or information about an individual's ancestry or relationship to others **(ancestry testing)**. Other direct-to-consumer tests are designed to make predictions about health and/or to identify pathogenic variants associated with specific genetic disorders. In some cases, individuals ordering these tests may have the option of reviewing their results with a healthcare provider employed by the company performing the test.

One of the main benefits of direct-to-consumer testing is that it allows individuals to privately access their genetic information without having to involve a healthcare provider or their insurance company. Although this could be seen as a means of empowering individuals with regards to their healthcare, the benefits derived from such testing depend heavily on the appropriateness of the test ordered, the quality of

the testing/reporting services, the capacity of the individual to understand the test results, and their ability to make informed choices based on those results.

ETHICS ISSUES

Genetic testing, diagnosis, and treatment should be performed *confidentially*. Nothing is as personal as one's genetic information, and all efforts should be made to avoid any stigma for the patient. Many people worry that results of genetic testing will put them, or their child, at risk for genetic discrimination. **Genetic discrimination** occurs when people are treated unfairly because of a difference in their DNA that suggests they have a genetic disorder or they are at an increased risk of developing a certain disease. In the United States the Genetic Information Nondiscrimination Act of 2008 protects individuals from genetic discrimination at the hands of health insurers and employers but does not extend protection against discrimination from providers of life, disability, or long-term care insurance.

The decisions about genetic testing should be based on a careful evaluation of the potential benefits and risks. In the pediatric setting, these decisions may be more difficult because physicians and parents are often called on to make decisions for a child who cannot directly participate in discussions about testing. Molecular diagnostic tests are often used to diagnose malformation syndromes, cognitive delay, or other disabilities in which there is a clear benefit to the child. In other cases, such as genetic testing for susceptibility to adult-onset diseases, it is appropriate to wait until the child or adolescent is mature enough to weigh the potential risks and benefits and make their own decisions about genetic testing.

Policies regarding genetic testing of children have been developed collaboratively by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics and Genomics (ACMG; *Pediatrics* 131[3]:620–622, 2013). These recommendations are outlined in the following list.

General Recommendations

1. Decisions about whether to offer genetic testing and screening should be driven by the best interest of the child.
2. Genetic testing is best offered in the context of genetic counseling. Genetic counseling can be performed by clinical geneticists, genetic counselors, or any other healthcare provider with appropriate training and expertise. AAP and ACMG support the expansion of educational opportunities in human genomics and genetics for medical students, residents, and practicing pediatric primary care providers.

Diagnostic Testing

3. In a child with symptoms of a genetic condition, the rationale for genetic testing is similar to other medical diagnostic evaluations. Parents or guardians should be informed about the risks and benefits of testing, and their permission should be obtained. Ideally, and when appropriate, the assent of the child should be obtained.
4. When performed for therapeutic purposes, pharmacogenetic testing of children is acceptable, with permission of parents or guardians and, when appropriate, the child's assent. If a pharmacogenetic test result carries implications beyond drug targeting or dose responsiveness, the broader implications should be discussed before testing.

Newborn Screening

5. AAP and ACMG support the mandatory offering of newborn screening for all children. After education and counseling about the substantial benefits of newborn screening, its remote risks, and the next steps in the event of a positive screening result, parents should have the option of refusing the procedure, and an informed refusal should be respected.

Carrier Testing

6. AAP and ACMG do not support routine carrier testing in minors when such testing does not provide health benefits in childhood. The AAP and ACMG advise against school-based testing or screening programs, because the school environment is unlikely to be conducive to voluntary participation, thoughtful consent, privacy, confidentiality, or appropriate counseling about test results.
7. For pregnant adolescents or for adolescents considering reproduction, genetic testing and screening should be offered as clinically indicated, and the risks and benefits should be explained clearly.

Predictive Genetic Testing

8. Parents or guardians may authorize predictive genetic testing for asymptomatic children at risk of childhood-onset conditions. Ideally, the assent of the child should be obtained.
9. Predictive genetic testing for adult-onset conditions generally should be deferred unless an intervention initiated in childhood may reduce morbidity or mortality. An exception might be made for families for whom diagnostic uncertainty poses a significant psychosocial burden, particularly when an adolescent and the parents concur in their interest in predictive testing.
10. For ethical and legal reasons, healthcare providers should be cautious about providing predictive genetic testing to minors without the involvement of their parents or guardians, even if a minor is mature. Results of such tests may have significant medical, psychologic, and social implications, not only for the minor but also for other family members.

Histocompatibility Testing

11. Tissue compatibility testing of minors of all ages is permissible to benefit immediate family members but should be conducted only after thorough exploration of the psychosocial, emotional, and physical implications of the minor serving as a potential stem cell donor. A donor advocate or similar mechanism should be in place from the outset to avert coercion and safeguard the interests of the child.

Adoption

12. The rationale for genetic testing of children in biological families should apply for adopted children and children awaiting placement for adoption. If a child has a known genetic risk, prospective adoptive parents must be made aware of this possibility. In rare cases, it may be in a child's best interest to undergo predictive genetic testing for a known risk before adoption to ensure the child's placement with a family capable of and willing to accept the child's potential medical and developmental challenges. In the absence of such indications, genetic testing should not be performed as a condition of adoption.

Disclosure

13. At the time of genetic testing, parents or guardians should be encouraged to inform their child of the test results at an appropriate age. Parents or guardians should be advised that, under most circumstances, a request by a mature adolescent for test results should be honored.
14. Results from genetic testing of a child may have implications for the parents and other family members. Healthcare providers have an obligation to inform parents and the child, when appropriate, about these potential implications. Healthcare providers should encourage patients and families to share this information and offer to help explain the results to the extended family or refer them for genetic counseling.
15. Misattributed paternity, use of donor gametes, adoption, or other questions about family relationships may be uncovered "incidentally" whenever genetic testing is performed, particularly when testing multiple family members. This risk should be discussed, and a plan about disclosure or nondisclosure should be in place before testing.

Direct-to-Consumer Testing

16. AAP and ACMG strongly discourage the use of direct-to-consumer and home-kit genetic testing of children because of the lack of oversight on test content, accuracy, and interpretation.

Chapter 96

Principles of Human Genetics

Daryl A. Scott and Brendan Lee

THE HUMAN GENOME

The human genome has approximately 20,000 genes that encode the wide variety of proteins found in the human body. Reproductive or germline cells contain one copy (N) of this genetic complement and are **haploid**, whereas somatic (nongermline) cells contain two complete copies (2N) and are **diploid**. Genes are organized into long segments of deoxyribonucleic acid (**DNA**), which, during cell division, are compacted into intricate structures together with proteins to form chromosomes. Each somatic cell has 46 chromosomes: 22 pairs of **autosomes**, or nonsex chromosomes, and one pair of **sex chromosomes** (XY in a male, XX in a female). Germ cells (ova or sperm) contain 22 autosomes and one sex chromosome, for a total of 23. At fertilization, the full diploid chromosome complement of 46 is again realized in the embryo.

Most of the genetic material is contained in the cell's nucleus. The mitochondria (the cell's energy-producing organelles) contain their own unique genome. The **mitochondrial chromosome** consists of a double-stranded circular piece of DNA, which contains 16,568 base pairs (bp) of DNA and is present in multiple copies per cell. The proteins that occupy the mitochondria are produced either in the mitochondria, using information contained in the mitochondrial genome, or are produced outside of the mitochondria, using information contained in the nuclear genome, and then transported into the organelle. Sperm do not usually contribute mitochondria to the developing embryo, so all mitochondria are maternally derived, and a child's mitochondrial genetic makeup derives exclusively from the child's biologic mother (see Chapter 108).

FUNDAMENTALS OF MOLECULAR GENETICS

DNA consists of a pair of chains of a sugar-phosphate backbone linked by pyrimidine and purine bases to form a **double helix** (Fig. 96.1). The sugar in DNA is deoxyribose. The pyrimidines are cytosine (C) and thymine (T), and the purines are guanine (G) and adenine (A). The bases are linked by hydrogen bonds such that A always pairs with T and G with C. Each strand of the double helix has polarity, with a free phosphate at one end (5′) and an unbonded hydroxyl on the sugar at the other end (3′). The two strands are oriented in opposite polarity in the double helix.

The replication of DNA follows the pairing of bases in the parent DNA strand. The original two strands unwind by breaking the hydrogen bonds between base pairs. Free nucleotides, consisting of a base attached to a sugar-phosphate chain, form new hydrogen bonds with their complementary bases on the parent strand; new phosphodiester bonds are created by enzymes called **DNA polymerases.** Replication of chromosomes begins simultaneously at multiple sites, forming replication bubbles that expand bidirectionally until the entire DNA molecule (chromosome) is replicated. Errors in DNA replication, or pathogenic variants induced by environmental mutagens such as irradiation or chemicals, are detected and potentially corrected by DNA repair systems.

Information encoded in DNA, predominantly located in the cell's nucleus, is transcribed into **messenger** ribonucleic acid **(mRNA)**, which is then transported to the cytoplasm, where it is translated into protein. A prototypical gene consists of a regulatory region, segments called **exons** that encode the amino acid sequence of a protein, and intervening segments called **introns** (Fig. 96.2).

Transcription is initiated by attachment of ribonucleic acid (RNA) polymerase to the promoter site upstream of the beginning of the coding sequence. Specific proteins bind to the region to repress or activate transcription by compacting or opening chromatin, which is a complex of DNA and histone proteins. It is the action of these regulatory proteins **(transcription factors)** that determines, in large part, when a gene is turned on or off. Some genes are also turned on and off by methylation of cytosine bases that are adjacent to guanine bases **(cytosine-phosphate-guanine bases** [**CpGs**]). Methylation is an example of an **epigenetic** change, meaning a change that can affect gene expression, and possibly the characteristics of a cell or organism, but that *does not* involve a change in the underlying genetic sequence. Gene regulation is flexible and responsive, with genes being turned on or off during development and in response to internal and external environmental conditions and stimuli. Another epigenetic mechanism that controls gene expression is the biochemical modification of histone proteins around which DNA is wound. These modifications can affect the relative accessibility of chromatin by enzymes for transcription.

Transcription proceeds through the entire length of the gene in a 5′ to 3′ direction to form an mRNA transcript whose sequence is complementary to that of one of the DNA strands. RNA is a sugar-phosphate chain with pyrimidines and purines. In RNA the sugar is ribose, and uracil replaces the thymine found in DNA. A "cap" consisting of 7-methylguanosine is added to the 5′ end of the RNA in a 5′-5′ bond and, for most transcripts, several hundred adenine bases are enzymatically added to the 3′ end after transcription.

mRNA processing occurs in the nucleus and consists of excision of the introns and splicing together of the exons. Specific sequences at the start and end of introns mark the sites where the splicing machinery will act on the transcript. In some cases, there may be tissue-specific patterns to splicing, so that the same primary transcript can produce multiple distinct proteins.

The processed transcript is next exported to the cytoplasm, where it binds to ribosomes, which are complexes of protein and **ribosomal** RNA **(rRNA)**. The genetic code is then read in triplets of bases, each triplet corresponding with a specific amino acid or providing a signal that terminates **translation**. The triplet codons are recognized by **transfer** RNAs **(tRNAs)** that include complementary anticodons and bind the corresponding amino acid, delivering it to the growing peptide. New amino acids are enzymatically, sequentially attached to the growing peptide. Each time an amino acid is added, the ribosome moves one triplet codon step along the mRNA. Eventually a **stop codon** is reached, at which point translation ends and the peptide is released. In some proteins, there are **posttranslational modifications**, such as attachment of sugars **(glycosylation)**. The protein is then delivered to its destination within or outside the cell by trafficking mechanisms that recognize portions of the peptide.

Another mechanism of gene regulation is **noncoding** RNAs, which are RNAs transcribed from DNA but not translated into proteins. Noncoding RNAs function in many contexts, including mediating splicing, the processing of coding RNAs in the nucleus, and the translation of coding mRNAs in ribosomes. The roles of *long* noncoding RNAs (>200 bp) and *short* noncoding RNAs (<200 bp) extend beyond these processes to impact a diverse set of biologic functions, including the regulation of gene expression. **MicroRNAs (miRNAs)** are a class of small RNAs that control gene expression in the cell by directly targeting specific sets of coding RNAs by direct RNA–RNA binding. This RNA–RNA interaction can lead to degradation of the target-coding RNA or inhibition of translation of the protein specified by that coding RNA. miRNAs often target and regulate several hundred mRNAs.

GENETIC VARIATION

The process of producing protein from a gene is subject to disruption at multiple levels because of alterations in the DNA sequence (Fig. 96.3). Changes in the regulatory region can lead to altered gene expression, including increased or decreased rates of transcription, failure of gene activation, or activation of the gene at inappropriate times or in inappropriate cells. Changes in the coding sequence can lead to **substitution** of one amino acid for another (**missense variant** or **nonsynonymous variant**) or creation of a stop codon in the place of an amino acid codon (**nonsense** or **stop-gain variant**).

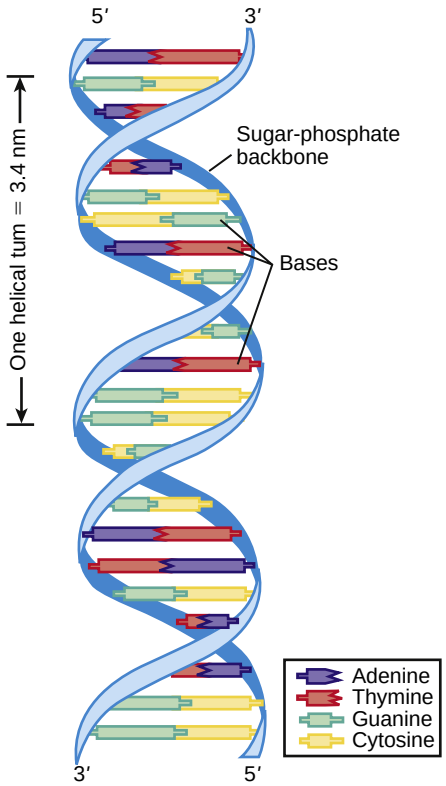

Fig. 96.1 DNA double helix, with sugar-phosphate backbone and nitrogenous bases. (*From Jorde LB, Carey JC, Bamshad MJ, et al., eds. Medical Genetics, 2nd ed. St Louis: Mosby; 1999: p. 8.*)

Overall, missense and nonsense variants are the most common (56% of variants); small deletions or insertions represent approximately 24% of variants (Table 96.1). Some single-base changes do not affect the amino acid (**silent**, **wobble**, or **synonymous variants**) because there may be several triplet codons that correspond to the same single amino acid. Amino acid substitutions can have a profound effect on protein function if the chemical properties of the substituted amino acid are markedly different. Other substitutions can have a subtle or no effect on protein function, particularly if the substituted amino acid is chemically similar to the original. Single nucleotide changes, whether silent or missense, are termed **single nucleotide variants (SNV)**.

Genetic changes can also include **insertions** or **deletions** ("**indels**"). Insertions or deletions of a nonintegral multiple of three bases into the coding sequence leads to a **frameshift,** altering the grouping of bases into triplets. This leads to translation of an incorrect amino acid sequence and often a premature stop to translation. Insertion or deletion of an integral multiple of three bases into the coding sequence will insert or delete a corresponding number of amino acids from the protein, leading to **in-frame** alterations that maintain the amino acid sequence outside the deleted or duplicated amino acids. Larger scale insertions or deletions can disrupt a coding sequence or result in complete deletion of an entire gene or group of genes.

Pathogenic variants usually can be classified as causing a loss of function or a gain of function. **Loss-of-function variants** lead to a reduction in the level of protein function as a result of decreased expression or production of a protein that does not work as efficiently. In some cases, loss of protein function from one of two alleles is sufficient to cause disease. **Haploinsufficiency** describes the situation in which maintenance of a normal phenotype requires the proteins produced by both alleles of a gene, and a 50% decrease in gene function results in an abnormal phenotype. *Haploinsufficient phenotypes are dominantly inherited.* Loss-of-function variants can also have a **dominant**

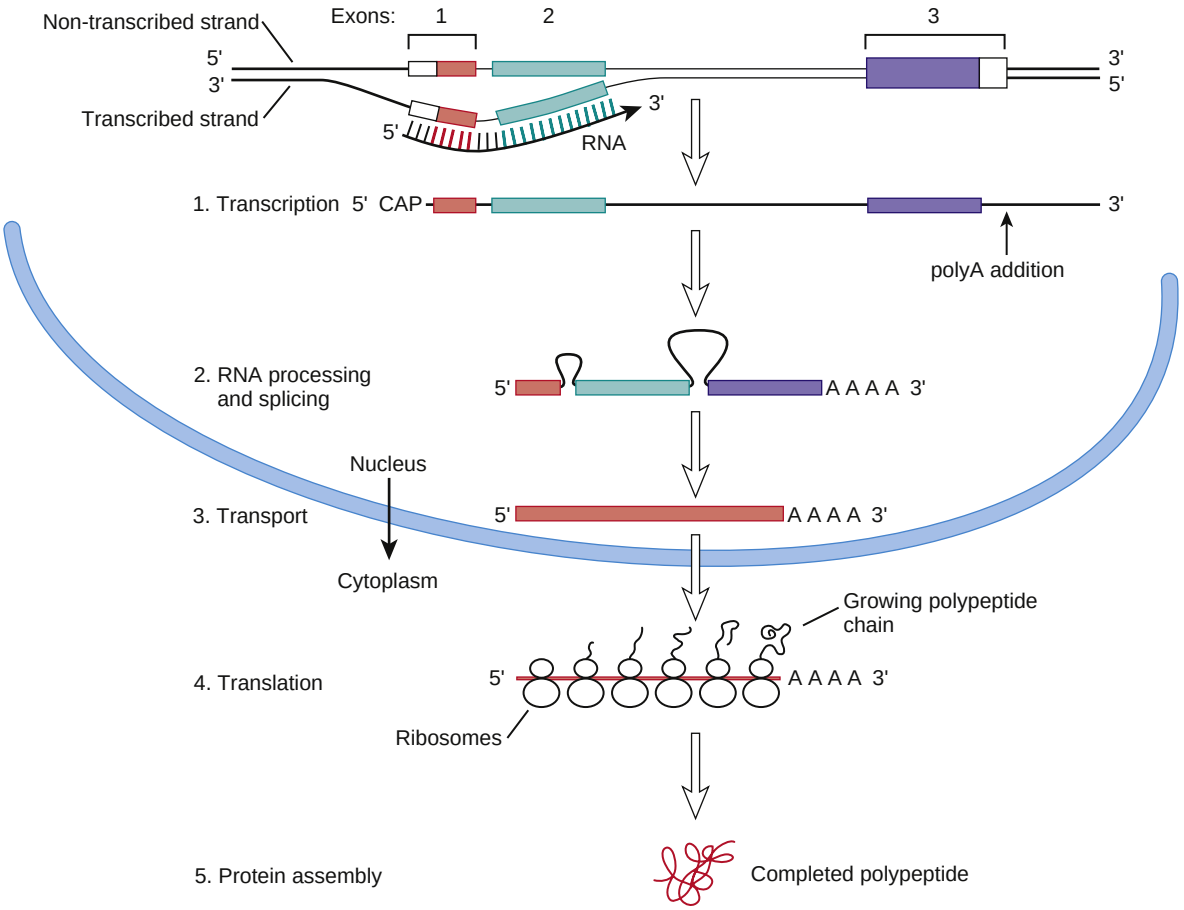

Fig. 96.2 Flow of information from DNA to RNA to protein for a hypothetical gene with three exons and two introns. Within the exons, *colored regions* indicate coding sequences. Steps include transcription, RNA processing and splicing, RNA transport from the nucleus to the cytoplasm, translation, and protein assembly. (*From Nussbaum RL, McInnis RR, Willard HF, Hamosh A, eds. Thompson & Thompson Genetics in Medicine, 7th ed. Philadelphia: Saunders; 2007: p. 31.*)

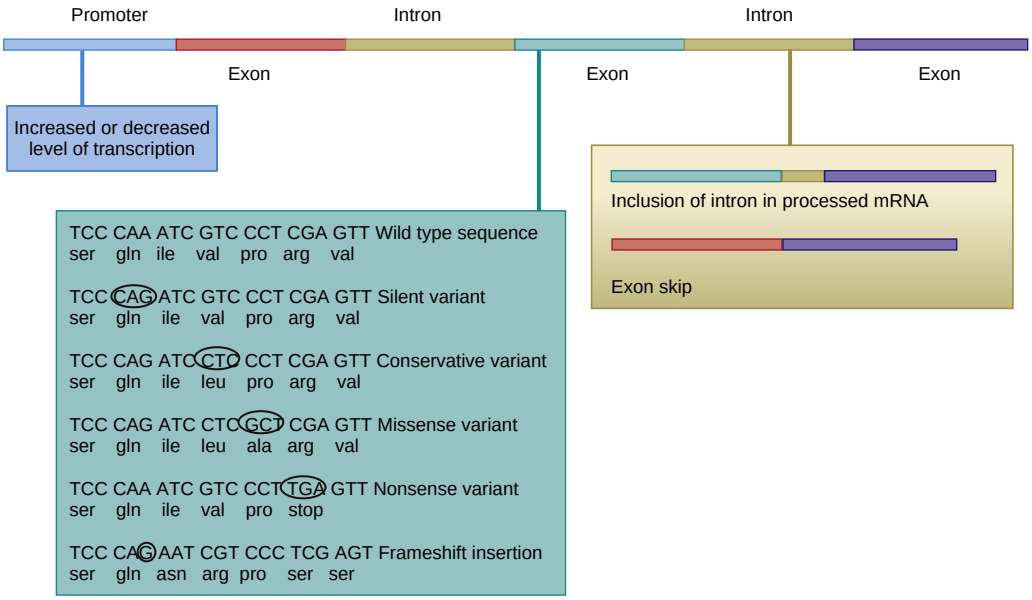

Fig. 96.3 Various types of intragenic sequence variants. Promoter variants alter rate of transcription or disrupt gene regulation. Base changes within exons can have various effects, as shown. Variants within introns can lead to inclusion of some intronic sequence in the final processed mRNA, or it can lead to exon skipping.

Table 96.1 Main Classes, Groups, and Types of Sequence Variants and Their Effects on Protein Products

CLASS	GROUP	TYPE	EFFECT ON PROTEIN PRODUCT
Substitution	Synonymous	Silent*	Same amino acid
	Nonsynonymous	Missense*	Altered amino acid—may affect protein function or stability
		Nonsense or stop-gain*	Stop codon—loss of function or expression from degradation of mRNA
		Splice site	Aberrant splicing—exon skipping or intron retention
		Promoter	Altered gene expression
Deletion	Multiple of three (codon)		In-frame deletion of one or more amino acid(s)—may affect protein function or stability
	Not multiple of three	Frameshift	Likely to result in premature termination with loss of function or expression
	Large deletion	Partial gene deletion	May result in premature termination with loss of function or expression
		Whole gene deletion	Loss of expression
Insertion	Multiple of three (codon)		In-frame insertion of one or more amino acid(s)—may affect protein function or stability
	Not multiple of three	Frameshift	Likely to result in premature termination with loss of function or expression
	Large insertion	Partial gene duplication	May result in premature termination with loss of function or expression
		Whole gene duplication	May have an effect because of increased gene dosage
	Expansion of trinucleotide repeat	Dynamic pathogenic variant	Altered gene expression or altered protein stability or function

*Some have been shown to cause aberrant splicing.
From Turnpenny P, Ellard S, eds. *Emery's Elements of Medical Genetics*, 14th ed. Philadelphia: Churchill Livingstone; 2012: p. 23.

negative effect when the abnormal protein product actively interferes with the function of the normal protein product. Both situations lead to diseases inherited in a dominant fashion. Haploinsufficiency of type I collagen can cause relatively mild osteogenesis imperfecta (OI) type I. In contrast, heterozygous, missense glycine substitutions in type I collagen can act in a dominant negative fashion to cause severe OI type II, III, and IV. In other cases, loss-of-function variants must be present in both copies of a gene before an abnormal phenotype results. This situation typically results in diseases inherited in a **recessive** fashion (see Chapter 97). Some conditions are **semidominant** where one affected copy (heterozygous pathogenic variant) causes a milder phenotype than when both copies are affected (compound heterozygous or homozygous pathogenic variants). This is seen in classical achondroplasia vs homozygous achondroplasia

Gain-of-function variants typically cause dominantly inherited diseases. These variants can result in production of a protein molecule with an increased ability to perform a normal function or can confer a novel property on the protein. The gain-of-function variant

in **achondroplasia**, the most common of the disproportionate, short-limbed short stature disorders, exemplifies the enhanced function of a normal protein. Achondroplasia results from a pathogenic variant in the fibroblast growth factor (FGF) receptor three gene *(FGFR3)*, which leads to activation of the receptor, even in the absence of FGF. In **sickle cell disease**, an amino acid is substituted into the hemoglobin molecule and has little effect on the ability of the protein to transport oxygen. However, sickle hemoglobin chains have a novel property. Unlike normal hemoglobin, sickle hemoglobin chains aggregate under conditions of deoxygenation, forming fibers that deform the red cells.

Other gain-of-function variants result in overexpression or inappropriate expression of a gene product. Many cancer-causing genes **(oncogenes)** are normal regulators of cellular proliferation during development. However, expression of these genes in adult life and/or in cells in which they usually are not expressed can result in neoplasia.

In some cases, changes in gene expression are caused by changes in the number of copies of a gene that are present in the genome (Fig. 96.4). Although some **copy number variations** are common and do not appear to cause or predispose to disease, others are clearly disease causing. **Charcot-Marie-Tooth disease type 1A**, the most common inherited form of chronic peripheral neuropathy of childhood, is caused by duplications of the gene for peripheral myelin protein 22, resulting in overexpression due to the existence of three active copies of this gene (see Chapter 653.1). Deletions of this same gene, leaving only one active copy, are responsible for a different disorder, **hereditary neuropathy with liability to pressure palsies**.

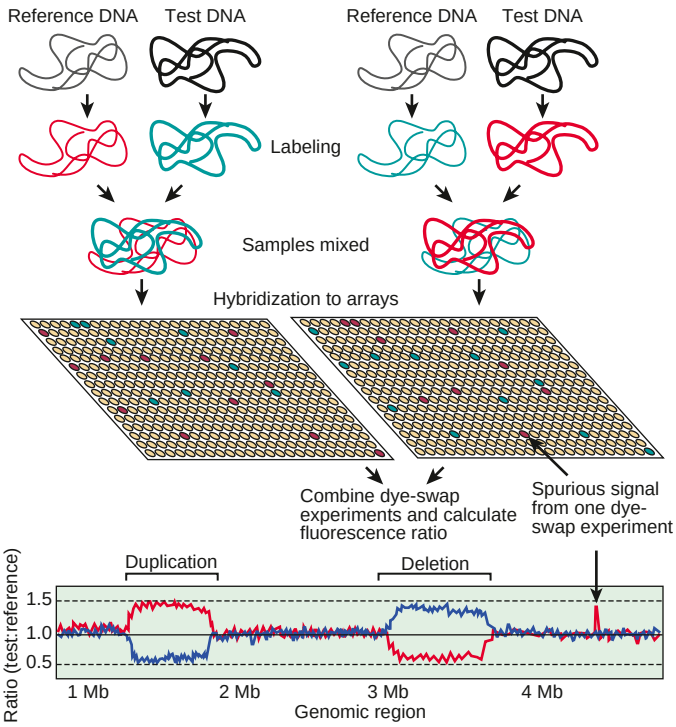

Fig. 96.4 Array comparative genomic hybridization. Test and reference DNA samples are differentially labeled, mixed, and passed over a target array of probes (e.g., bacterial artificial chromosome clones or oligonucleotides) containing DNA fragments from across the whole human genome. The experiment is often repeated with reversal of the test and reference dyes to detect dye effects or identify spurious signals. DNA samples hybridize with their corresponding probe, and the ratio of fluorescence from each probe *(test:reference)* is used to detect regions that vary in copy number between the test and the reference sample (*red line*, original hybridization; *blue line*, dye-swapped hybridization). Equal copy number for both the test and the reference DNA is identified by equal binding, resulting in a ratio of 1:1. Duplication in a genomic region of the test sample is identified by an increased ratio, and a deletion is identified by a decreased ratio, but a deletion in the test sample is indistinguishable from a duplication in the reference sample. These ratios are usually converted to log2 scale for further analysis. *Mb*, megabase. (*Adapted from Feuk L, Carson AR, Scherer SW. Structural variation in the human genome. Nat Rev Genet 2006;7:85–97.*)

Deletions and duplications can vary in their extent and can involve several genes, even when they are not detectable using a traditional chromosome analysis. Such changes are commonly called **microdeletions** and **microduplications**. When deletion or duplication of two or more genes in the same chromosomal region each play a role in the resulting clinical features, the condition can also be referred to as a **contiguous gene disorder**.

In some cases, the recognition of a specific constellation of features leads clinicians to suspect a specific microdeletion or microduplication syndrome. Examples of such disorders include Smith-Magenis, DiGeorge, and Williams syndromes. In other cases, the clinician may be alerted to this possibility by an unusually diverse array of clinical features in one patient or the presence of unusual features in a person with a known condition. Because of the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of ichthyosis, Kallmann syndrome, ocular albinism, intellectual disability, chondrodysplasia punctata, and short stature.

DNA rearrangements can also take place in **somatic cells** (cells that do not go on to produce ova or sperm). Rearrangements that occur in **lymphoid** cells are required for the normal formation of functional immunoglobulin in B cells and antigen-recognizing receptors on T cells. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor (TCR), are physically joined at a specific stage in the development of an immunocompetent lymphocyte. These rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and TCR molecules. Because of this postgermline DNA rearrangement, no two individuals, not even identical twins, are fully identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

The human genome demonstrates that any two individuals will differ in about one base in 1,000. Some of these differences are silent; some result in changes that explain phenotypic differences (hair or eye color, physical appearance); and some have medical significance, causing single-gene disorders such as sickle cell anemia or explaining susceptibility to common pediatric disorders such as asthma. Genetic variants in a single gene that occur at a frequency of >1% in a population are often referred to as **polymorphisms**. These variations may be silent or subtle or may have significant phenotypic effects.

GENOTYPE-PHENOTYPE CORRELATIONS IN GENETIC DISEASE

The term **genotype** is used to signify the internally coded, heritable information of an individual and can also be used to refer to which particular alternative version **(allele)** of a gene is present at a specific location **(locus)** on a chromosome. A **phenotype** is the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and can also refer to the observed structural and functional effects of a variant allele at a specific locus. Many sequence variants result in predictable phenotypes; physicians can predict clinical outcomes and plan appropriate treatment strategies based on a patient's genotype. There is also phenotypic expansion where multiple alleles (variants) within a gene can be associated with often diverse and distinct clinical presentations.

Long QT syndrome exemplifies a disorder with predictable associations between a patient's genotype and his or her phenotype (see Chapter 484.5). Long QT syndrome is genetically heterogeneous, meaning that pathogenic variants in *several different genes* can cause the same disorder. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher in patients with long QT syndrome involving *KCNQ1* (63%) or *KCNH2* (46%) than in those with pathogenic variants in *SCN5A* (18%). In addition, individuals with *KCNQ1* variants experience most of their episodes during exercise and rarely during rest or sleep. In contrast, individuals with pathogenic variants in *KCNH2* and *SCN5A* are more likely to have episodes during sleep or rest and rarely during exercise. Therefore variants in specific genes

(genotype) are correlated with specific manifestations (phenotype) of long QT syndrome. These types of relationships are commonly referred to as *genotype-phenotype correlations.*

Pathogenic variants in the fibrillin-1 gene associated with **Marfan syndrome** represent another example of predictable genotype-phenotype correlations (see Chapter 743). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. The fibrillin-1 gene consists of 65 exons, and pathogenic variants have been found in almost all these. The location of the variant within the gene (genotype) might play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is often caused by variants in exons 24-27 and in exons 31 and 32, whereas milder forms are caused by variants in exons 59-65 and in exons 37 and 41.

Genotype-phenotype correlations have also been observed in some complications of **cystic fibrosis** (CF; see Chapter 454). Although pulmonary disease is the major cause of morbidity and mortality, CF is a multisystem disorder that affects not only the epithelia of the respiratory tract but also the exocrine pancreas, intestine, male genital tract, hepatobiliary system, and exocrine sweat glands. CF is caused by pathogenic variants in the CF transmembrane conductance regulator *(CFTR)* gene. More than 1,600 different pathogenic *CFTR* variants have been identified. The most common is a deletion of three nucleotides that removes the amino acid phenylalanine (F) at the 508th position on the protein (ΔF508 variant), which accounts for approximately 70% of all pathogenic CF variants and is associated with severe disease. The best genotype-phenotype correlations in CF are seen in the context of pancreatic function, with common pathogenic variants being classified as either *pancreatic sufficient* or *pancreatic insufficient.* Persons with pancreatic sufficiency usually have either one or two pancreatic-sufficient alleles, indicating that pancreatic-sufficient alleles are dominant. In contrast, the genotype-phenotype correlation in pulmonary disease is much weaker, and persons with identical genotypes have wide variations in the severity of their pulmonary disease. This finding may be accounted for, in part, by genetic modifiers or environmental factors.

In many disorders, the effects of variants on phenotype can be modified by changes in the other allele of the same gene, by changes in specific **modifier genes**, and/or by variations in a number of unspecified genes **(genetic background)**. When sickle cell anemia is co-inherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF can influence the development of congenital meconium ileus, or colonization with *Pseudomonas aeruginosa.* Modifier genes can also affect the manifestations of Hirschsprung disease, neurofibromatosis type 2, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic variants producing glucose-6-phosphate dehydrogenase deficiency and longer versions of the TATAA element in the uridine diphosphate–glucuronosyltransferase gene promoter exacerbates neonatal physiologic hyperbilirubinemia.

HUMAN GENOME PROJECT

A rudimentary genetic map can be made using genetic linkage, which is based on the principle that alleles at two genetic loci that are located near each other segregate together in a family unless they are separated by genetic **recombination**. In contrast to linkage maps, physical maps rely on overlapping DNA fragments to determine the location of loci with respect to one another. Overlapping segments of the genomic regions can be identified and used to piece together a map composed of overlapping DNA fragments to obtain the DNA sequence of the entire region. An alternative strategy involves breaking the entire genome into random fragments, sequencing the fragments, and then computationally assembling them into overlapping segments. This whole genome approach in combination with next-generation sequencing technologies has resulted in a dramatic reduction in the cost of sequencing an individual's entire genome.

Analysis of the human genome has produced some surprising results. The number of genes appears to be ~20,000. *However, the number of protein products encoded by the genome is far greater than the number of genes.* This is a result of the presence of alternative promoter regions, alternative splicing, and posttranslational modifications, which can allow a single gene to encode a number of protein products.

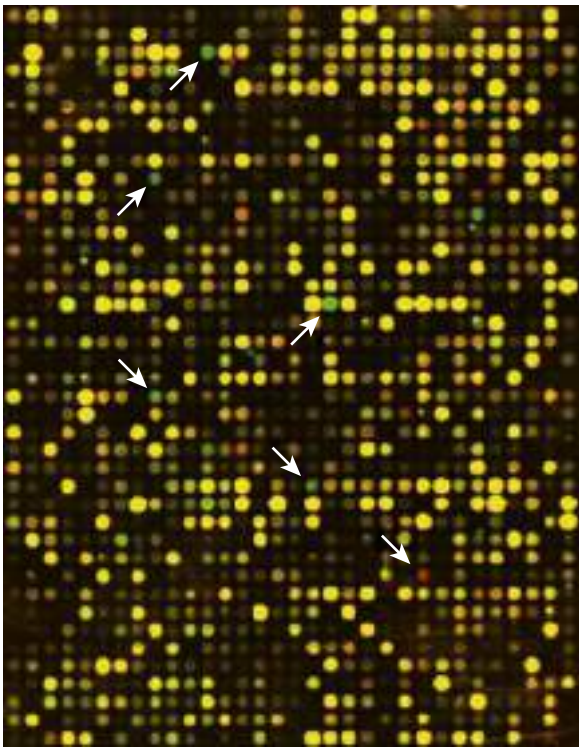

Fig. 96.5 Microarray containing 36,000 oligonucleotides. The microarray was exposed to RNA from normal fibroblasts (labeled in *red*; see *arrows*) and fibroblasts from a patient with Niemann-Pick disease, type C (labeled *green*). *Arrows* point to regions in which there was a strong hybridization signal with either normal or disease RNA. This microarray was used to search for genes that are highly expressed in the fibroblasts of patients. (*From Jorde LB, Carey JC, Bamshad MJ, White RL. Medical Genetics, 3rd ed. St Louis: Mosby; 2006: p. 116.*)

It is also apparent that most of the human genome *does not* encode protein, with <5% being transcribed and translated, although a much larger percentage may be transcribed without translation. Many transcribed sequences are not translated but represent genes that encode RNAs that serve *regulatory* roles. A large fraction of the genome consists of repeated sequences that are interspersed among the genes. Some of these are transposable genetic elements that can move from place to place in the genome. Others are static elements that were expanded and dispersed in the past during human evolution. Other repeated sequences might play a structural role. There are also regions of *genomic duplications.* Such duplications are substrate for evolution, allowing genetic motifs to be copied and modified to serve new roles in the cell. Duplications can also play a role in chromosomal rearrangement, permitting nonhomologous chromosome segments to pair during meiosis and exchange material. This is another source of evolutionary change and a potential source of chromosomal instability leading to congenital anomalies or cancer. Low copy repeats also play an important role in causing genomic disorders. When low copy repeats flank unique genomic segments, these regions can be duplicated or deleted through a process known as *nonallelic homologous recombination.*

Availability of the entire human genomic sequence permits the study of large groups of genes, looking for patterns of gene expression or genome alteration. Studies of gene expression are performed using next-generation sequencing techniques to obtain information about all RNA transcripts in a tissue or single cell. The patterns of gene expression may provide signatures for particular disease states, such as cancer, or change in response to therapy (Fig. 96.5).

Chapter 97

Patterns of Genetic Transmission

Daryl A. Scott and Brendan Lee

FAMILY HISTORY AND PEDIGREE NOTATION

The family history remains the most important screening tool for pediatricians in identifying a patient's risk for developing a wide range of diseases, from multifactorial conditions such as diabetes and attention-deficit/hyperactivity disorder, to single-gene disorders such as sickle cell anemia and cystic fibrosis. Through a detailed family history, the physician can often ascertain the mode of genetic transmission and the risks to family members. Because not all familial clustering of disease is caused by genetic factors, a family history can also identify common environmental and behavioral factors that influence the occurrence of disease. The main goal of the family history is to identify genetic susceptibility, and the cornerstone of the family history is a systematic and standardized pedigree.

A **pedigree** provides a graphic depiction of a family's structure and medical history. It is important when taking a pedigree to be systematic and use standard symbols and configurations so that anyone can read and understand the information (Figs. 97.1-97.4). In the pediatric setting, the **proband** is typically the child or adolescent who is being evaluated. The proband is designated in the pedigree by an arrow.

A three- to four-generation pedigree should be obtained for every new patient as an initial screen for genetic disorders segregating within the family. The pedigree can provide clues to the inheritance pattern of these disorders and can aid the clinician in determining the risk to the proband and other family members. The closer the relationship of the proband to the person in the family with the genetic disorder, the greater is the shared genetic complement. **First-degree** relatives, such as a parent, full sibling, or child, share one half their genetic information on average; first cousins share one eighth. Sometimes the person providing the family history may mention a distant relative who is affected with a genetic disorder. In such cases a more extensive pedigree may be needed to identify the risk to other family members. For example, a history of a distant maternally related cousin with intellectual disability caused by fragile X syndrome can still place a male proband at an elevated risk for this disorder.

MENDELIAN INHERITANCE

There are three classic forms of genetic inheritance: **autosomal dominant, autosomal recessive,** and **X-linked**; these are referred to as **mendelian inheritance** forms.

Autosomal Dominant Inheritance

Autosomal dominant inheritance is determined by the presence of one abnormal gene on one of the **autosomes** (chromosomes 1-22). Autosomal genes exist in pairs, with each parent contributing one copy. In an autosomal dominant trait, a change in one of the paired genes affects the phenotype of an individual, even though the other copy of the gene is functioning correctly. A **phenotype** can refer to a physical manifestation, a behavioral characteristic, or a difference detectable only through laboratory tests.

The pedigree for autosomal dominant disorders demonstrates certain characteristics. These disorders show a **vertical transmission** (parent-to-child) pattern and can appear in multiple generations (Fig. 97.5). An affected individual has a 50% chance of passing on the deleterious gene in *each* pregnancy and, therefore, of having a child affected by the disorder. This is referred to as the **recurrence risk** for the disorder. Unaffected individuals (family members who do not manifest the trait and do not harbor a copy of the deleterious gene) do not pass the disorder to their children. Males and females are equally affected.

Although not a characteristic per se, the finding of male-to-male transmission essentially confirms autosomal dominant inheritance. Vertical transmission can also be seen with X-linked traits. However, because a father passes on his Y chromosome to a son, male-to-male transmission cannot be seen with an X-linked trait. Therefore male-to-male transmission eliminates X-linked inheritance as a possible explanation. Although male-to-male transmission can occur with Y-linked genes as well, there are very few Y-linked disorders, compared with thousands having the autosomal dominant inheritance pattern.

Although parent-to-child transmission is a characteristic of autosomal dominant inheritance, many patients with an autosomal dominant disorder have no history of an affected family member, for several possible reasons. First, the patient may have the disorder due to a **de novo** (new) pathogenic variant that occurred in the DNA of the egg or sperm that formed that individual. Second, many autosomal dominant conditions demonstrate **incomplete penetrance**, meaning that not all individuals who carry the pathogenic variant have phenotypic manifestations. In a pedigree, this can appear as a **skipped generation**, in which an unaffected individual links two affected persons (Fig. 97.6). There are many potential reasons that a disorder might exhibit incomplete penetrance including the effect of modifier genes, environmental factors, gender, and age. Third, individuals with the same autosomal dominant variant can manifest the disorder to different degrees. This is termed **variable expression** and is a characteristic of many autosomal dominant disorders.

Fourth, some spontaneous genetic pathogenic variants occur not in the egg or sperm that forms a child, but rather in a *cell* in the developing embryo or in a tissue after birth. Such events are referred to as **somatic pathogenic variants**. Because only a subset of cells in the body are affected, the change is said to be **mosaic**. The phenotypes caused by a somatic pathogenic variant can vary but are usually milder than if all cells were affected by the pathogenic variant. Some cancers typically arise from cells that have been affected by multiple somatic pathogenic variants. In **germline mosaicism,** the pathogenic variant occurs in a subset of cells that ultimately produce ova or sperm. An individual who is germline mosaic for a pathogenic variant might not have any manifestations of the associated disorder but may pass that change on to his or her offspring by producing ova or sperm that carry the pathogenic variant. Children whose bodies derive from those ova or sperm will carry the pathogenic variant in all of their cells unless the change undergoes a rare reversion of the somatic pathogenic variant. Recurrence of a dominantly inherited condition to apparently unaffected parents can sometimes be explained by germline mosaicism for the dominantly transmitted variant in one of the parents.

Autosomal Recessive Inheritance

Autosomal recessive inheritance requires deleterious variants in both copies of a gene to cause disease. Examples include cystic fibrosis and sickle cell disease. Autosomal recessive disorders are characterized by **horizontal transmission**, the observation of multiple affected members of a kindred in the same generation, but no affected family members in other generations (Fig. 97.7). They are associated with a recurrence risk of 25% for carrier parents who have had a previous affected child. Male and female offspring are equally likely to be affected, although some traits exhibit differential expression between sexes. The offspring of consanguineous parents are at increased risk for rare, autosomal recessive traits due to the increased chance that both parents may carry a gene affected by a deleterious variant that they inherited from a common ancestor. **Consanguinity** between parents of a child with a suspected genetic disorder implies, but certainly does not prove, autosomal recessive inheritance. Although consanguineous unions are uncommon in Europe and the Americas, in other parts of the world (southern India, Japan, and the Middle East) as high as 50% of all children may be conceived in consanguineous unions. The risk of a genetic disorder in the offspring of a first-cousin union (6–8%) is about double the risk in the general population (3–4%).

Instructions:
—Key should contain all information relevant to interpretation of pedigree (e.g., define fill/shading)
—For clinical (non-published) pedigrees include:
a) name of proband/consultand
b) family names/initials of relatives for identification, as appropriate
c) name and title of person recording pedigree
d) historian (person relaying family history information)
e) date of intake/update
f) reason for taking pedigree (e.g., abnormal ultrasound, familial cancer, developmental delay, etc.)
g) ancestry of both sides of family
—Recommended order of information placed below symbol (or to lower right)
a) age; can note year of birth (e.g., b.1978) and/or death (e.g., d. 2007)
b) evaluation (see Fig. 97.4)
c) pedigree number (e.g., I-1, I-2, I-3)
—Limit identifying information to maintain confidentiality and privacy

	Male	Female	Gender not specified	Comments
1. Individual	b.1925	30 y	4 mo	Assign gender by phenotype (see text for disorders of sex development, etc.). Do not write age in symbol.
2. Affected individual				Key/legend used to define shading or other fill (e.g., hatches, dots, etc.). Use only when individual is clinically affected.
			With ≥2 conditions, the individual's symbol can be partitioned accordingly, each segment shaded with a different fill and defined in legend.	
3. Multiple individuals, number known	5	5	5	Number of siblings written inside symbol. (Affected individuals should not be grouped.)
4. Multiple individuals, number unknown or unstated	n	n	n	"n" used in place of "?".
5. Deceased individual	d. 35	d. 4 mo	d. 60's	Indicate cause of death if known. Do not use a cross (†) to indicate death to avoid confusion with evaluation positive (+).
6. Consultand				Individual(s) seeking genetic counseling/testing.
7. Proband	P	P		An affected family member coming to medical attention independent of other family members.
8. Stillbirth (SB)	SB 28 wk	SB 30 wk	SB 34 wk	Include gestational age and karyotype, if known.
9. Pregnancy (P)	P LMP: 7/1/2007 47,XY,+21	P 20 wk 46, XX	P	Gestational age and karyotype below symbol. Light shading can be used for affected; define in key/legend.

Pregnancies not carried to term	Affected	Unaffected	
10. Spontaneous abortion (SAB)	17 wks female cystic hygroma	<10 wks	If gestational age/gender known, write below symbol. Key/legend used to define shading.
11. Termination of pregnancy (TOP)	18 wks 47, XY,+18		Other abbreviations (e.g., TAB, VTOP) not used for sake of consistency.
12. Ectopic pregnancy (ECT)	ECT		Write ECT below symbol.

Fig. 97.1 Common pedigree symbols, definitions, and abbreviations. (*From Bennett RL, French KS, Resta RG, et al. Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors. J Genet Couns. 2008;17:424–433.*)

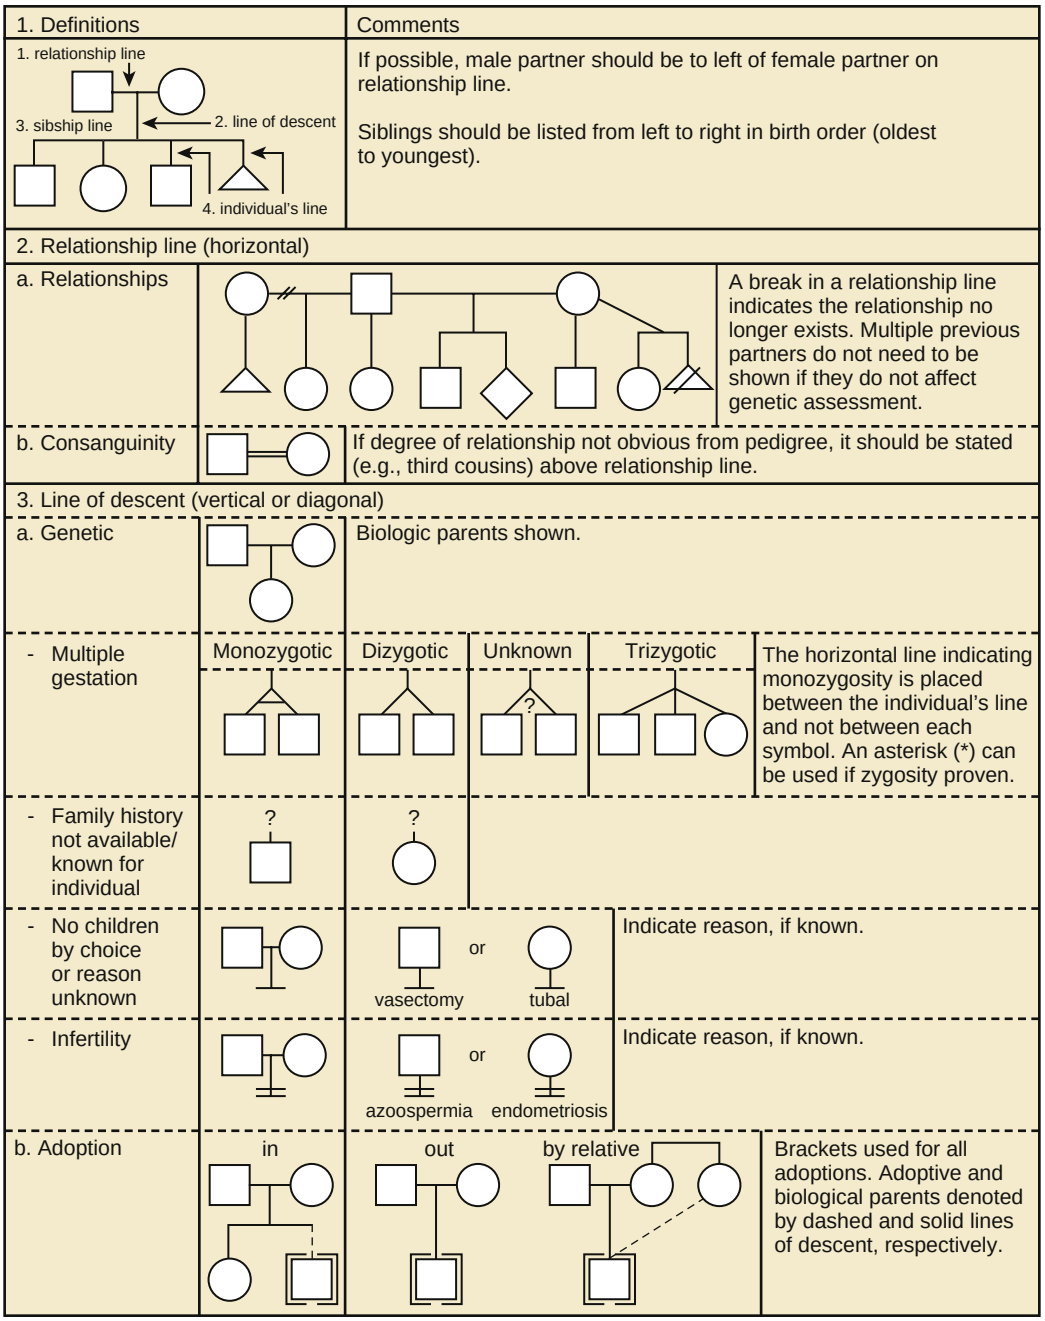

Fig. 97.2 Pedigree line definitions. (*From Bennett RL, French KS, Resta RG, et al. Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors. J Genet Couns. 2008;17:424–433.*)

Every individual probably carries several rare, deleterious recessive pathogenic sequence variants. Because most pathogenic variants carried in the general population occur at a very low frequency, it does not make economic sense to screen the entire population to identify the small number of persons who carry these variants. These variants typically remain undetected unless an affected child is born to a couple who both carry pathogenic variants affecting the same gene.

However, in some **genetic isolates** (small populations isolated by geography, religion, culture, or language), certain rare recessive pathogenic variants are much more common than in the general population. Even though there may be no known consanguinity, couples from these genetic isolates have a greater chance of sharing pathogenic alleles inherited from a common ancestor. Screening programs have been developed among some such groups to detect persons who carry common disease-causing variants and, therefore, are at increased risk for having affected children.

A variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. Couples of Ashkenazi Jewish ancestry should be offered prenatal or preconception screening for Gaucher disease type one (carrier rate 1:14), cystic fibrosis (1:25), Tay-Sachs disease (1:25), familial dysautonomia (1:30), Canavan disease (1:40), glycogen storage disease type 1A (1:71), maple syrup urine disease (1:81), Fanconi anemia type C (1:89), Niemann-Pick disease type A (1:90), Bloom syndrome (1:100), mucolipidosis IV (1:120), and possibly neonatal familial hyperinsulinemic hypoglycemia.

The prevalence of carriers of certain autosomal recessive variants in some larger populations is unusually high. In such cases, **heterozygote advantage** is postulated. The carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from the rate of new pathogenic variants. In these populations,

Instructions:
— D represents egg or sperm donor
— S represents surrogate (gestational carrier)
— If the woman is both the ovum donor and a surrogate, in the interest of genetic assessment, she will only be referred to as a donor (e.g., 4 and 5); the pregnancy symbol and its line of descent are positioned below the woman who is carrying the pregnancy
— Available family history should be noted on the gamete donor and/or gestational carrier

Possible Reproductive Scenarios		Comments
1. Sperm donor		Couple in which woman is carrying pregnancy using donor sperm. No relationship line is shown between the woman carrying the pregnancy and the sperm donor.
2. Ovum donor		Couple in which woman is carrying pregnancy using a donor egg and partner's sperm. The line of descent from the birth mother is solid because there is a biologic relationship that may affect the fetus (e.g., teratogens).
3. Surrogate only		Couple whose gametes are used to impregnate a woman (surrogate) who carries the pregnancy. The line of descent from the surrogate is solid because there is a biological relationship that may affect the fetus (e.g., teratogens).
4. Surrogate ovum donor		Couple in which male partner's sperm is used to inseminate (a) an unrelated woman or (b) a sister who is carrying the pregnancy for the couple.
5. Planned adoption		Couple contracts with a woman to carry a pregnancy using ovum of the woman carrying the pregnancy and donor sperm.

Fig. 97.3 Assisted reproductive technology symbols and definitions. (*From Bennett RL, French KS, Resta RG, et al. Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors. J Genet Couns. 2008;17:424–433.*)

heterozygous carriers may have had an advantage in terms of survival and reproduction over noncarriers. In sickle cell disease, the carrier state is thought to confer some resistance to malaria. In cystic fibrosis, the carrier state has been postulated to confer resistance to cholera or enteropathogenic *Escherichia coli* infections. Population-based **carrier screening** for cystic fibrosis is recommended for persons of northern European and Ashkenazi Jewish ancestry, and population-based screening for sickle cell disease is recommended for persons of African ancestry.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the **Hardy-Weinberg formula:**

$$p^2 + 2pq + q^2 = 1$$

where p is the frequency of one of a pair of alleles and q is the frequency of the other. For example, if the frequency of cystic fibrosis among White Americans is one in 2,500 (p^2), then the frequency of the heterozygote ($2pq$) can be calculated: If $p^2 = 1/2{,}500$, then $p = 1/50$ and $q = 49/50$; $2pq = 2 \times (1/50) \times (49/50) = 98/2{,}500$, or 3.92%.

Pseudodominant Inheritance

Pseudodominant inheritance refers to the observation of apparent dominant (parent to child) transmission of a known autosomal recessive disorder (Fig. 97.8). This occurs when a homozygous affected individual has a partner who is a heterozygous carrier. This is most likely to occur for relatively common recessive traits within a population, such as sickle cell anemia or nonsyndromic autosomal recessive hearing loss caused by deleterious variants in *GJB2*, the gene that encodes connexin 26.

X-Linked Inheritance

X-linked inheritance describes the inheritance pattern of most disorders caused by deleterious changes in genes located on the X chromosome (Fig. 97.9). In X-liked disorders, males are more commonly

Instructions:
- E is used for evaluation to represent clinical and/or test information on the pedigree
  a. E is to be defined in key/legend
  b. If more than one evaluation, use subscript (E_1, E_2, E_3) and define in key
  c. Test results should be put in parentheses or defined in key/legend
- A symbol is shaded only when an individual is clinically symptomatic
- For linkage studies, haplotype information is written below the individual. The haplotype of interest should be on left and appropriately highlighted
- Repetitive sequences, trinucleotides, and expansion numbers are written with affected allele first and placed in parentheses
- If variant known, identify in parentheses

Definition	Symbol	Scenario
1. Documented evaluation (*) Use only if examined/evaluated by you or your research/clinical team or if the outside evaluation has been reviewed and verified.	*	Woman with negative echocardiogram. * E− (echo)
2. Carrier—not likely to manifest disease regardless of inheritance pattern		Male carrier of Tay-Sachs disease by patient report (* not used because results not verified).
3. Asymptomatic/presymptomatic carrier—clinically unaffected at this time but could later exhibit symptoms		Woman age 25 with negative mammogram and positive BRCA1 DNA test. * 25 y E_1− (mammogram) E_2+ (5385insC BRCA1)
4. Uninformative study (u)	Eu	Man age 25 with normal physical exam and uninformative DNA test for Huntington disease (E_2). * 25 y E_1− (physical exam) E_2u (36n/18n)
5. Affected individual with positive evaluation (E+)	E+	Individual with cystic fibrosis and positive variant study; only one variant has currently been identified. E+(ΔF508) Eu * E+(ΔF508/u)
		10 week male fetus with a trisomy 18 karyotype. P * 10 wk E+(CVS) 47,XY,+18

Fig. 97.4 Pedigree symbols of genetic evaluation and testing information. (*From Bennett RL, French KS, Resta RG, et al. Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors. J Genet Couns. 2008;17:424–433.*)

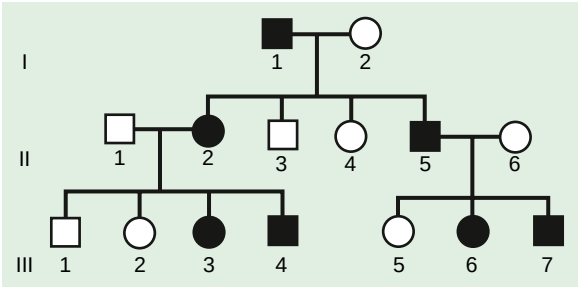

Fig. 97.5 Autosomal dominant pedigree. Pedigree showing typical inheritance of a form of achondroplasia *(FGFR3)* inherited as an autosomal dominant trait. *Black,* Affected patients.

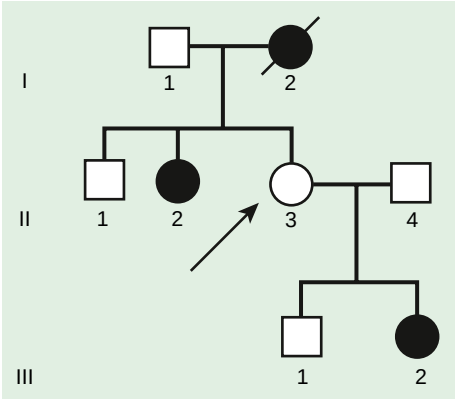

Fig. 97.6 Incomplete penetrance. This family segregates a familial cancer syndrome, familial adenomatous polyposis. Individual II.3 is an obligate carrier *(arrow),* but there are no findings to suggest the disorder. This disorder is nonpenetrant in this individual. *Black,* Affected patients.

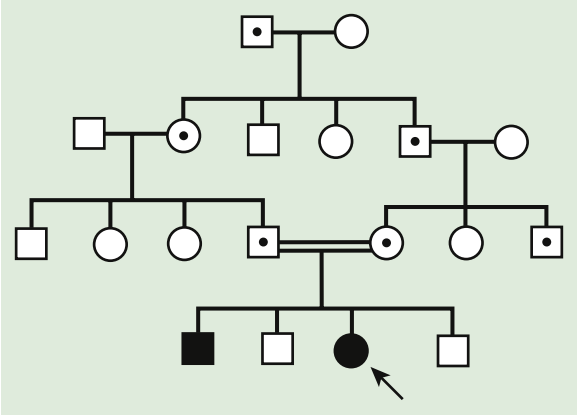

Fig. 97.7 Autosomal recessive pedigree with parental consanguinity. *Central dot,* Carriers; *Black,* affected patients.

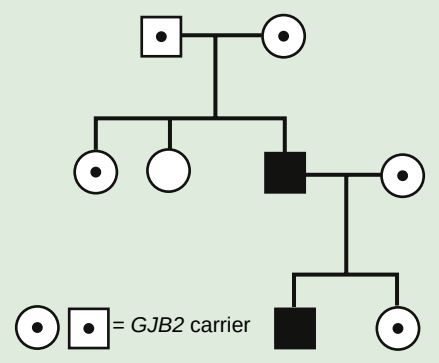

Fig. 97.8 Pseudodominant inheritance. *Black,* Affected (deaf); *central dot* shows carrier who is asymptomatic (unaffected).

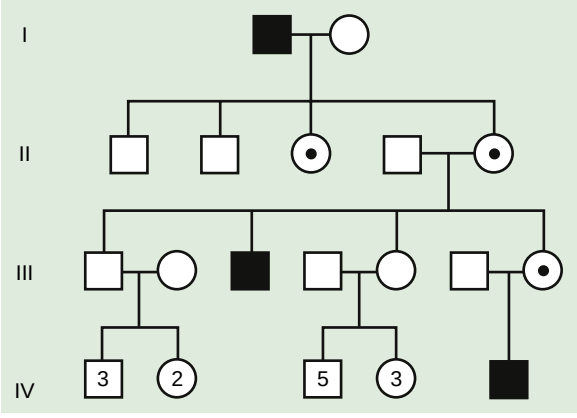

Fig. 97.9 Pedigree demonstrating X-linked recessive inheritance. *Central dot,* Carriers; *black,* affected patients.

affected than females. Female carriers of these disorders are generally unaffected, or if affected, they are affected more mildly than males. In each pregnancy, female carriers have a 25% chance of having an affected son, a 25% chance of having a carrier daughter, and a 50% chance of having a child that does not inherit the mutated X-linked gene. Because affected males pass their X chromosome to all their daughters and their Y chromosome to all their sons, they have a 50% chance of having a daughter who is a carrier. Male-to-male transmission excludes X-linked inheritance but is seen with autosomal dominant and Y-linked inheritance.

A female occasionally exhibits signs of an X-linked trait similar to a male. This occurs rarely from homozygosity for an X-linked trait or the presence of a sex chromosome abnormality (45,X or 46,XY female) but more commonly from skewed or nonrandom X-inactivation. **X chromosome inactivation** occurs early in development and involves the random and irreversible inactivation of most genes on one X chromosome in female cells (Fig. 97.10). In some cases, a preponderance of cells inactivates the same X chromosome, resulting in phenotypic expression of an X-linked pathogenic variant if it resides on the active chromosome. This can occur because of chance, selection against cells that have inactivated the X chromosome carrying the normal gene, or an X chromosome abnormality that results in inactivation of the X chromosome carrying the normal gene.

In some X-linked disorders, both **hemizygous** males and **heterozygous** females who carry an affected X-linked gene have similar phenotypic manifestations. In these cases, an affected male will have a 50% chance of having an affected daughter and a 50% chance of having an unaffected son in each pregnancy, whereas half the male and female offspring of an affected mother will be affected (Fig. 97.11). Some X-linked conditions are lethal in a high percentage of males, such as **incontinentia pigmenti**. In such cases the pedigree typically shows only affected females and an overall female/male ratio of 2:1, with an increased number of miscarriages (Fig. 97.12).

Y-LINKED INHERITANCE

There are few Y-linked traits. These demonstrate *only* male-to-male transmission, and only males are affected (Fig. 97.13). Most Y-linked genes are related to male sex determination and reproduction and are associated with infertility. Therefore it is rare to see familial transmission of a Y-linked disorder. However, advances in assisted reproductive technologies might make it possible to have familial transmission of male infertility.

INHERITANCE ASSOCIATED WITH PSEUDOAUTOSOMAL REGIONS

There are pseudoautosomal regions on the X and Y chromosomes. Because these regions are made up of homologous sequences of nucleotides, genes that are located in these regions are present in equal numbers among both males and females. *SHOX* is one of the best-characterized disease genes located in these regions. Heterozygous *SHOX* pathogenic variants cause **Leri-Weil dyschondrosteosis**, a rare skeletal dysplasia that involves bilateral bowing of the forearms with dislocations of the ulna at the wrist and generalized short stature. Homozygous *SHOX* pathogenic variants cause the much more severe **Langer mesomelic dwarfism**.

DIGENIC INHERITANCE

Digenic inheritance explains the occasional occurrence of **retinitis pigmentosa (RP)** in children of parents who each carry a pathogenic variant in a different RP-associated gene (Fig. 97.14). Both parents have normal vision, as would be expected, but their offspring who are **double heterozygotes**—having inherited both variants—develop RP. Digenic pedigrees can exhibit characteristics of both autosomal dominant (vertical transmission) and autosomal recessive inheritance (one in four recurrence risk). A couple in which the two unaffected partners are carriers for variants in two different RP-associated genes that show digenic inheritance have a one in four risk of having an affected child, similar to what is seen in autosomal recessive inheritance. However, their affected children, and affected children in subsequent generations, have a one in four risk of transmitting both variants to their offspring, who would be affected (vertical transmission).

PSEUDOGENETIC INHERITANCE AND FAMILIAL CLUSTERING

Sometimes nongenetic causes of a particular disease in multiple family members can produce a pattern that mimics genetic transmission. These nongenetic factors can include identifiable environmental factors, teratogenic exposures, or undetermined or undefined factors.

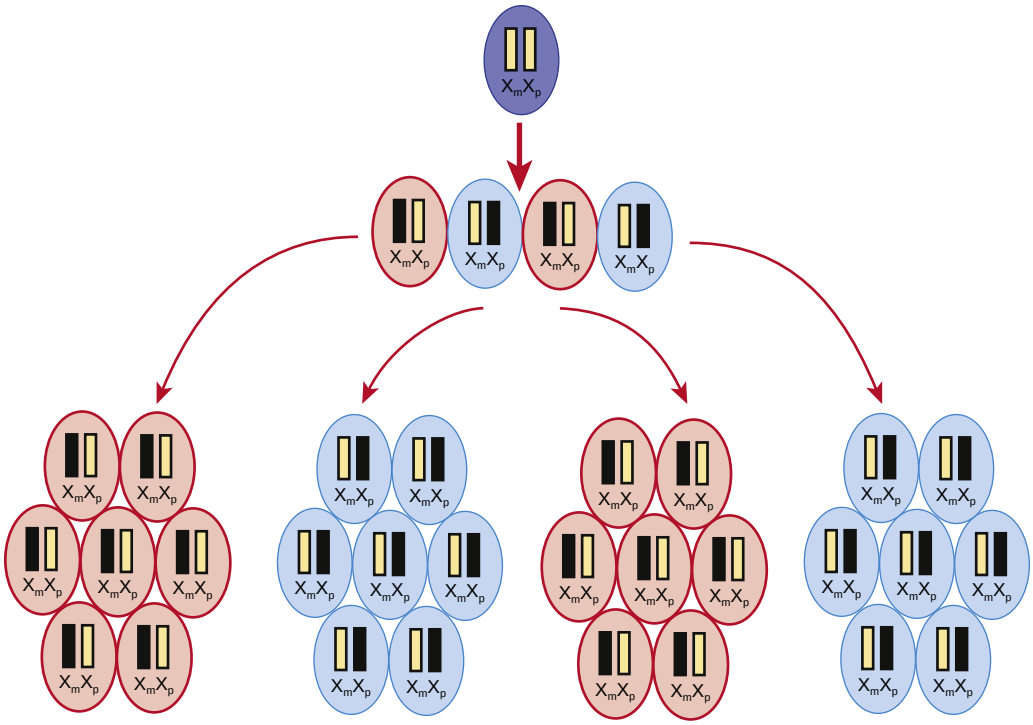

Fig. 97.10 X-inactivation. *Black* marks the active X chromosome. Color of the cell represents its active X chromosome is paternally (X_p, *blue*) or maternally (X_m, *pink*) derived.

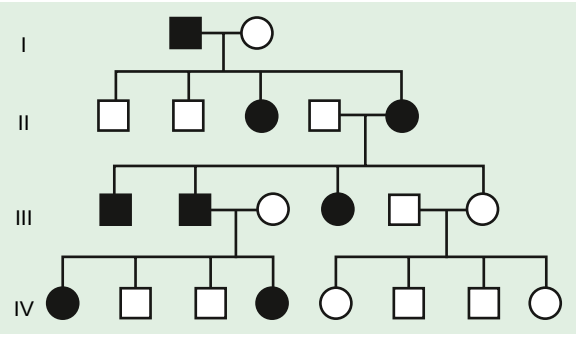

Fig. 97.11 Pedigree pattern demonstrating X-linked dominant inheritance. *Black,* Affected patients. Note there is no father-to-son transmission in this situation, and hemizygosity (i.e., X-linked gene in a male) is not lethal. In some X-linked dominant conditions, X-linked males have a more severe phenotype and might not survive. In that case, only females manifest the disease (see Fig. 97.12).

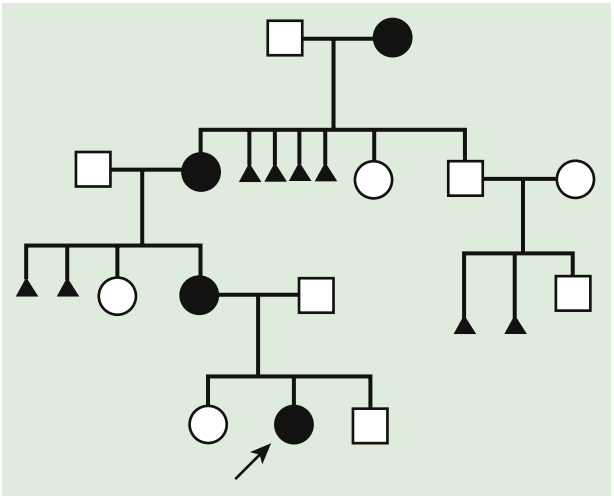

Fig. 97.12 Pedigree of an X-linked dominant disorder with male lethality, such as incontinentia pigmenti. *Black,* Affected patients.

Examples of identifiable factors might include multiple siblings in a family having asthma because of exposure to cigarette smoke from their parents or having failure to thrive, developmental delay, and unusual facial appearance caused by exposure to alcohol during pregnancy.

In some cases, the disease is sufficiently common in the general population that some familial clustering occurs simply by chance. Breast cancer affects 11% of all women, and it is possible that several women in a family will develop breast cancer even in the absence of a specific genetic predisposition. However, hereditary breast cancer associated with pathogenic variants in *BRCA1* and *BRCA2* should be suspected in any individual who has a personal history of breast cancer with onset before age 50, early-onset breast and ovarian cancer at any age, bilateral or multifocal breast cancer, a family history of breast cancer or breast and ovarian cancer consistent with autosomal dominant inheritance, or a personal or family history of male breast

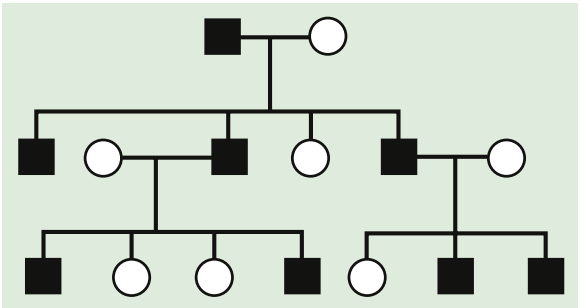

Fig. 97.13 Y-linked inheritance. *Black,* Affected patients.

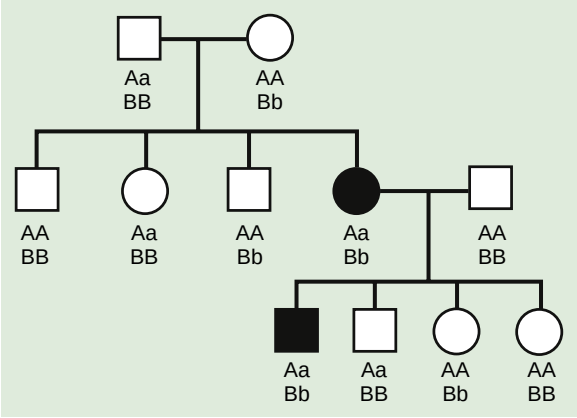

Fig. 97.14 Digenic pedigree. Here, the disease alleles are *a* and *b* and they reside on distinct genetic loci or genes. For a person to have the disease, heterozygosity for variant alleles in both genes (A/a; B/b) is required. *Black,* Affected patients.

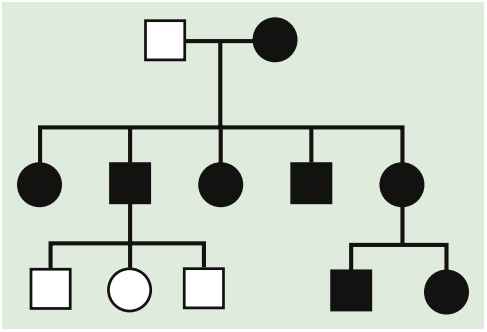

Fig. 97.15 Pedigree of a mitochondrial disorder, exhibiting maternal inheritance. *Black,* Affected patients.

cancer. In other cases, clustering within a family may be caused by undefined genetic factors or unidentified pathogenic sequence variants (nuclear or mitochondrial).

NONTRADITIONAL INHERITANCE

Some genetic disorders are inherited in a manner that does not follow classical mendelian patterns. Nontraditional inheritance is seen in mitochondrial disorders, triplet repeat expansion diseases, and imprinting defects.

Mitochondrial Inheritance

An individual's mitochondrial genome is entirely derived from the mother because sperm contain relatively few mitochondria, which are degraded after fertilization. It follows that **mitochondrial inheritance** is, essentially, **maternal inheritance**. A female with a mitochondrially inherited genetic disorder can have affected offspring of either sex, but an affected father cannot pass on the disease to his offspring (Fig. 97.15). Mitochondrial DNA pathogenic variants are often deletions or point pathogenic variants. Overall, one person in 400 has a maternally inherited pathogenic mitochondrial DNA pathogenic variant (see Chapter 108). In individual families, mitochondrial inheritance may be difficult to distinguish from autosomal dominant or X-linked inheritance, but in many cases, the sex of the transmitting and nontransmitting parents can suggest a mitochondrial basis (Table 97.1).

Mitochondria are the cell's suppliers of energy; the organs that are most affected by the presence of abnormal mitochondria are those that have the greatest energy requirements, such as the brain, muscle, heart, and liver (see Chapters 107.4, 409, 638.2, and 651.4; Fig. 97.16). Common manifestations include developmental delay, seizures, cardiac dysfunction, decreased muscle strength and tone, and hearing and vision problems.

Mitochondrial diseases can be highly variable in their clinical manifestations. This is partly because cells can contain multiple mitochondria, each bearing several copies of the mitochondrial genome. Thus a cell can have a mixture of normal and abnormal mitochondrial genomes, which is referred to as **heteroplasmy**. In contrast, **homoplasmy** refers to a state in which all copies of the mitochondrial genome carry the same sequence variant. Unequal segregation of mitochondria carrying normal and abnormal genomes and replicative advantage can result in varying degrees of heteroplasmy in the cells of an affected individual, including the individual ova of an affected female. Because of this, a mother may be asymptomatic and yet have children who are severely affected. The level of heteroplasmy at which disease symptoms typically appear can also vary based on the type of mitochondrial variant.

Detection of variants in the mitochondrial genome may require sampling of the affected tissue for DNA analysis. In some tissues, such as blood, testing for mitochondrial DNA variants may be inadequate because the variant may be found primarily in affected tissues such as muscle (Fig. 97.17). Growth and differentiation factor 15 (GDF-15) and blood lactate levels are screening tests for mitochondrial disorders. GDF-15 is only accurate in children ≥1 year of age and in the absence of heart, liver, or renal disease.

Triplet Repeat Expansion Disorders

Triplet repeat expansion disorders are distinguished by the special dynamic nature of the disease-causing variant. Triplet repeat expansion disorders include fragile X syndrome, myotonic dystrophy, Huntington disease, and spinocerebellar ataxias (Table 97.2 and Fig. 97.18). These disorders are caused by expansion in the number of 3-bp repeats. The fragile X gene, *FMR1,* normally has 5-40 CGG triplets. An error in replication can result in expansion of that number to a level in the gray zone between 41 and 58 repeats or to a level referred to as a **prepathogenic variant**, which comprises 59-200 repeats. Some prepathogenic variant carriers, more often males, develop fragile X–associated tremor/ataxia syndrome (FXTAS) as adults. Female prepathogenic variant carriers are at risk for fragile X–associated primary ovarian insufficiency (FXPOI). Persons, especially females, with a prepathogenic variant are also at risk for having the repeat expand further in subsequent meiosis, thus crossing into the range of a **full pathogenic variant** (>200 repeats) in offspring. With this number of repeats, the *FMR1* gene becomes hypermethylated, and protein production is lost.

Some triplet expansions associated with other genes can cause disease through a mechanism other than decreased protein production. In Huntington disease, the expansion causes the gene product to have a new, toxic effect on the neurons of the basal ganglia. For most triplet repeat disorders, there is a clinical correlation to the size of the expansion, with a greater expansion causing more severe symptoms and having an earlier age of disease onset. The observation of increasing severity of disease and early age at onset in subsequent generations is termed **genetic anticipation** and is a defining characteristic of many triplet repeat expansion disorders (Fig. 97.19).

Genetic Imprinting

The two copies of most autosomal genes are functionally equivalent. However, in some cases, only one copy of a gene is transcribed, and the second copy is silenced. This gene silencing is typically associated with methylation of DNA, which is an **epigenetic** modification; it does not change the nucleotide sequence of the DNA (Fig. 97.20). In **imprinting**, gene expression depends on the *parent of origin* of the chromosome (see Chapter 99.7). Imprinting disorders result from an imbalance of active copies of a given gene, which can occur for several reasons. Prader-Willi and Angelman syndromes,

Table 97.1 Representative Examples of Disorders Caused by Pathogenic Variants in Mitochondrial DNA and Their Inheritance

DISEASE	PHENOTYPE	MOST FREQUENT PATHOGENIC VARIANT IN mtDNA MOLECULE	HOMOPLASMY vs HETEROPLASMY	INHERITANCE
Leber hereditary optic neuropathy	Rapid optic nerve atrophy, leading to blindness in young adult life; sex bias approximately 50% males with visual loss, only 10% females	Substitution p.Arg340His in *ND1* gene of complex I of electron transport chain; other complex I missense pathogenic variants	Homoplasmic (usually)	Maternal
NARP, Leigh disease	*N*europathy, *a*taxia, *r*etinitis *p*igmentosa, developmental delay, intellectual disability lactic academia	Point pathogenic variants in ATPase subunit six gene	Heteroplasmic	Maternal
MELAS	*M*itochondrial encephalomyopathy, *l*actic *a*cidosis, and *s*trokelike episodes; may manifest only as diabetes mellitus or deafness	Point pathogenic variant in $tRNA^{Leu}$	Heteroplasmic	Maternal
MERRF	*M*yoclonic *e*pilepsy, *r*agged *r*ed *f*ibers in muscle, ataxia, sensorineural deafness	Point pathogenic variant in $tRNA^{Lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics	m.1555A>G pathogenic variant in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	m.7445A>G pathogenic variant in 12S rRNA	Homoplasmic	Maternal
Chronic progressive external ophthalmoplegia (CPEO)	Progressive weakness of extraocular muscles, cardiomyopathy, ptosis, heart block, ataxia, retinal pigmentation, diabetes	The common MELAS point pathogenic variant in $tRNA^{Lys}$; large deletions similar to KSS	Heteroplasmic	Maternal if point pathogenic variants
Pearson syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletions	Heteroplasmic	Sporadic, somatic pathogenic variants
Kearns-Sayre syndrome (KSS)	PEO of early onset with heart block, retinal pigmentation	5-kb large deletion	Heteroplasmic	Sporadic, somatic pathogenic variants

two distinct disorders associated with developmental impairment, are caused by microdeletions of chromosome 15q11-12. The microdeletion in **Prader-Willi syndrome** is always on the *paternally* derived chromosome 15, whereas in **Angelman syndrome** it is on the *maternal* copy. *UBE3A* is the gene responsible for Angelman syndrome. The paternal copy of *UBE3A* is transcriptionally silenced in the brain, but the maternal copy continues to be transcribed. If an individual has a maternally derived deletion, an insufficient amount of UBE3A protein is produced in the brain, resulting in the neurologic deficits seen in Angelman syndrome.

Uniparental disomy (UPD), the rare occurrence of a child inheriting both copies of a chromosome from the *same parent*, is another genetic mechanism that can cause Prader-Willi and Angelman syndromes. Inheriting both chromosomes 15 from the mother is functionally the same as deletion of the paternal 15q12 region and results in Prader-Willi syndrome. Approximately 30% of cases of Prader-Willi syndrome are caused by maternal UPD15, whereas paternal UPD15 accounts for only 3% of Angelman syndrome (see Chapter 99.7). Pathogenic variants in *UBE3A* account for ~11% of patients with Angelman syndrome and result in familial transmission. The least common cause is a pathogenic variant affecting the imprinting center, which results in an inability to correctly imprint *UBE3A*. In a mother, inability to reset the imprinting on her paternally inherited chromosome 15 imprint results in a 50% risk of passing on an incorrectly methylated copy of *UBE3A* to a child, who would then develop Angelman syndrome.

Other imprinted regions of clinical interest include the short arm of chromosome 11, where the genes for Beckwith-Wiedemann syndrome and nesidioblastosis map, and the long arm of chromosome seven with maternal UPD of 7q being associated with some cases of idiopathic short stature and Russell-Silver syndrome.

Imprinting of a gene can occur during gametogenesis or early embryonic development **(reprogramming)**. Genes can become inactive or active by various mechanisms including DNA methylation or demethylation or histone acetylation or deacetylation, with different patterns of (de)methylation noted on paternal or maternal imprintable chromosome regions. Some genes demonstrate tissue-specific imprinting (see Fig. 97.20). There is a small but increased incidence of imprinting disorders, specifically Beckwith-Wiedemann and Angelman syndrome, following assisted reproductive technologies such as in vitro fertilization and intracytoplasmic sperm injection. The overall incidence of these disorders in children conceived using assisted reproductive technologies is likely to be <1%.

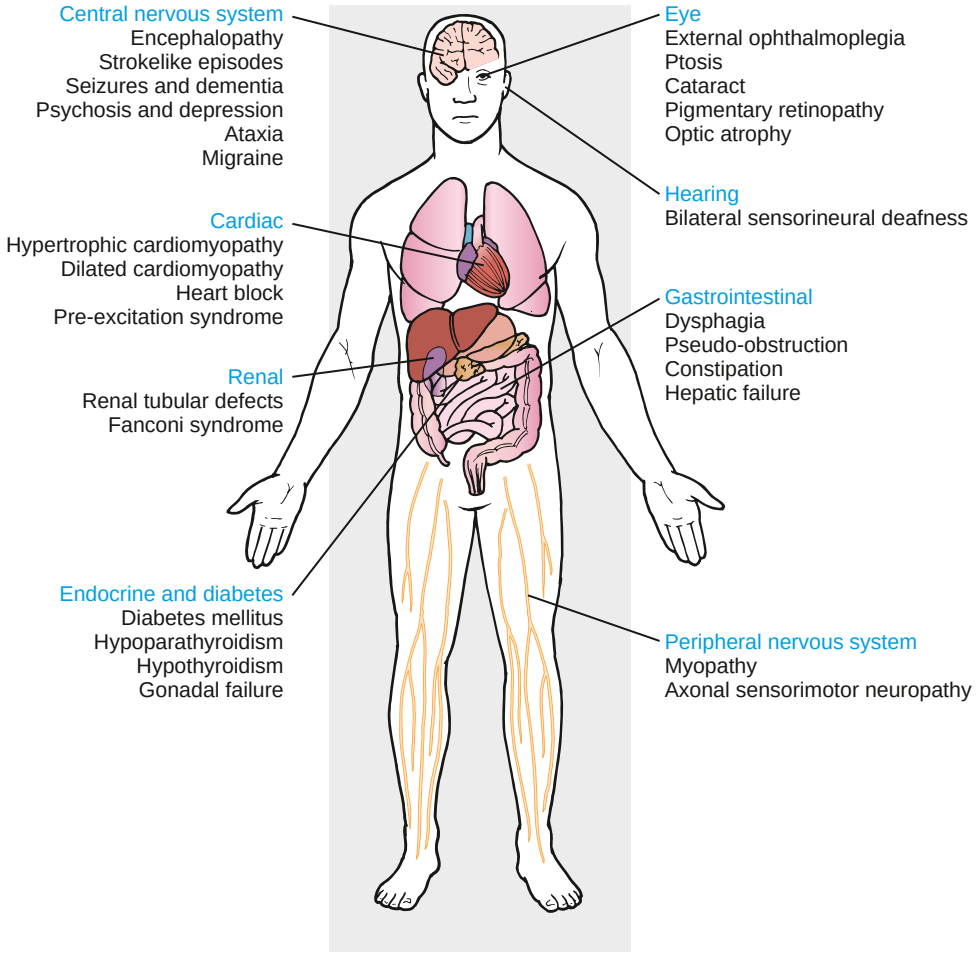

Fig. 97.16 The range of affected tissues and clinical phenotypes associated with pathogenic variants in mitochondrial DNA (mtDNA). (*Modified from Chinnery PF, Turnbull DM. Mitochondrial DNA and disease. Lancet. 1999;345:SI17–SI21.*)

MULTIFACTORIAL AND POLYGENIC INHERITANCE

Multifactorial inheritance refers to traits that are caused by a combination of inherited, environmental, and stochastic factors (Fig. 97.21). Multifactorial traits differ from polygenic inheritance, which refers to traits that result from the additive effects of multiple genes. Multifactorial traits segregate within families but do not exhibit a consistent or recognizable inheritance pattern. Characteristics include the following:

- There is a similar rate of recurrence among all first-degree relatives (parents, siblings, offspring of affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than second degree to the index case.
- The risk of recurrence is related to the incidence of the disease.
- Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. With an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less often affected than relatives of an index case of the more frequently affected gender. The risk to the son of an affected female with infantile pyloric stenosis is 18%, compared with the 5% risk for the son of an affected male. An affected female presumably has a greater genetic susceptibility, which can be passed on to offspring.
- The likelihood that both identical twins will be affected with the same malformation is <100% but much greater than the chance that both members of a nonidentical twin pair will be affected. This contrasts with the pattern seen in mendelian inheritance, in which identical twins almost always share fully penetrant genetic disorders.
- The risk of recurrence is increased when multiple family members are affected. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with one affected child and increases to 9% with two affected children. It is sometimes difficult to distinguish between a multifactorial and mendelian etiology in families with multiple affected individuals.
- The risk of recurrence may be greater when the disorder is more severe. For example, an infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

There are two types of multifactorial traits. One exhibits **continuous variation**, with "normal" individuals falling within a statistical range—often defined as having a value two standard deviations (SDs) above and/or below the mean—and "abnormals" falling outside that range. Examples include such traits as intelligence, blood pressure, height, and head circumference. For many of these traits, offspring values can be estimated based on a modified average of their parental values, with nutritional and environmental factors playing an important role.

Table 97.2 Diseases Associated with Polynucleotide Repeat Expansions—cont'd

DISEASE	DESCRIPTION	REPEAT SEQUENCE	NORMAL RANGE	ABNORMAL RANGE	PARENT IN WHOM EXPANSION USUALLY OCCURS	LOCATION OF EXPANSION
CATEGORY 1						
Spinocerebellar ataxia type 6	Progressive ataxia, dysarthria, nystagmus	CAG	4-16	21-27	—	Exon
Spinocerebellar ataxia type 7	Progressive ataxia, dysarthria, retinal degeneration	CAG	7-35	38-200	More often through father	—
Spinocerebellar ataxia type 17	Progressive ataxia, dementia, bradykinesia, dysmetria	CAG	29-42	47-55	—	Exon
Dentatorubral-pallidoluysian atrophy/Haw River syndrome	Cerebellar atrophy, ataxia, myoclonic epilepsy, choreoathetosis, dementia	CAG	7-25	49-88	More often through father	Exon
CATEGORY 2						
Pseudoachondroplasia, multiple epiphyseal dysplasia	Short stature, joint laxity, degenerative joint disease	GAC	5	6-7	—	Exon
Oculopharyngeal muscular dystrophy	Proximal limb weakness, dysphagia, ptosis	GCG	6	7-13	—	Exon
Cleidocranial dysplasia	Short stature, open skull sutures with bulging calvaria, clavicular hypoplasia, shortened fingers, dental anomalies	GCG, GCT, GCA	17	27 (expansion observed in one family)	—	Exon
Synpolydactyly	Polydactyly and syndactyly	GCG, GCT, GCA	15	22-25	—	Exon
CATEGORY 3						
Myotonic dystrophy (DM1; chromosome 19)	Muscle loss, cardiac arrhythmia, cataracts, frontal balding	CTG	5-37	100 to several thousand	Either parent, but expansion to congenital form through mother	3′ untranslated region
Myotonic dystrophy (DM2; chromosome 3)	Muscle loss, cardiac arrhythmia, cataracts, frontal balding	CCTG	<75	75-11,000	—	3′ untranslated region
Friedreich ataxia	Progressive limb ataxia, dysarthria, hypertrophic cardiomyopathy, pyramidal weakness in legs	GAA	7-2	200-900 or more	Autosomal recessive inheritance, so disease alleles are inherited from both parents	Intron
Fragile X syndrome (FRAXA)	Intellectual impairment, large ears and jaws, macroorchidism in males	CGG	6-52	200-2,000 or more	Exclusively through mother	5′ untranslated region
Fragile site (FRAXE)	Mild intellectual impairment	GCC	6-35	>200	More often through mother	5′ untranslated region
Spinocerebellar ataxia type 8	Adult-onset ataxia, dysarthria, nystagmus	CTG	16-37	107-127	More often through mother	3′ untranslated region
Spinocerebellar ataxia type 10	Ataxia and seizures	ATTCT	12-16	800-4,500	More often through father	Intron
Spinocerebellar ataxia type 12	Ataxia, eye movement disorders; variable age at onset	CAG	7-28	66-78	—	5′ untranslated region
Progressive myoclonic epilepsy type 1	Juvenile-onset seizures, myoclonus, dementia	12-bp repeat motif	2-3	30-75	Autosomal recessive inheritance, so transmitted by both parents	5′ untranslated region

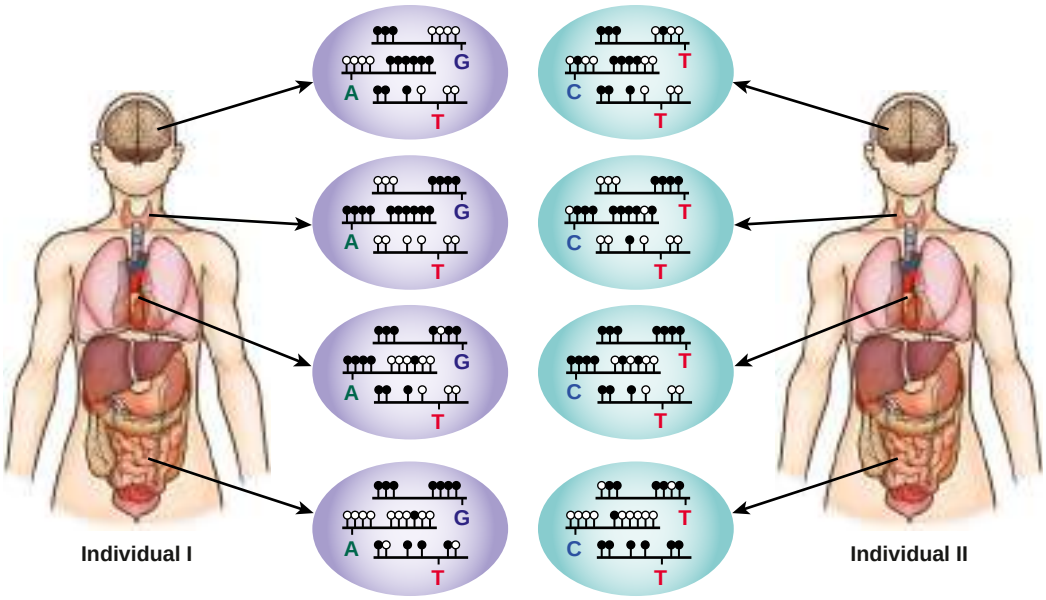

Fig. 97.20 Tissue-specific DNA methylation and epigenetic heterogeneity among individuals. A subset of the DNA methylation patterns within a cell is characteristic of that cell type. Cell type–specific and tissue-specific DNA methylation patterns are illustrated by organ-to-organ variations in the clusters of methylated cytosine-phosphate-guanine bases (CpGs) within the same individual. Despite overall consistency in tissue-specific DNA methylation patterns, variations in these patterns exist among different individuals. Methylated CpGs are indicated by a *filled circle* and unmethylated CpGs by an *open circle*. Single nucleotide polymorphisms (SNPs) are indicated by the corresponding base. (*Redrawn from Brena RM, Huang THM, Plass C. Toward a human epigenome. Nat Genet. 2006;38:1359–1360.*)

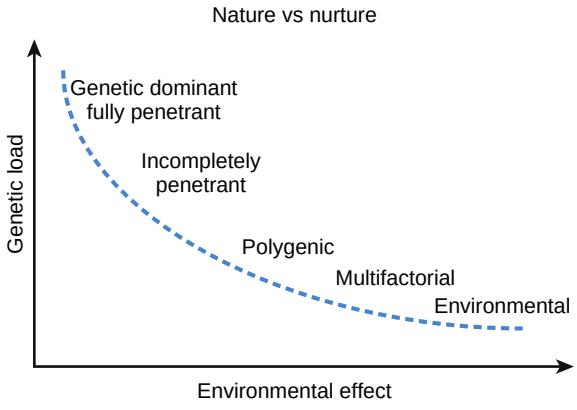

Fig. 97.21 The progressive decrease in the genetic load contributing to the development of a disease creates a smooth transition in the distribution of illnesses on an etiologic diagram. In theory, no diseases are completely free from the influence of both genetic and environmental factors. (*From Bomprezzi R, Kovanen PE, Martin R. New approaches to investigating heterogeneity in complex traits. J Med Genet. 2003;40:553–559.*)

With other multifactorial traits, the distinction between normal and abnormal is based on the **qualitative** presence or absence of a particular trait. Examples include pyloric stenosis, neural tube defects, congenital heart defects, and cleft lip and cleft palate. Such traits follow a **threshold model** (see Fig. 97.15). A distribution of liability because of genetic and nongenetic factors is postulated in the population. Individuals who exceed a threshold liability develop the trait, and those below the threshold do not.

The balance between genetic and environmental factors is demonstrated by neural tube defects. Genetic factors are implicated by the increased recurrence risk for parents of an affected child compared with the general population, yet the recurrence risk is about 3%, less than what would be expected if the trait was caused by a single, fully penetrant pathogenic variant. The role of nongenetic environmental factors is shown by the recurrence risk decreasing up to 87% if the mother-to-be takes 4 mg of folic acid daily starting 3 months before conception.

Chapter 98

Integration of Genetics into Pediatric Practice

Brendan Lee and Nicola Brunetti-Pierri

Genetic testing involves analyzing genetic material to obtain information related to a person's health status using chromosomal (cytogenetic) analysis (see Chapter 99) and nucleic acid (primarily DNA but also RNA)-based testing.

DIAGNOSTIC TESTING

Diagnostic genetic testing helps to aggregate a set of signs and symptoms (phenotype) for disease diagnosis. The list of disorders for which specific genetic tests are available is extensive and growing. The website http://www.ncbi.nlm.nih.gov/gtr/ provides one database of reported available tests.

Single-gene disorders can be tested by at least three different approaches: linkage analysis (a classical approach now rarely used), chromosome microarray (CMA), and direct pathogenic variant analysis, usually by DNA sequencing (Table 98.1). Linkage analysis is used if the responsible gene is mapped but not yet identified, or if it is impractical to find specific pathogenic variants, usually because of the large size and large number of different pathogenic variants in some genes. CMA can be used to detect large, multigene deletions or duplications **(copy number variations, or CNVs)**. In addition, with increasing resolution, single-gene or smaller intragenic deletions or duplications can be detected by CMA, although it is important to note that coverage of each gene varies by array type used. *Direct DNA pathogenic variant identification is readily available with the advent of the complete human genome sequence next-generation sequencing (NGS) tools.* We also recognize the relatively frequent co-occurrence of multiple disorders, each caused by distinct pathogenic variants, in patients with complex or "blended" features. This may include partial to minimal clinical manifestations in a substantial percentage of individuals harboring pathogenic variants in known disease genes that remain undiagnosed. The ability to simultaneously sequence hundreds to thousands of genes (via NGS approaches) has provided insight into this complexity of disease pathogenesis.

Linkage testing involves tracking a genetic trait through a family using closely linked polymorphic markers as a surrogate for the trait (Fig. 98.1). It requires testing an extended family and is vulnerable to several pitfalls, such as genetic recombination, genetic heterogeneity, and incorrect diagnosis in the proband or family member. **Genetic recombination** occurs between any pair of loci, with the frequency being proportional to the distance between them. This problem is minimized using very closely linked markers and, if possible, using markers that flank the specific gene. **Genetic heterogeneity** can be problematic for a linkage-based test if there are multiple distinct genomic loci that can cause the same phenotype, resulting in the risk that the locus tested for is not the one responsible for disease in the family. **Incorrect diagnosis** in the proband also leads to tracking the wrong gene. Linkage testing remains useful for several genetic conditions, but it has been superseded by the availability of DNA sequencing of either single gene, panel, or exome sequencing.

CMAs can detect CNVs in a patient's DNA (see Chapter 99). CMA provides a level of genetic resolution between that available with DNA sequencing (single nucleotide) and that available with chromosome analysis (~5 million base pairs). CMA can resolve deletions or duplications of several kilobases within one gene. In theory, this approach can detect deletion and duplication pathogenic variants that would be missed by either chromosome analysis or direct pathogenic variant testing by DNA sequencing. However, because the specific resolution and coverage of different CMA platforms can vary tremendously for different gene regions, the sensitivity for detecting deletions and duplications can vary for different diseases and laboratories. The highest resolution used is detection of a deletion or duplication at the single exon level.

Direct DNA-based pathogenic variant testing avoids the pitfalls of linkage testing by detecting the specific gene pathogenic variant (i.e., sequence change). The specific approach used is customized to the biology of the gene being tested. In some disorders, one or a few distinct pathogenic variants occur in all affected individuals and a specific assay for that variant could be used. This is the case in sickle cell anemia, in which the same single-base substitution occurs in everyone with the disorder. In other conditions, many possible pathogenic variants may account for the disorder in different individuals. In cystic fibrosis, for example, >1,000 distinct pathogenic variants have been found in the *CFTR* gene. Pathogenic variant analysis is challenging because no single technique can detect all possible pathogenic variants (e.g., single nucleotide variation [SNV]), small (several nucleotide) insertion-deletions ("indels"), CNV (larger deletion or duplications), complex structural variations (e.g., translocations, inversions, etc.), DNA repeat expansions (e.g., variable repeat expansions), and epigenetic alterations (e.g., changes in DNA methylation without changing the underlying DNA sequence). However, with high-throughput DNA sequencing technology, the most frequently used approach is to

Table 98.1 Approaches for Genetic Testing

TYPE OF TESTING	RESOLUTION	ADVANTAGES	DISADVANTAGES	SAMPLE REQUIREMENTS
Linkage analysis	Depends on location of polymorphic markers near putative disease gene	Possible when specific disease-causing genetic pathogenic variant is not identifiable or found	Can give only diagnostic probability based on likelihood of genetic recombination between presumed DNA pathogenic variant and polymorphic markers	Requires multiple family members with documented Mendelian pattern of inheritance within family
Chromosome microarray (CMA)	Several hundred base pairs to several hundreds of kilobases	Able to detect small deletion or duplications within one or more genes	Can miss small deletions or insertions depending on the resolution of the array used	Single patient sample sufficient, but having sample from biological parents can help with interpretation
Direct DNA-based testing (e.g., DNA sequencing)	Single–base-pair changes	High specificity if previously described deleterious pathogenic variant is found	Can miss deletion or duplication of a segment of gene	Single patient sample sufficient, but having sample from biological parents and siblings (affected or unaffected) can help with interpretation

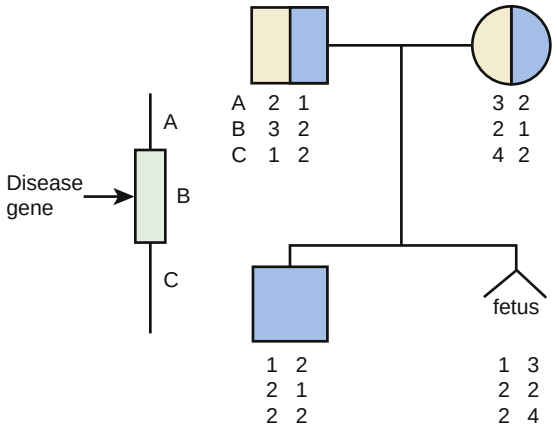

Fig. 98.1 Use of linkage analysis in prenatal diagnosis of an autosomal recessive disorder. Both parents are carriers, and they have one affected son. The numbers below the symbols indicate alleles at three polymorphic loci: A, B, and C. Locus B resides within the disease gene. The affected son inherited the 1-2-2 chromosome from his father and the 2-1-2 chromosome from his mother. The fetus has inherited the same chromosome from the father but the 3-2-4 chromosome from the mother and therefore is most likely to be a carrier.

directly sequence DNA segments "captured" and amplified from DNA isolated from peripheral blood white blood cells. The limitation of this approach is that only amplified DNA segments are sequenced and are usually restricted to the *coding exonic* regions of a gene. Because pathogenic variants sometimes occur in the *noncoding* and *intronic* regions, failure to detect a pathogenic variant does not fully exclude the diagnosis. In addition, deleted genes or regions may not be detected.

NGS tests panels of genes that target disease symptoms (e.g., epilepsy, brain malformations, sensorineural deafness, or skeletal dysplasias) or the majority of the exome **(exome sequencing)**. **Genome sequencing**, where both *coding* and *noncoding* sequences are sequenced, can provide even more information. However, clinical interpretation is limited predominantly to the coding sequences of the approximately 20,000 human genes, the "digital exome," as it is extracted electronically from genome data. Genome sequencing, compared with exome sequencing, also has the advantage of providing improved detection of CNV, structural variation, and repeat expansions, although this is highly dependent on the bioinformatics algorithms used in interpretation.

With NGS, the challenge is the interpretation of enormous genetic variation within a single individual. Direct sequencing of tens to hundreds of genes in NGS panels offers a potentially higher sensitivity because the "depth" of read is higher without complicating high discovery rate of **variants of unknown sequences (VUS)** (Fig. 98.2). Exome and genome sequencing also offer the potential for identifying new disease-gene associations as well as the ability to detect clinical presentations caused by more than one altered gene (i.e., oligogenic phenotypes).

An important ethical consideration is the reporting of *incidental findings,* whether medically actionable or not medically actionable in a patient. For example, exome and genome sequencing may identify pathogenic variants that cause aminoglycoside-sensitive hearing loss, which would be medically actionable but unrelated to the primary indication for which the test was ordered. At the same time, the discovery of apolipoprotein E variants in a child that increase Alzheimer disease risk susceptibility would not typically be medically actionable. Therefore counseling for patients undergoing these tests is important so that only requested results are reported back to the patient. Guidelines continue to evolve for reporting of incidental findings from exome and genome sequencing by the American College of Medical Genetics and Genomics (www.acmg.net). Practice and recommendations continue to vary among international genetic organizations revealing incidental findings to patients, and many strongly advocate the engagement of the patient and family in the decision. Some groups require revealing to the patient and/or family significant diseases (actionable) with a specific and successful treatment or prevention strategy (Table 98.2).

Genetic testing is interpreted by three factors: analytic validity, clinical validity, and clinical utility. **Analytical validity** is test accuracy: Does the test correctly detect the presence or absence of pathogenic variant? Most genetic tests have a very high analytical validity assuming human error has not occurred. Human errors are possible, and unlike most medical tests, a genetic test is unlikely to be repeated because it is assumed that the result will not change over time. Therefore human errors can go undetected for long periods of time. *In addition, variants may be reinterpreted over time as our knowledge base of disease-causing pathogenic variants and genes increases.*

Clinical validity is the degree to which the test correctly predicts presence or absence of disease. False-positive and false-negative test results can occur. **False-positive results** are more likely for predictive tests than for diagnostic tests. An important contributing factor is **nonpenetrance**, where an individual with an at-risk genotype might not clinically express the condition. Another factor is the finding of a **VUS**. Detection of a base sequence variation in an affected patient does not prove that it is the cause of the patient's disorder. Exome sequencing of an individual may identify more than 30,000 VUS and more than 3,000,000 VUS for genome sequencing. Various lines of evidence are used to establish pathogenicity. These include the absence of the variant in large populations of control individuals, finding the variant in affected individuals, demonstration or inference that the variant alters the function of the gene product, noting that the amino acid altered by the pathogenic variant is conserved in evolution, and segregation of the variant with disease in a family. For many variants, it is possible to be certain whether the variant is pathogenic or benign, but for others it might be impossible to definitively assign causality or noncontribution with 100% confidence. For these reasons, they are noted as **VUS.** *Notably, interpretation of pathogenicity for a specific VUS may change over time as our knowledge base increases, underscoring the importance of counseling and reinterpretation.*

False-negative results reflect an inability to detect a pathogenic variant in an affected patient. This occurs principally in disorders with genetic heterogeneity—**allelic** (different pathogenic variants occur in one causative gene) or **locus** (>1 gene can cause a disease) heterogeneity. It is often difficult to detect all possible pathogenic variants within a gene because pathogenic variants vary, both in location within the gene and in the type of variant. Direct sequencing can miss gene deletions or rearrangements (i.e., structural variants), and pathogenic variants may be found within noncoding sequences such as introns or promoter. Therefore a negative DNA test does not necessarily exclude a diagnosis.

Clinical utility is the degree to which the results of a test guide clinical management. For genetic testing, clinical utility includes establishing a diagnosis that obviates the need for additional workup or guiding surveillance or treatment. Test results may also be used as a basis for genetic counseling. For some disorders, genetic testing is possible, but the test results do not add to the clinical assessment. If the diagnosis and genetic implications are already clear, it might not be necessary to pursue genetic testing.

Predictive genetic testing involves performing a test in a person at risk for developing a genetic disorder **(presymptomatic)**, usually on the basis of family history, yet who does not manifest signs or symptoms. This is usually done for disorders that display age-dependent penetrance (e.g., the likelihood of manifesting signs and symptoms increases with age, as in cancer genetic syndromes or Huntington disease).

A major caution with predictive testing is that the presence of a gene pathogenic variant does not necessarily mean that the disease will develop. Many of the disorders with age-dependent penetrance display *incomplete penetrance*. A person who inherits a pathogenic variant may never develop signs of the disorder. There is concern that a positive DNA test could result in stigmatization of the person and might not provide information that will guide medical management. Stigmatization might include psychologic stress, but it could also include

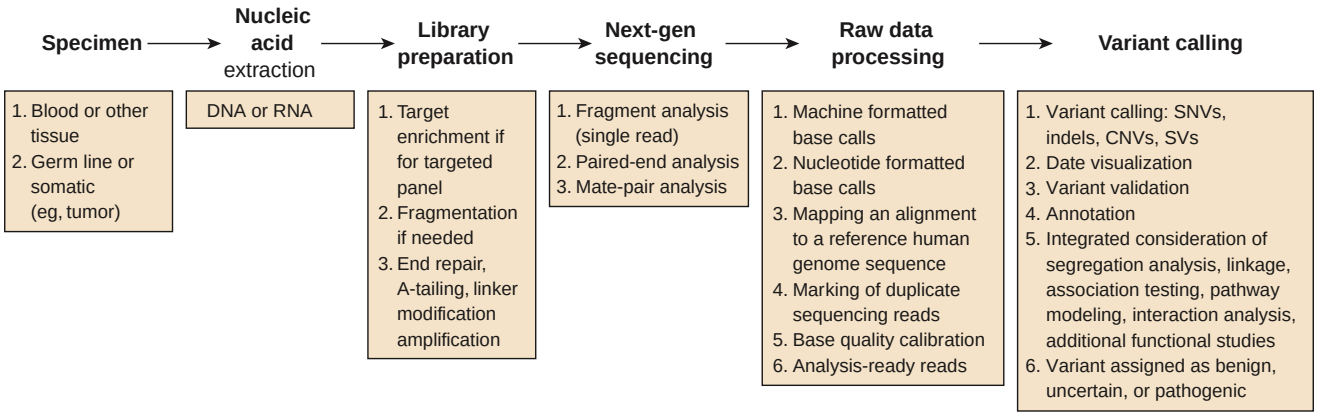

Fig. 98.2 Overview of the next-generation DNA sequencing workflow. CNV, Copy number variant; Indels, insertions and deletions; SNV, single nucleotide variant; SV, structural variant. (*Adapted from Casey G, Conti D, Haile R, et al. Next generation sequencing and a new era of medicine. Gut. 2013;62[6]:920–932.*)

Table 98.2 Variants That Are Incidental Findings Are Assigned to One of Four Categories

Childhood onset	Medically actionable*
Childhood onset	Not medically actionable†
Adult onset	Medically actionable*
Adult onset	Not medically actionable†

*"Medically actionable" refers to a variant in a gene in which knowledge of the particular variant will affect medical decision-making, such as initiation of a treatment or family planning.

†"Not medically actionable" refers to variants that increase the individual's risk for a disease in which no treatment is proven to significantly change the disease natural history.

From Bick D, Dimmock D. Whole exome and whole genome sequencing. *Curr Opin Pediatr.* 2011;23:594–600.

discrimination, including denial of health, life, or disability insurance, or employment (see Chapter 95).

It is generally agreed that predictive genetic tests should be performed for children only if the results of the test will benefit the medical management during childhood; otherwise, the test should be deferred until the individual understands the risks and benefits of testing and can provide their own informed consent. Individual states offer varying degrees of protection from discrimination on the basis of genetic testing. A major milestone in the prevention of genetic discrimination was the passage of the **Genetic Information Nondiscrimination Act** (GINA) in 2008, which is a U.S. federal law that prohibits discrimination in health coverage or employment based on genetic information. *Of note, it does not* protect against refusal of life insurance.

Predispositional genetic testing is available with the goal of predicting risk of disease. The rationale for predispositional testing is that the results would lead to strategies aimed at risk reduction as part of a *personalized approach* to healthcare maintenance. This might include avoidance of environmental exposures that would increase risk of disease (cigarette smoking and α_1-antitrypsin deficiency), medical surveillance (familial breast cancer and mammography), or in some cases, pharmacologic treatment (statins and hypercholesterolemia).

Common disorders are multifactorial in etiology, and many different genes may contribute to risk of any specific condition (see Chapter 103). Most genetic variants found to correlate with risk of a common disease add small increments of relative risk and, in most cases, too little to guide management based on a single variant.

Statistical models for predicting risk based on a collection of DNA variants has been integrated into approaches such as *polygenic risk scores*. By combining the relative risk conferred by a group of DNA variants, the goal is to quantify a larger proportion of risk for a specific disease. These predictions are confounded by the source of data from which they are generated, and current population genetic data have limitations including lack of ethnic diversity and population stratification.

PHARMACOGENETICS

Polymorphisms in drug metabolism genes can result in distinctive patterns of drug absorption, metabolism, excretion, or effectiveness. Knowledge of individual genotypes can guide pharmacologic therapy, allowing customization drug choice and dosage to avoid toxicity and provide a therapeutic response. Well-known examples include testing for polymorphisms within the methylenetetrahydrofolate reductase *(MTHFR)* gene for susceptibility of potentially increased toxicity to methotrexate antimetabolite therapy and thiopurine *S*-methyltransferase (*TPMT)* to avoid adverse effects with 6-mercaptopurine therapy (Fig. 98.3).

Pediatric Pharmacogenomics

Pharmacogenomics is the study of how variants contribute to interindividual variability in drug response. The finding that drug responses can be influenced by the patient's genetic profile offers great hope for realizing *individualized* pharmacotherapy, in which the relationship between genotype and phenotype (either disease and/or drug response) is predictive of drug response. In addition to genetic differences, environmental factors (e.g., diet, concomitant drug or toxic exposure), physiologic variables (age, sex, pregnancy), and patient adherence all contribute to variations in drug metabolism and response. Interindividual differences in children are further complicated by the changing patterns of gene expression occurring during the developmental processes from birth through adolescence. Combining these genetic and nongenetic individual-specific variables, it is expected that children will benefit from the promise of precision medicine, e.g., identifying the right drug for the right patient at the right time and dosing (Fig. 98.4).

Examples of pharmacogenomic traits include specific adverse drug reactions, such as prolonged respiratory muscle paralysis due to succinylcholine, hemolysis associated with antimalarial therapy, carbamazepine-induced Stevens-Johnson syndrome, isoniazid-induced neurotoxicity, and others (Table 98.3). The pharmacokinetic properties of a drug are determined by genes that control drug absorption, distribution, metabolism, and excretion. Drug-metabolizing enzymes and drug transporters play a particularly important role in this process. One of the better recognized clinical manifestations of pharmacogenomic variability in drug biotransformation is an increased risk of concentration-dependent toxicity caused by reduced clearance and consequent tissue drug accumulation. Equally important is the lack of efficacy caused by variations in metabolism of prodrugs that require biotransformation to be converted into a pharmacologically active form. The pharmacogenomics of drug receptors and other target proteins involved in signal transduction or disease pathogenesis are also expected to contribute to interindividual variability in drug disposition and response.

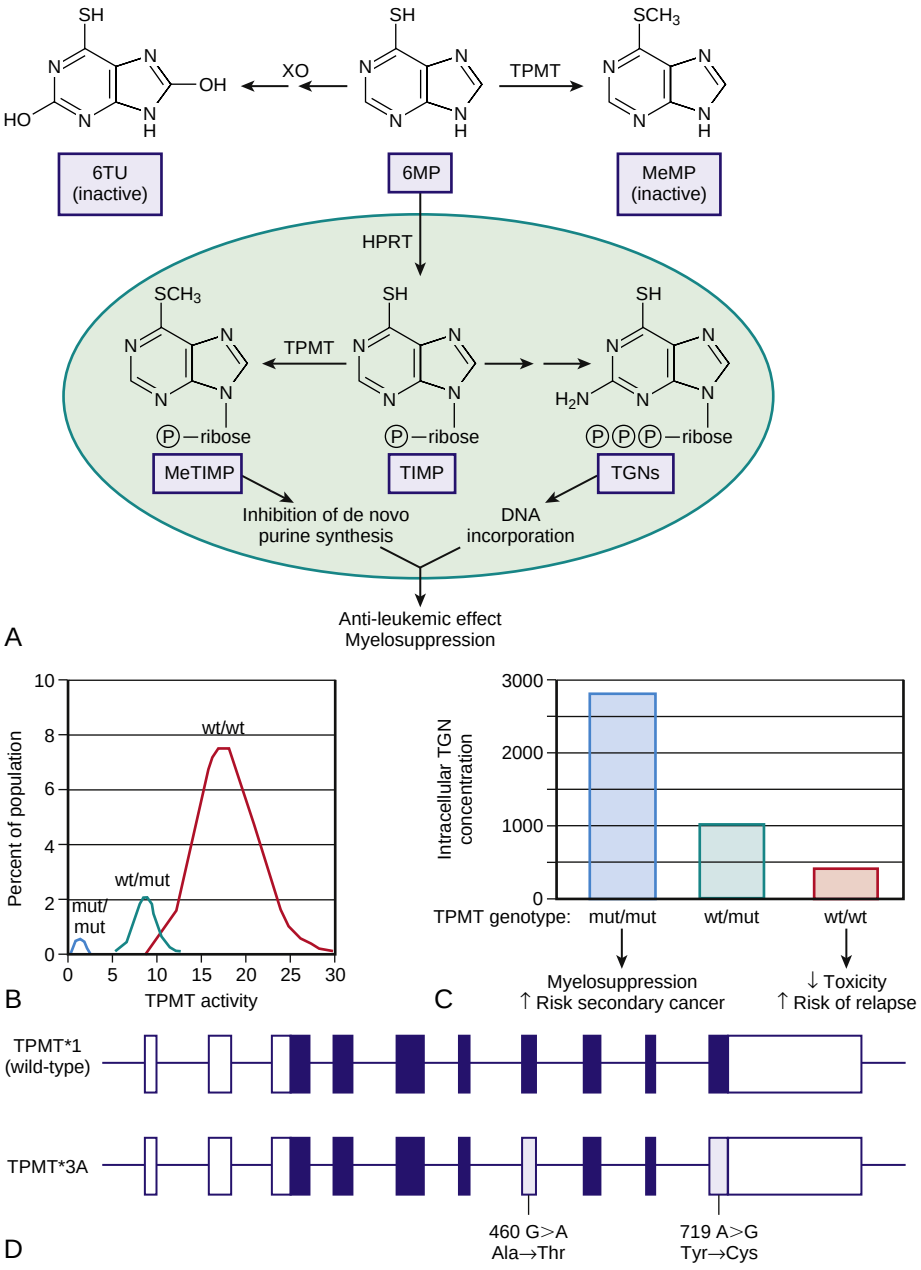

Fig. 98.3 Thiopurine *S*-methyltransferase (TPMT) polymorphism. **A,** 6-Mercaptopurine (6MP) undergoes metabolism to thioguanine nucleotides (TGNs) to exert its cytotoxic effects. TPMT and xanthine oxidase reduce the amount of 6MP available for the bioactivation pathway to TGNs. TPMT can also methylate 6-thioinosine 5′-monophosphate (TIMP) to generate a methylated compound capable of inhibiting de novo purine synthesis. **B,** Distribution of TPMT activity in humans. Of the population, 89% has high activity, whereas 11% has intermediate activity. Approximately 1 in 300 individuals homozygous for two loss-of-function alleles has very low activity. **C,** Correlation between the TPMT genotype and intracellular TGN concentrations. In TPMT-poor metabolizers, more 6MP is available to go down the bioactivation pathway to form TGNs; this situation is associated with an increased risk of myelosuppression. **D,** The most common variant TPMT allele is the result of two pathogenic variants that give rise to an unstable protein product that undergoes proteolytic degradation. Each box represents an exon. Non-coding sequences are shown as white boxes and colored boxes indicate coding sequences. 6TU, 6-Thiouric acid; MeMP, 6-methylmercaptopurine; HPRT, 6-thiomethylinosine 5-monophosphate; MeTIMP, hypoxanthine-guanine phosphoribosyl transferase; wt, wild type; mut, mutant; Ala, alanine; Thr, threonine; Tyr, tyrosine; Cys, cysteine. (*Modified from Relling MV, Dervieux T. Pharmacogenetics and cancer therapy. Nat Rev Cancer. 2001;11:99–108.*)

Individuals are classified as "fast," "rapid," or "extensive" metabolizers at one end and "slow" or "poor" metabolizers at the other end of the continuum. For biotransformation, fetuses and newborns may be phenotypically "slow" or "poor" metabolizers for certain drug-metabolizing pathways because of their stage of development, and they may acquire a phenotype consistent with their genotype at some point later in the developmental process. Moreover, not all infants acquire drug metabolism activity at the same rate, and there is interindividual variability in the trajectory (i.e., rate and extent) of drug biotransformation capacity (Fig. 98.5). The primary organ responsible for drug metabolism is the liver, although the kidney, intestine, lung, adrenals, blood (phosphatases, esterases), and skin can also biotransform certain compounds. Drug biotransformation is characterized by three important features: (1) broad substrate specificity, in which a single isozyme may metabolize a large variety of chemically diverse compounds; (2) many different enzymes may be involved in the biotransformation of a single drug (enzyme multiplicity); and (3) a given drug may undergo several different types of reactions. Drug biotransformation reactions are classified into phase I reactions that introduce or reveal (through oxidation, reduction, or hydrolysis) a functional group within the substrate drug molecule that serves as a site for phase II reactions. These reactions involve conjugation with endogenous substrates (such as acetate, glucuronic acid, glutathione, glycine, and sulfate), making the compound more water soluble to be excreted in urine. A supergene family with at least 16 primary cytochrome P450 (CYP) enzymes are quantitatively the most important phase I enzymes and catalyze the metabolism of many lipophilic endogenous (steroids, fatty acids, fat-soluble vitamins, prostaglandins, leukotrienes, thromboxanes) and exogenous compounds, including a multitude of drugs and environment toxins. The specific CYP isoforms responsible for the majority of human drug metabolism are CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. These enzymes are the products of genes that in some cases are polymorphically expressed, with allelic variants producing enzymes generally resulting in either no or reduced catalytic activity. At birth the activities of drug-oxidizing enzymes in the liver are reduced, which results in slow clearance (and prolonged elimination) of several substrate drugs (e.g., phenytoin, caffeine, diazepam). Phase

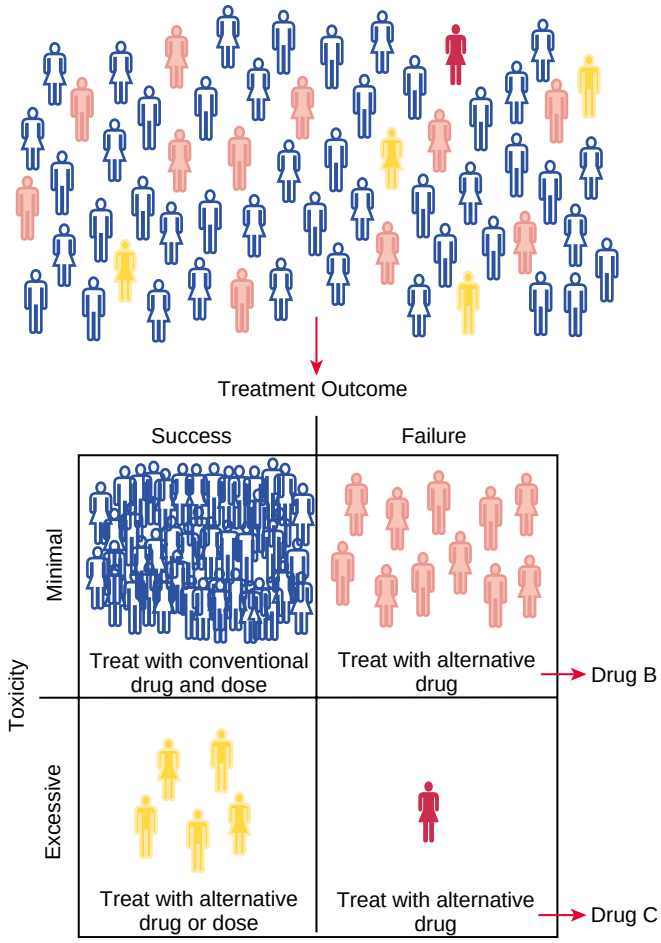

Fig. 98.4 The promise of genomic medicine to human health and disease. The goal of personalized medicine is to identify subgroups of patients who will respond favorably to a given drug with minimum side effects, as well as those who will not respond or who will show toxicity with standard doses. A further benefit of pharmacogenomics is to select the most appropriate alternative drug for patients who cannot be treated successfully with conventional drugs and doses. (*Adapted from Yaffe SJ, Aranda JV. Neonatal and Pediatric Pharmacology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2004.*)

II enzymes include arylamine *N*-acetyltransferases (NAT1, NAT2), uridine diphospho-glucuronosyltransferases (UGTs), epoxide hydrolase, glutathione *S*-transferases (GSTs), sulfotransferases (SULTs), and methyltransferases (catechol *O*-methyltransferase, thiopurine *S*-methyltransferase, several *N*-methyltransferases). Phase II enzyme activity is decreased in the newborn and increases into childhood. Conjugation of compounds metabolized by isoforms of UGT (e.g., morphine, bilirubin, chloramphenicol) is reduced at birth but can exceed adult values by 3-4 years of age.

Membrane transporters are involved in drug disposition and actively transport substrate drugs between organs and tissues. They include organic anion transporters (OATs), organic anion–transporting polypeptides (OATPs), organic cation transporters (OCTs), and the adenosine triphosphate–binding cassette (ABC) transporters, such as P-glycoprotein and the multidrug-resistant proteins. Drug transporters are expressed at numerous barriers, such as intestinal epithelial cells, hepatocytes, renal tubular cells, and the blood-brain barrier (Fig. 98.6). Transporters are often determinants of drug resistance, and many drugs work by affecting the function of transporters. Polymorphisms in the genes encoding these transporters might affect drug absorption, distribution, metabolism, and excretion.

98.1 Genetic Counseling

Brendan Lee and Pilar L. Magoulas

Genetic counseling is a communication process in which the genetic contribution to health, specific risks of transmission of a trait, and options to manage the condition are explained to individuals and their family members (Table 98.4). Genetic counselors are specialized healthcare providers trained in the psychosocial aspects of counseling and the science of medical genetics who may serve as members of medical teams in many different specialties. The genetic counselor is expected to present information in a neutral, nondirective manner while providing resources and psychosocial support to the individual and family to cope with decisions that are made (see Table 98.4).

In the prenatal setting, a common indication for genetic counseling is to assess risk of occurrence or recurrence of having a child with a genetic condition and to discuss management or treatment options that might be available before, during, or after the pregnancy, such as preimplantation genetic testing, noninvasive prenatal screening, prenatal diagnosis or fetal intervention, and perinatal management. In pediatric and adult genetics practices, the goals of genetic counseling are to help establish a diagnosis in an individual, provide longitudinal care and psychosocial support to the family, and discuss the genetic basis and inheritance of the condition as it relates to immediate and distant family members.

The genetic counseling role has expanded, particularly with advances in understanding the genetics of adult-onset or common and rare disease therapeutics. In the former context, genetic counseling has a major role in risk assessment for cancer, especially breast, ovarian, or colon cancer, for which well-defined risk models and genetic tests are available to assess risk to an individual. In the latter, the genetic counselor may discuss developments in rare disease therapeutics and make appropriate referral for medical therapies.

There are several situations in which genetic counseling plays a particularly important role. The first situation is the **prenatal diagnosis** of a congenital anomaly or genetic disease. The need for information is urgent because a family must often make time-sensitive decisions about treatment and management options, such as fetal intervention or continuation of a pregnancy in the context of fetal anomalies. Risks to the mother must also be considered. The second type of situation occurs when a child is born with a life-threatening **congenital anomaly** or suspected **genetic disease**. Decisions must be made immediately on how much support should be provided to the child and whether certain types of therapy should be attempted. The third situation arises when there are concerns about a **genetic condition** affecting one later in life. This may occur in an adolescent or young adult with a family history of an adult-onset genetic disorder (e.g., Huntington disease, hereditary breast/ovarian cancer), in an individual with a suspected yet undiagnosed genetic condition, or if a couple with a personal or family history of a genetic condition (or a carrier) is planning a family. In these situations, it is often necessary to have several meetings with a family to discuss possible testing, screening, and management options. Urgency is not as much of an issue as being sure that they have as much information and as many options as are available. Last, with the advent of genomic testing in all areas of clinical care, **pretest genetic counseling** before testing is essential to provide individuals with accurate information regarding the types of results they may receive. During this process, individuals are also given the option of what type of results they want reported back to them, such as medically actionable results unrelated to the primary indication for testing and incidental findings.

GENETIC COUNSELING ELEMENTS

Components of a genetic counseling session and providing accurate information to families requires the following:

- Taking a targeted family history and constructing a pedigree that diagrams the patient's relatives (including miscarriages, abortions, stillbirths, deceased persons) with their sex, age, ethnicity, and state of health, up to and including third-degree relatives.

Table 98.3 Examples of Effects of Gene Polymorphisms on Drug Response

GENE	ENZYME/TARGET	DRUG	CLINICAL RESPONSE
BCHE	Butyrylcholinesterase	Succinylcholine	Prolonged paralysis
CYP2C9	Cytochrome P450 2C9	Warfarin	Individuals having ≥1 reduced function alleles require lower doses of warfarin for optimal anticoagulation, especially initial anticoagulant control.
CYP2C19	Cytochrome P450 2C19	Clopidogrel	Individuals having ≥1 loss-of-function alleles have reduced capacity to form pharmacologically active metabolite of clopidogrel and reduced antiplatelet effect.
CYP2D6	Cytochrome P450 2D6	Codeine	Poor metabolizers (individuals with two loss-of-function alleles) do not metabolize codeine to morphine and thus experience no analgesic effect. Ultrarapid metabolizers (individuals with ≥3 functional alleles) may experience morphine toxicity.
G6PD	Glucose-6-phosphate dehydrogenase	Primaquine (others)	Hemolysis
*HLA-A*3101*	Human leukocyte antigen A31	Carbamazepine	Carriers of *HLA-A*3101* allele have increased risk of SJS and TEN from carbamazepine.
*HLA-B*1502*	Human leukocyte antigen B15	Allopurinol	Han Chinese carriers of *HLA-B*1502* allele have increased risk of SJS and TEN from carbamazepine.
*HLA-B*5701*	Human leukocyte antigen B57	Abacavir Flucloxacillin	Carriers of *HLA-B*5701* allele have increased risk of hypersensitivity reactions to abacavir- and flucloxacillin-induced liver injury.
*HLA-B*5801*	Human leukocyte antigen B58	Allopurinol	Carriers of *HLA-B*5801* allele have increased risk of severe cutaneous adverse reactions to allopurinol, including hypersensitivity reactions, SJS, and TEN.
NAT2	*N*-Acetyltransferase 2	Isoniazid, hydralazine	Individuals homozygous for "slow acetylation" polymorphisms are more susceptible to isoniazid toxicity, or hydralazine-induced systemic lupus erythematosus.
SLCO1B1	Organic anion–transporting protein (OATP) 1B1	Simvastatin	Carriers of the *SLCO1B1*5* allele are at increased risk for musculoskeletal side effects from simvastatin.
TPMT	Thiopurine *S*-methyltransferase	Azathioprine 6-Mercaptopurine	Individuals homozygous for an inactivating pathogenic variant have severe toxicity if treated with standard doses of azathioprine or 6-mercaptopurine; rapid metabolism causes undertreatment.
UGT1A1	Uridine diphospho-glucuronosyltransferase 1A1	Irinotecan	*UGT1A1*28* allele is associated with decreased glucuronidation of SN-38, the active metabolite of irinotecan, and increased risk of neutropenia.
VKORC1	Vitamin K oxidoreductase complex 1	Warfarin	Individuals with a haplotype associated with reduced expression of VKORC1 protein (therapeutic target of warfarin) require lower doses of the drug for stable anticoagulation.

SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

- Gathering information from hospital records about the affected individual and, in some cases, about other family members.
- Documenting prenatal, pregnancy, and delivery histories.
- Reviewing the latest available medical, laboratory, and genetic information concerning the disorder.
- Reviewing a careful physical examination of the affected individual (photographs, measurements) and of apparently unaffected individuals in the family (typically performed by a physician rather than a genetic counselor).
- Reviewing genetic testing and screening options.
- Establishing or confirming the diagnosis by the diagnostic tests available.
- Providing psychosocial support to the individual and family throughout the diagnostic process.
- Giving the family information about support groups and local and national resources.
- Providing new information to the family as it becomes available (a mechanism for updating needs to be established).

Genetic counseling sessions often include anticipatory guidance regarding the occurrence or risk of occurrence of a specific condition, knowledge of the diagnosis of the particular condition, natural history of the condition, genetic aspects of the condition, risk of recurrence, prenatal diagnosis and reproductive options, therapies and referrals, and provision of support resources.

The Diagnostic Process

If a specific diagnosis is made and confirmed, this should be discussed with the family and information provided in writing. Often, however, the disorder fits into a spectrum (e.g., one of many types of arthrogryposis) or the diagnosis is clinical rather than confirmed with molecular testing. In these situations, the family needs to understand the limits of the diagnostic process and present knowledge, and that additional research will probably lead to better information in the future.

Although it is not always possible to make an exact diagnosis, having a diagnosis *as accurate as possible* is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis that

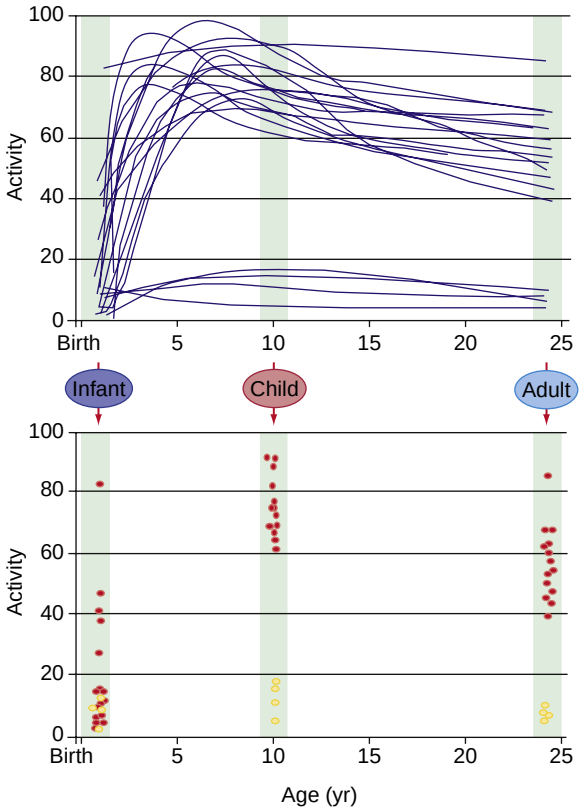

Fig. 98.5 "Developmental" phenotypes. Variability in developmental changes in gene expression and functional enzyme activity are superimposed on pharmacogenetic determinants. **Top,** Developmental profile of a theoretical drug-metabolizing enzyme over a 25-year span in 20 individuals. **Bottom,** At maturity (adults), allelic variation within the coding region of the gene gives rise to two distinct phenotypes: high activity in 92% of the population ("extensive metabolizers"; *red circles*) and low activity in 8% of the population ("poor metabolizers"; *yellow circles*). However, there is also interindividual variability in the rate at which functional activity is acquired after birth. For example, the two phenotypes may not be readily distinguishable in newborn infants. Furthermore, there may be discrete periods during childhood in which the genotype-phenotype relationship may differ from that observed in adults (e.g., developmental stages at which enzyme activity appears to be greater in children than in adults). (*Adapted from Leeder JS. Translating pharmacogenetics and pharmacogenomics into drug development for clinical pediatric and beyond. Drug Discov Today. 2004;9:567–573.*)

considers the likelihood that a particular finding is isolated, associated with a syndrome, or nonsyndromic (e.g., isolated cleft lip and palate). When a specific diagnosis cannot be made (as in many cases of multiple congenital anomalies), the various possibilities in the differential diagnosis should be discussed with the family and empirical information provided. If available, specific diagnostic tests should be discussed. Often, empirical recurrence risks can be given even without a specific laboratory-based diagnosis. At the same time, even negative laboratory testing can further modify this risk.

Natural History of the Condition

It is important to discuss the natural history of the specific genetic disorder in the family. Affected persons and their families have questions regarding the prognosis and potential management or therapy that can be answered only with knowledge of the natural history. If there are other possible diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the range of possible outcomes and variability of the condition, as well as treatment and referral to the appropriate specialist, should be addressed.

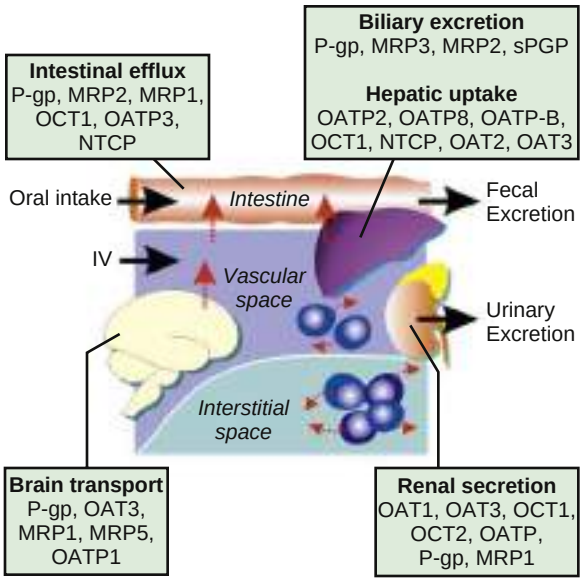

Fig. 98.6 Schematic diagram of important transport proteins and their known locations in humans. *Spheres* correspond to drug molecules. (*From American Pharmacists Association. Ritschel WA, Kearns GL, eds. Handbook of Basic Pharmacokinetics Including Clinical Applications, 7th ed. Washington, DC: American Pharmacists Association, 2009. p 45.*)

Genetic Aspects of the Condition and Recurrence Risk

The genetic aspects and risk of recurrence are important because all family members should be informed of their reproductive choices. The genetic basis of the disorder can be explained with visual aids (e.g., diagrams of chromosomes and inheritance patterns). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals. If a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks. Genetic counseling gives patients the necessary information to understand the various options and to make their own informed decisions regarding pregnancy, adoption, assistive reproductive technologies, prenatal diagnosis, screening, carrier detection, or termination of pregnancy. It may be necessary to have more than one counseling session. Even if a specific molecular diagnosis has been made and a well-defined inheritance pattern has been described for the condition, it is important to recognize that the principles of incomplete penetrance, variable expressivity, and germline/somatic mosaicism can contribute uncertainty to the recurrence risk and severity of a potentially affected pregnancy conception or child.

Prenatal Diagnosis and Prevention

Many different methods of prenatal screening and diagnosis are available, depending on the specific genetic disorder (see Chapter 117). The use of ultrasonography allows prenatal screening of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening, including noninvasive prenatal screening by direct analysis of cell-free fetal DNA found in maternal blood, which is used for screening of conditions such as trisomy 21 and other aneuploidies. In addition, this source of cell-free fetal DNA has also been used clinically for DNA sequencing for selected dominant de novo conditions in the fetus that may occur with increased frequency with increasing paternal age. Current tests of fetal DNA from maternal blood should be considered screening tests, and invasive testing like amniocentesis or chorionic villus sampling should be considered for confirmatory diagnostic testing.

Table 98.4 Indications for Genetic Counseling

Advanced parental age
• Maternal age ≥35 years
• Paternal age ≥40 years
Previous child with or family history of:
• Congenital abnormality
• Dysmorphology
• Intellectual disability
• Isolated birth defect
• Metabolic disorder
• Chromosome abnormality
• Single-gene disorder
Adult-onset genetic disease (presymptomatic testing)
• Cancer
• Huntington disease
Pharmacogenomics
Consanguinity
Teratogen exposure (occupational, abuse)
Repeated pregnancy loss or infertility
Pregnancy screening abnormality
• Maternal serum α-fetoprotein
Maternal first-trimester screen
• Maternal triple or quad screen or variant of this test
• Fetal ultrasonography
Noninvasive prenatal testing (NIPT)
• Fetal karyotype
Heterozygote screening based on ethnic risk
• Sickle cell anemia
• Tay-Sachs, Canavan, and Gaucher diseases
• Thalassemias
Universal carrier screening panels
Follow-up to abnormal neonatal genetic testing
Prior to whole genome or exome sequencing
Prior to preimplantation genetic testing

Therapies and Referral

Some genetic disorders require the care of multiple specialists. Many genetic conditions have diagnosis and management guidelines to aid in the treatment and management of these complex patients. Prevention of known complications is a priority, so close follow-up with the necessary specialists involved in the child's care is essential to identify any potentially concerning issues early. The psychologic adjustment of the family might also require specific intervention. Some challenges may involve when to discuss the diagnosis of a chronic disease with the patient, siblings, and other family members or friends. The decision to do so should always involve the parents and an assessment of the maturity and capacity of the child or adolescent.

Alternative medicines or nontraditional therapies are often brought to attention by parents after exhaustive internet searches. Such treatments should not necessarily be dismissed since the physician and genetic counselor should serve as an important resource for helping parents navigate the maze of nonstandard treatments. Instead, the relative merits of treatments should be framed in the context of cost and benefit, scientific rationale, evidence from controlled and observational studies, the placebo effect, safety of the treatment, and the gaps in our own scientific knowledge base.

Support Groups

A large number of community and online lay disease–specific support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to patients and to suggest a contact person for the families. Many groups have established websites and social media platforms with very helpful information. With the rise of social media and its ability to connect families with rare syndromes from around the world, it is important to stress to families that their individual disease course will be unique and significant biases of reporting occur on such platforms. This should be balanced by the benefit of sharing potential important natural history elements of the underlying rare disease.

Follow-Up

Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders.

Nondirective Counseling

Genetic counseling is usually nondirective; choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

98.2 Principles of Management and Treatment of Genetic Disorders

Brendan Lee and Nicola Brunetti-Pierri

TREATMENT OF GENETIC DISEASES

Genetic conditions are often chronic disorders. Some are amenable to curative therapies, although there has been a rapid increase in the number of treatable disorders. Based on ongoing preclinical and clinical investigations, new therapies for a growing number of diseases are expected to become available in the near future. Surgical management is available for many conditions that are associated with congenital anomalies or predisposition to tumors. All patients and families should be provided information about the disorder, genetic counseling, anticipatory guidance, and appropriate medical surveillance.

Resources for patients include the National Organization of Rare Disorders (www.rarediseases.org), the Genetic Alliance (www.geneticalliance.org), the National Library of Medicine (www.nlm.nih.gov/medlineplus/geneticdisorders.html), and a large number of disease-specific websites. A current listing of federally and privately funded clinical trials, including many for genetic diseases, is available at www.ClinicalTrials.gov.

Specific medical therapies for genetic disorders can be classified into **physiologic** and **replacement** therapies. Another approach to *correct protein misfolding* induced by missense pathogenic variants is through use of small molecules that specifically bind to mutant proteins, stabilizing their conformation, thereby preventing early degradation, and allowing proper cellular trafficking and localization. This strategy has found successful applications for therapy of cystic fibrosis caused by specific *CFTR* pathogenic variants, including the F508del (see Chapter 454).

PHYSIOLOGIC THERAPIES

Physiologic therapies attempt to ameliorate the phenotype of a genetic disorder by modifying the physiology of the affected individual. The underlying defect itself is not altered by treatment. Physiologic therapies are used in the treatment of **inborn errors of metabolism** (see Chapter 104). These include dietary manipulations, such as reducing phenylalanine intake by persons with phenylketonuria, coenzyme supplementation for some patients with methylmalonic acidemia and mitochondrial diseases, stimulation of alternative pathways to excrete ammonia for those with urea cycle disorders, phototherapy to increase excretion of neurotoxic unconjugated bilirubin in Crigler-Najjar syndrome, bisphosphonate treatment for those with osteogenesis imperfecta to reduce bone fractures, and avoiding cigarette smoking by persons with α_1-antitrypsin deficiency or specific foods and drugs by persons with glucose-6-phosphate dehydrogenase deficiency or acute intermittent porphyria. Physiologic treatments can be highly effective, but they usually need to be maintained for a lifetime because they do not affect the underlying genetic disorder. Many of these treatments are most effective early in life

before irreversible damage has occurred. This is the rationale for comprehensive newborn screening for inborn errors of metabolism.

Many physiologic therapies use small-molecule pharmaceuticals (e.g., to remove ammonia in those with urea cycle disorders). **Pharmacologic treatments** directly target a defective cellular pathway that is altered by an abnormal or a missing gene product. One approach is the inhibition of an enzyme reaction that is upstream of the deficient enzyme to prevent accumulation of the toxic metabolites, such as the nitisinone (NTBC) for therapy of tyrosinemia type I. A similar approach focuses on partially reducing the synthesis of the substrate of the abnormal enzyme or its precursors in lysosomal storage disorders (see Chapter 106.4). Other examples include targeting the FGFR3 signaling pathway by the C-type natriuretic peptide in achondroplasia, FGF23 by the monoclonal antibody burosumab in X-linked hypophosphatemia, or the angiopoietin-like protein 3 (ANGPTL3) by the monoclonal antibody evinacumab in homozygous familial hypercholesterolemia.

REPLACEMENT THERAPIES

Replacement therapies include replacement of a missing metabolite, an enzyme, an organ, or even a specific gene.

Enzyme Replacement

Enzyme replacement therapy is a component of the treatment of cystic fibrosis to manage intestinal malabsorption. Pancreatic enzymes are easily administered orally, because they must be delivered to the gastrointestinal tract. Recombinant alkaline phosphatase coupled to a bone-targeting motif is available for intravenous therapy of hypophosphatasia, a skeletal disorder caused by alkaline-phosphatase deficiency.

Enzyme replacement strategies are effective for several lysosomal storage disorders. Enzymes are targeted for the lysosome by modification with mannose-6-phosphate, which binds to a specific receptor. This receptor is also present on the cell surface, so lysosomal enzymes with exposed mannose-6-phosphate residues can be infused into the blood and are taken into cells and delivered to lysosomes. Enzyme replacement therapies are available for Gaucher disease and Fabry disease, most of the mucopolysaccharidoses (MPS I, II, IVA, VI, VII), acid lipase deficiency, α-mannosidosis, neuronal ceroid lipofuscinosis late infantile (CLN2), and Pompe disease, and are being tested for MPS IIIA and IIIB, metachromatic leukodystrophy, and Niemann-Pick disease type B. Other examples include enzyme replacement therapy with pegylated recombinant phenylalanine ammonia lyase for phenylketonuria that is effective at reducing blood phenylalanine concentrations in most patients, such that most of them can come off a phenylalanine-restricted diet.

One complication of enzyme replacement therapy is antibody response to the infused recombinant enzyme. The magnitude of this response is not always predictable and varies depending on the enzyme preparation and the disease. In most cases, the patient's antibody response does not affect the treatment's efficacy (e.g., Gaucher disease), but in other situations it may be a significant hurdle (e.g., Pompe disease and phenylketonuria).

Transplantation

Cell transplantation and organ transplantation are potentially effective approaches to replacement of a defective gene. Aside from transplantation to replace damaged tissues, transplantation of stem cells, liver, or bone marrow is also used for several diseases, mainly inborn errors of metabolism, and hematologic or immunologic disorders. A successful transplant can be essentially curative, although there may be significant risks and side effects (see Chapters 177-181). Cell and tissue transplantation is effective in many clinical scenarios, but there is always short-term morbidity, often associated with either surgical (liver) or preparative (bone marrow) regimens, and long-term morbidity related to chronic immunosuppression and graft failure. Bone marrow transplantation is the best example of stem cell therapy, but much effort also is focused on identifying, characterizing, expanding, and using other tissue stem cells for regenerative therapies. In contrast to transplantation from a healthy donor, the infused cells are the patient's own cells in ex vivo gene therapy of hematopoietic stem cells. Therefore, although it requires preparative myeloablation akin to regular bone marrow transplantation from healthy donors, engraftment of genetically modified hematopoietic stem cells is devoid of risks of rejection or graft-versus-host disease. Increasingly, this approach is combined with gene therapy after genetic correction of autologous stem cells.

Gene Therapy

Another approach focuses on replacing or correcting a defective gene **(gene therapy)**. In theory, if one can target the specific tissue that has a deficiency in the gene or gene product, this can offer a less invasive means of achieving a cure for a genetic disorder compared to transplantations. Ultimately, gene therapy depends on the unique interaction of the disease pathophysiology, which is specific to the patient, and the gene delivery vehicle.

Gene-transfer vehicles include viral and nonviral vectors administered through ex vivo or in vivo approaches. In ex vivo approaches the patient's cells are removed and after gene correction or replacement are infused into the patient. An example of this is the US Food and Drug Administration (FDA)-approved chimeric antigen receptor (CAR) T-cell therapy for lymphomas and leukemias. In the in vivo approaches the gene therapy vector is directly injected into the body by either systemic (e.g., intravenous) or localized (e.g., intracerebral, intraocular) injections. Most human clinical trials have used viral vectors because of their efficiency of gene delivery to tissues. In some diseases, such as X-linked and adenosine deaminase–deficient severe combined immunodeficiency, chronic granulomatous disease, and Wiskott-Aldrich syndrome, clinical gene therapy is a viable and effective option. Ex vivo gene transfer of hematopoietic stem cells can be considered at least as effective to allogenic hematopoietic stem cell transplantation in presymptomatic patients with X-linked adrenoleukodystrophy, metachromatic leukodystrophy and Hurler syndrome.

In vivo gene therapy is also promising for Leber congenital amaurosis by intraocular delivery, and hemophilias and several inborn errors of liver metabolism by systemic intravenous injection. In vivo gene therapy is FDA approved for treatment of a specific RPE65-deficient form of retinitis pigmentosa using adeno-associated virus (AAV)-mediated expression of the normal RPE65 gene via subretinal injections. In vivo AAV-mediated gene therapy is also an approved treatment that has significantly changed the early course of the disease and improved motor function in children with spinal muscular atrophy (SMA) (see Chapter 652.2). Although patients with SMA typically present with muscle atrophy, respiratory failure, and die before 2 years of age, treated patients have remained healthy and attained motor milestones that are typically not achieved in any of the untreated patients. Similar efficacy has also been achieved by intrathecal delivery of antisense oligonucleotides (ASOs) correcting *SMN2* splicing. Brain-directed gene therapy is available for aromatic L-amino acid decarboxylase (AADC) deficiency by intracerebral injections of an AAV-based vector. Systemic intravenous AAV-based gene therapy vectors have been approved for both hemophilia A and B.

Gene editing with *direct correction* of a disease-causing pathogenic variant is another possible approach to genetic therapy. Various nucleases with specific DNA-recognition sequences are available for genome editing; they include zinc finger nucleases (ZFNs), transcription activator–like effector nucleases (TALENs), and clustered regularly interspaced short palindromic repeat (CRISPR)/CRISPR-associated nine (Cas9). They all permit permanent gene modification of genes in cells. This is achieved by DNA site-specific double-strand breaks (DSBs) induced by the endonuclease and a template encompassing the wild-type sequence to be used as a substrate for repair by **homology-directed repair (HDR)**. Following site-specific DSB, DNA repair is mediated by either nonhomologous end joining (NHEJ) or HDR that repairs DNA in the presence of a donor sequence (Fig. 98.7A and B). NHEJ repairs the DSB by joining the two ends of the DSB, often introducing small insertions or deletions (indels) at the DSB site that generally inactivate gene function (see Fig. 98.7A). Compared with NHEJ, HDR is less efficient and requires a donor DNA template (see Fig. 98.7C). The wild-type copy of the mutated gene can be integrated into the endogenous locus or into "safe harbors" that allow high expression levels of the therapeutic gene (see Fig. 98.7A). Based on

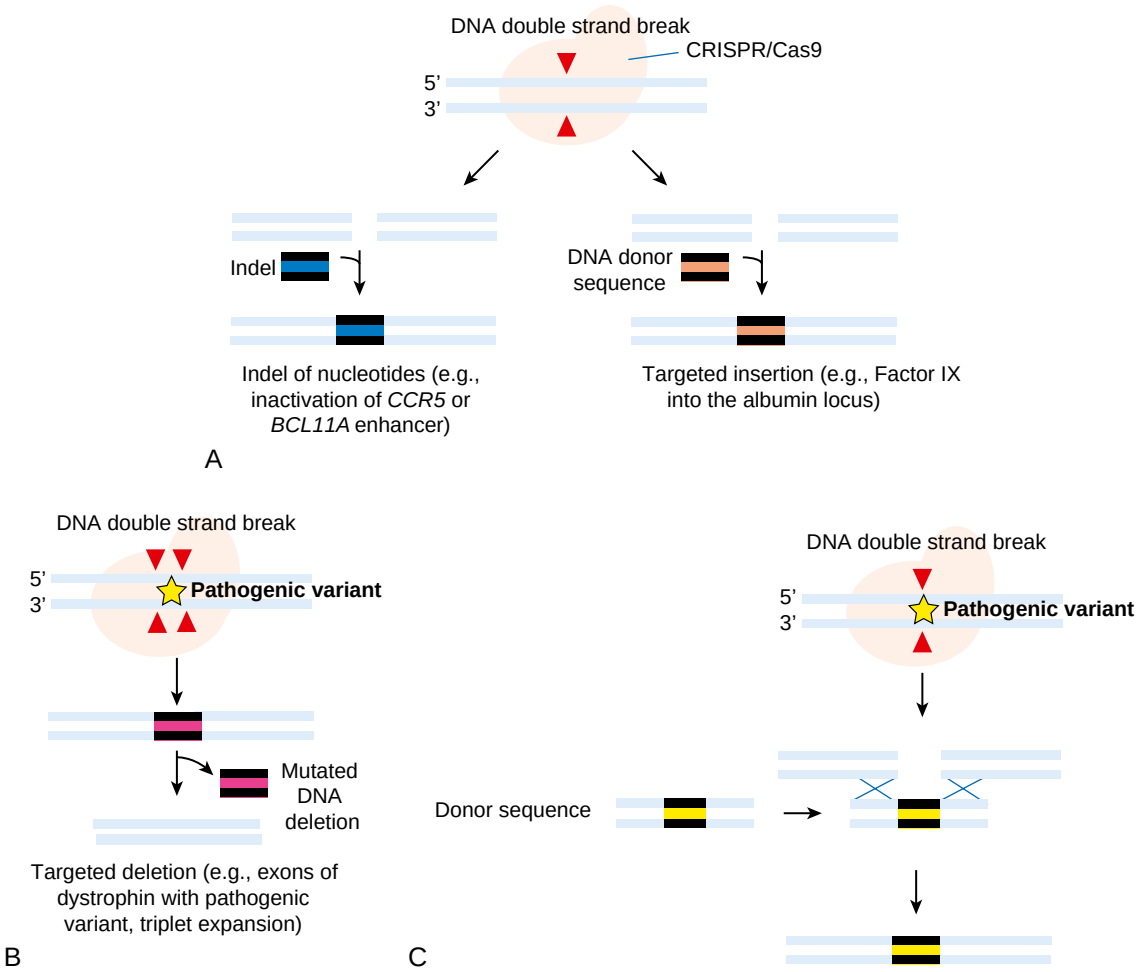

Fig. 98.7 A, Double-strand breaks can be repaired by nonhomologous end-joining (NHEJ) repair mechanisms, giving rise to small insertions and deletions (Indel) that can disrupt gene expression *(blue)*. B, Two double-strand breaks can also be corrected by NHEJ and can eliminate the DNA carrying the pathogenic variant *(pink)* located between the two breaks. C, Double-strand breaks can be repaired by homology-directed repair mechanisms in the presence of a donor template allowing the incorporation of a donor sequence *(yellow)* that correct the mutated gene. CRISPR/Cas9, Clustered regularly interspaced short palindromic repeat/CRISPR-associated nine (Cas9).

these features, genome editing has the potential to overcome several limitations of gene replacement therapy. First, genotoxicity due to ectopic activation of nearby protooncogenes or knockout of tumor suppressor genes does not occur with on-target editing. Second, genome editing allows physiologic regulation of the expression of the corrected gene in contrast to gene replacement therapy. Third, gene editing is maintained in proliferating cells, and it overcomes the dilution effect due to cell division that is observed with gene replacement therapy by nonintegrating vectors such as AAV vectors.

Genome editing tools have corrected the gene defect in several preclinical murine models and are in clinical trials. ZFNs have been used ex vivo to disrupt CCR5 expression in human T cells to induce resistance to HIV infection. ZFNs and CRISPR/Cas9 are being used to boost fetal hemoglobin in β-thalassemia and sickle cell disease by disrupting the enhancer of the *BCL11A* gene, which suppresses fetal hemoglobin production. Moreover, ZFN-mediated targeted introduction of therapeutic genes downstream of the highly active albumin promoter in hepatocytes is currently under clinical investigation for several diseases.

RNA-Targeted Therapy

Antisense oligonucleotides (ASOs) are short synthetic nucleic acids that hybridize with cellular RNA using classic base pairing to modulate gene expression. To ensure specificity, their sequences are complementary to their target sequences (Fig. 98.8). Through binding to pre-mRNA or mRNA, ASOs can posttranscriptionally regulate protein synthesis by mechanisms including modification of pre-mRNA processing and splicing, competitive inhibition, steric blockade of translational machinery, and degradation of the target RNA. Clinical ASOs have been developed for treatment of Duchenne muscular dystrophy and SMA, respectively (Table 98.5). In SMA, *SMN1* and *SMN2* genes are identical (99% homology), except for an 11-nucleotide sequence in exon seven that alters splicing (see Chapter 652.2). Splicing of the *SMN2* pre-mRNA leads to the exclusion of exon seven, generating a truncated, unstable protein that is rapidly degraded. Therefore *SMN2* cannot compensate for *SMN1* loss in SMA. The ASO designed to correct *SMN2* splicing by promoting the inclusion of exon seven allows SMN2 to compensate for the loss of expression caused by the *SMN1* pathogenic variant. ASOs are also effective for treatment of homozygous familial hypercholesterolemia and have been also designed to inhibit HTT mRNA to reduce concentrations of mutant huntingtin in Huntington disease.

Conjugation of siRNA with GalNAc to target the asialoglycoprotein receptor is an efficient strategy to facilitate cell uptake and to increase siRNA liver accumulation (see Fig. 98.8). A GalNAc-siRNA targeting the mRNA for aminolevulinate synthase 1 (ALAS1), the first enzyme in the heme synthesis pathway, has been developed for treatment of acute hepatic porphyria, and a similar strategy targeting glycolate oxidase is effective at reducing oxalate levels for treatment of primary hyperoxaluria type 1.

Lipid nanoparticles (LNPs) are spherical structures with a composition very similar to cell membranes and are suitable carriers for

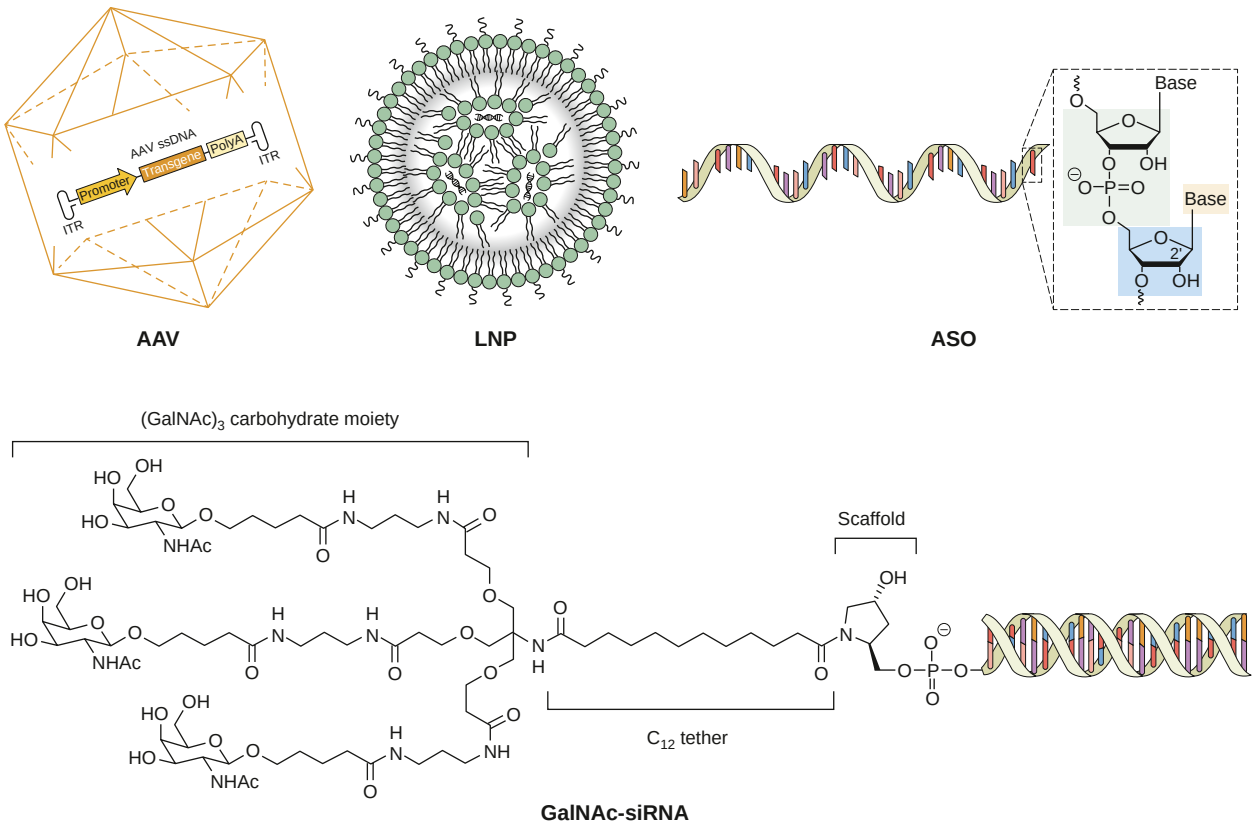

Fig. 98.8 Approved delivery technologies for in vivo gene therapy. Four platform technologies have been clinically approved for gene-based therapies of genetic diseases: adeno-associated virus (AAV) vector containing a 4.7-kb single-stranded DNA with inverted terminal repeats (ITRs), antisense oligonucleotides (ASO) therapeutics, lipid nanoparticle (LNP) containing siRNA or mRNA including key lipid components, and N-acetyl-galactosamine-short-interfering RNA (GALNAc-siRNA) therapeutics made of a trivalent ligand with terminal GalNAc moieties covalently linked to siRNA at the 3′-end of the sense strand.

Table 98.5 Approved In Vivo Gene-Based (DNA and RNA) Therapies for Genetic Disorders

PRODUCT	GENE TARGET	DISEASE	ROUTE OF ADMINISTRATION
ASO			
Eteplirsen	Dystrophin (exon 51)	Duchenne muscular dystrophy	Intrathecal
Golodirsen	Dystrophin (exon 53)	Duchenne muscular dystrophy	Subcutaneous
Casimersen	Dystrophin (exon 45)	Duchenne muscular dystrophy	Subcutaneous
Inotersen	Transthyretin (TTR)	TTR-mediated amyloidosis	Subcutaneous
Nusinersen	Survival of motor neuron two (SMN2)	Spinal muscular atrophy	Intrathecal
Mipomersen	Apolipoprotein B-100	Hypercholesterolemia	Subcutaneous
Volanesorsen	Apolipoprotein CIII	Familial chylomicronemia	Subcutaneous
GALNAc-sIRNA CONJUGATES			
Givosiran	ALAS1	Acute hepatic porphyrias	Subcutaneous
Inclisiran	PCSK9	Hypercholesterolemia	Subcutaneous
Lumasiran	Glycolate oxidase	Primary hyperoxaluria type 1	Subcutaneous
LNP-RNA			
Patisiran	TTR siRNA	TTR-mediated amyloidosis	Intravenous
AAV VECTORS			
Voretigene neparvovec-rzyl	RPE65 (AAV2)	Leber congenital amaurosis	Subretinal
Onasemnogene abeparvovec	SMN1 (AAV9)	Spinal muscular atrophy	Intravenous
Eladocagene exuparvovec	DDC (AAV2)	AADC deficiency	Bilateral intraputaminal infusions
Valoctocogene roxaparvovec	Factor VIII (AAV5)	Hemophilia A	Intravenous
Etranacogene dezaparvovec	Factor IX (AAV5)	Hemophilia B	Intravenous

AAV, Adeno-associated virus; AADC, aromatic L-amino acid decarboxylase; ASO, antisense oligonucleotides; LNP, lipid nanoparticle.

nucleic acid delivery, such as siRNA and mRNAs (see Fig. 98.8). A liver targeting LNP carrying an siRNA targeting transthyretin has been effective for treatment of hereditary transthyretin amyloidosis that has been recently approved. In various preclinical models, LNPs have been shown to deliver mRNA molecules to hepatocytes with high efficiency. LNPs are being used for the delivery of gene editing molecules such as ZFNs and Cas9 mRNA together with a single guide (sg)RNA. In addition, LNPs have been used for delivery of genome editing tools such as ZFNs and CRISPR/Cas9 together with a viral vector carrying a promoterless DNA sequence capable of homologous recombination that can result in high levels of the integrated sequence and short-term expression of the endonucleases.

Correction of Genetic Diseases in the Human Germline

Prevention of genetic diseases has been accomplished by **preimplantation genetic diagnosis (PGD)**. This procedure requires in vitro fertilization and single–embryo cell genetic testing of the known families' pathogenic variant and is performed with polymerase chain reaction (PCR) amplification of the affected gene. To avoid disease recurrence, only the unaffected embryos are implanted. With the advent of efficient genome editing by CRISPR/Cas9, editing human embryos is technically possible. The announcement of the birth of "CRISPR babies" has led to calls for a moratorium on human germline genome editing, and currently, germline and/or embryonic gene editing studies in humans have not been approved. Given the limited understanding of the consequences of CRISPR/Cas9-mediated DSBs on the germline human genome, it is unlikely that these approaches will become available any time soon.

In contrast, **mitochondrial replacement therapies** to avoid mitochondrial DNA pathogenic variants are available. In one technique, the pathogenic variant carrier mother's nuclear DNA is removed from the unfertilized oocyte and transferred to an unaffected mitochondrial donor oocyte (minus that cell's nuclear DNA). In another approach, the pronucleus from the pathogenic variant-carrier mother's fertilized oocyte is transferred to the unaffected mitochondrial donor's fertilized oocyte (minus the pronucleus).

Chapter 99

Chromosome Disorders

Carlos A. Bacino and Brendan Lee

99.1 Methods of Chromosome Analysis

Carlos A. Bacino and Brendan Lee

Clinical cytogenetics is the study of chromosomes, including their structure, function, inheritance, and abnormalities. Chromosome abnormalities are very common and occur in approximately 1–2% of live births, 5% of stillbirths, and 50% of early fetal losses in the first trimester of pregnancy (Table 99.1). Chromosome abnormalities are more common among individuals with intellectual disability and play a significant role in the development of some neoplasias.

Chromosome analyses are indicated in persons presenting with multiple congenital anomalies, dysmorphic features, and/or intellectual disability. The specific indications for studies include prenatal testing in conceptuses of women with advanced maternal age (>35 years), multiple abnormalities on fetal ultrasound, multiple congenital anomalies, unexplained growth restriction in the fetus, postnatal problems in growth and development, ambiguous genitalia, unexplained intellectual disability with or without associated anatomic abnormalities, primary amenorrhea or infertility, recurrent miscarriages (≥3) or prior history of stillbirths and neonatal deaths, a first-degree relative with a known or suspected structural chromosome abnormality, clinical findings consistent with a known anomaly, some malignancies, and chromosome breakage syndromes (e.g., Bloom syndrome, Fanconi anemia).

Cytogenetic studies are usually performed on peripheral blood lymphocytes, although cultured fibroblasts obtained from a skin biopsy may also be used. Prenatal (fetal) chromosome studies are performed with cells obtained from the amniotic fluid (amniocytes), chorionic villus tissue, and fetal blood or, in the case of preimplantation diagnosis, by analysis of a *blastomere* (cleavage stage) biopsy, polar body biopsy, or blastocyst biopsy. Cytogenetic studies of bone marrow have an important role in tumor surveillance, particularly among patients with leukemia. These are useful to determine induction of remission and success of therapy, or in some cases the occurrence of relapses.

Chromosome anomalies include abnormalities of number and structure and are the result of errors during cell division. There are two types of cell division: mitosis, which occurs in most somatic cells, and meiosis, which is limited to the germ cells. In **mitosis,** two genetically identical daughter cells are produced from a single parent cell. DNA replication (duplication of DNA material) has already occurred during **interphase** in the S phase of the cell cycle (DNA synthesis). Therefore, at the beginning of mitosis, the chromosomes consist of two double DNA strands joined together at the centromere, known as *sister chromatids*. Mitosis can be divided into four stages: prophase, metaphase, anaphase, and telophase. **Prophase** is characterized by condensation of the DNA. Also during prophase, the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In **metaphase** the chromosomes are maximally compacted and are clearly visible as distinct structures. The chromosomes align at the center of the cell, and spindle fibers connect to the centromere of each chromosome and extend to centrioles at the two poles of the mitotic figure. In **anaphase** the chromosomes divide along their longitudinal axes to form two separate daughter chromatids, which then migrate to opposite poles of the cell. **Telophase** is characterized by formation of two new nuclear membranes and nucleoli, duplication of the centrioles, and cytoplasmic cleavage to form the two daughter cells.

Meiosis begins in the female oocyte during fetal life and is completed years to decades later. In males it begins in a spermatogonial cell sometime between adolescence and adult life and is completed in a few days. Meiosis is preceded by DNA replication so that at the outset, each of the 46 chromosomes consists of two chromatids. In meiosis, a **diploid cell** (2n = 46 chromosomes) divides to form four **haploid cells** (n = 23 chromosomes). Meiosis consists of two major rounds of cell division. In **meiosis I**, each of the homologous chromosomes pair precisely so that **genetic recombination**, involving exchange between two DNA strands **(crossing over)**, can occur. This results in reshuffling of the genetic information for the recombined chromosomes and allows further genetic diversity. Each daughter cell then receives one of each of the 23 homologous chromosomes. In oogenesis, one of the daughter cells receives most of the cytoplasm and becomes the egg, whereas the other smaller cell becomes the first polar body. **Meiosis II** is similar to a mitotic division but without a preceding round of DNA replication. Each of the 23 chromosomes divides longitudinally, and the homologous chromatids migrate to opposite poles of the cell. This produces four spermatogonia in males, or an egg cell and a second polar body in females, each with a haploid (n = 23) set of chromosomes. Consequently, meiosis fulfills two crucial roles: It enables genetic recombination, and it reduces the chromosome number from diploid (46) to haploid (23) so that on fertilization a diploid number is restored.

Two common errors of cell division may occur during meiosis or mitosis, and either can result in an abnormal number of chromosomes. The first error is **nondisjunction**, in which two chromosomes fail to separate during meiosis and thus migrate together into one of the new cells, producing one cell with two copies of the chromosome and another with no copy. The second error is **anaphase lag**, in which a chromatid or chromosome is lost during mitosis because it fails to move quickly enough during anaphase to become incorporated into one of the new daughter cells (Fig. 99.1).

For chromosome analysis, cells are cultured (for varying periods depending on cell type), with or without stimulation, and then artificially arrested in mitosis during metaphase (or prometaphase), later subjected to a hypotonic solution to allow disruption of the nuclear cell membrane and proper dispersion of the chromosomes for analysis, fixed, banded, and finally stained. The most commonly used banding and staining method is the **GTG banding** (G bands by trypsin using Giemsa), also known as **G banding**, which produces a unique combination of dark (G-positive) and light (G-negative) bands that permits recognition of all individual 23 chromosome pairs for analysis.

Metaphase chromosome spreads are first evaluated microscopically, and then their images are photographed or captured by a video camera and stored on a computer for later analysis. Humans have 46 chromosomes or 23 pairs, which are classified as *autosomes* for chromosomes

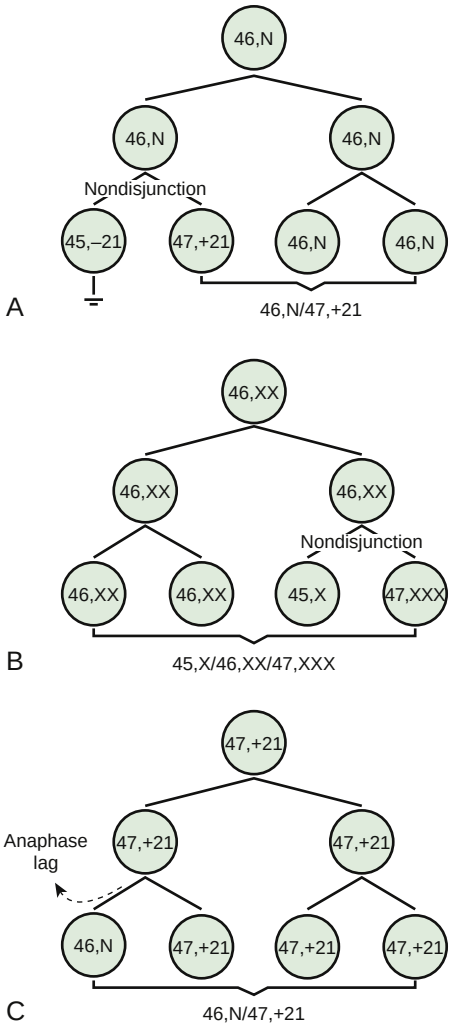

Fig. 99.1 Generation of mosaicism. **A,** Postzygotic nondisjunction in an initially normal conceptus. In this example, one cell line (monosomic 21) is subsequently lost, with the final karyotype 46,N/47,+21. **B,** Postzygotic nondisjunction in an initially 46,XX conceptus, resulting in 45,X/46,XX/47,XXX mosaicism. **C,** Postzygotic anaphase lag in an initially 47,+21 conceptus. *(From Gardner RJM, Sutherland GR. Chromosome Abnormalities and Genetic Counseling, 3rd ed. New York: Oxford University Press; 2003: Fig. 43.1, p. 33.)*

1-22, and the *sex chromosomes*, often referred as *sex complement*: XX for females and XY for males. The homologous chromosomes from a metaphase spread can then be paired and arranged systematically to assemble a karyotype according to well-defined standard conventions such as those established by International System for Human Cytogenetic Nomenclature (ISCN), with chromosome 1 being the largest and 22 the smallest. According to nomenclature, the description of the karyotype includes the total number of chromosomes followed by the sex chromosome constitution. A normal karyotype is 46,XX for females and 46,XY for males (Fig. 99.2). Abnormalities are noted after the sex chromosome complement.

Although the internationally accepted system for human chromosome classification relies largely on the length and banding pattern of each chromosome, the position of the centromere relative to the ends of the chromosome also is a useful distinguishing feature (Fig. 99.3). The centromere divides the chromosome in two, with the short arm designated the **p arm** and the long arm designated the **q arm**. A plus or minus sign before the number of a chromosome indicates that there is an extra or missing chromosome, respectively. Table 99.2 lists some of the abbreviations used for the descriptions of chromosomes and their abnormalities. A metaphase chromosome spread usually

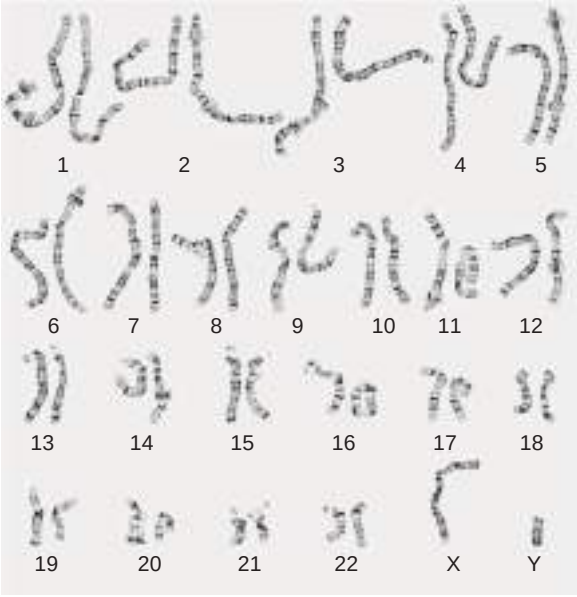

Fig. 99.2 Karyotype of a normal male at the 550-600 band level. The longer the chromosomes are captured at metaphase or sometimes prometaphase, the more bands can be visualized.

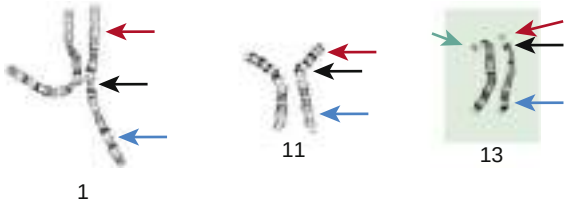

Fig. 99.3 Example of different chromosome types according to the position of the centromere. On the *left* is a chromosome one pair with the centromere equidistant from the short and long arm (also known as *metacentric*). In the *center* is a chromosome 11 pair that is submetacentric. On the *right* is a chromosome 13 pair that is an example of an acrocentric chromosome. Acrocentric chromosomes contain a very small short arm, stalks, and satellite DNA. The *black arrow* indicates the position of the centromere. The *blue arrow* shows the long arm of a chromosome. The *red arrow* shows the short arm of a chromosome. The *green arrow* highlights the satellite region, which is made of DNA repeats. The *light area* between the short arm and the satellite is known as the *stalk*.

shows 450-550 bands. Prophase and prometaphase chromosomes are longer, are less condensed, and often show 550-850 bands. High-resolution analysis may detect small chromosome abnormalities, although this has been mostly replaced by chromosome **microarray analysis (CMA)**, also called array comparative genomic hybridization (aCGH).

Molecular techniques (e.g., fluorescence in situ hybridization [FISH], CMA) identify subtle abnormalities that are often below the resolution of standard cytogenetic studies. **FISH** is used to identify the presence, absence, or rearrangement of *specific* DNA segments and is performed with gene- or region-specific DNA probes. Several FISH probes are used in the clinical setting: unique sequence or single-copy probes, repetitive-sequence probes (alpha satellites in the pericentromeric regions), and multiple-copy probes (chromosome specific or painting) (Fig. 99.4A,B). FISH involves using a unique, known DNA sequence or probe labeled with a fluorescent dye that is complementary to the studied region of disease interest. The labeled probe is exposed to the DNA on a microscope slide, typically metaphase or interphase chromosomal DNA. When the probe pairs with its complementary DNA sequence, it can then be visualized by fluorescence microscopy (Fig. 99.5). In metaphase chromosome spreads, the exact chromosomal location of each probe copy can be documented, and often the *number of copies* (deletions, duplications) of the DNA sequence as well. When the interrogated segments (as in genomic duplications) are close together, interphase cells can accurately determine the presence of two or more copies or signals, because in chromosome-condensed metaphase cells some duplications might falsely appear as a single signal.

Chromosome rearrangements <5 million bp (5 Mbp) cannot be detected by conventional cytogenetic techniques. FISH has facilitated the clinical characterization of several **microdeletion syndromes** (50-200 kb of DNA). Some FISH probes hybridize to repetitive sequences located in the pericentromeric regions. Pericentromeric probes are still used for rapid identification of certain trisomies in interphase cells of blood smears, or even in the rapid analysis of prenatal samples from cells obtained through amniocentesis. Such probes are available for chromosomes 13, 18, and 21 and for the sex pair X and Y (see Fig. 99.4C and D). FISH is *no longer* the first line of testing, and its role has also mostly changed to the confirmation of chromosome microarray findings. FISH is reserved for (1) confirmation studies of abnormalities detected by CMA, (2) rapid prenatal screening on interphase amniotic fluid cells, and (3) interphase blood smear for sex assignment of newborns who present with ambiguous genitalia.

Array comparative genomic hybridization (aCGH) is a type of **chromosomal microarray (CMA)** that uses a molecular-based technique that differentially labels the patient's DNA with a fluorescent dye (green fluorophore) and a normal reference DNA with a red fluorophore (Figs. 99.6 and 99.7). Oligonucleotides (short DNA segments) encompassing the entire genome are spotted onto a slide or **microarray** grid. Equal amounts of the two-labeled DNA samples are mixed, and the green:red fluorescence ratio is measured along each tested area. Regions of amplification of the patient's DNA display an excess of green fluorescence, and regions of loss show excess red fluorescence. If the patient's and the control DNA are equally represented, the green:red ratio is 1:1, and the tested regions are represented as yellow (see Chapter 96 and Fig. 96.5).

Another frequently used chromosome microarray type in the clinical setting is the **single nucleotide polymorphism (SNP) array**. SNPs are polymorphic variations between two nucleotides and, when analyzed in massive parallel fashion, they can provide valuable clinical information. Several million SNPs normally occur in the human genome. SNP arrays can help with the detection of **uniparental disomies** (i.e., genetic information derived from only one parent), as well as consanguinity in the family. Many arrays used in clinical practice combine the use of oligonucleotides for the detection of copy number variations (CNVs) in conjunction with SNPs.

The detection of abnormalities by CMA is possible at the single-exon resolution level, depending on the configuration of the array used. The many advantages of CMA include its ability to test for duplications or deletions in critical disease-causing regions of the genome at once, including single-gene and contiguous gene deletion syndromes. In addition, CMA does not require cell cultures to generate sufficient DNA, which may be important in the context of prenatal testing because of timing. However, CMA cannot detect balanced translocations or inversions and may not detect low levels of chromosomal mosaicism. **Targeted CMAs** can detect clinically known cryptic chromosomal aberrations associated with known disease phenotypes. CNV detection can also be diagnosed by next-generation sequencing in the context of whole *genome* sequencing.

There are large numbers of deletion and duplication CNVs in the human genome. Thus many detected genetic abnormalities, unless associated with well-known clinical phenotypes, may require *parental investigations* because a detected CNV that is inherited could be benign or an incidental polymorphic variant often described as variants of uncertain significance (VUS). A **de novo** abnormality (i.e., one found only in the child and not the parents) is often significant if it is associated with an abnormal phenotype found only in the child and if it involves genes with important functions.

Table 99.2 Some Abbreviations Used for Description of Chromosomes and Their Abnormalities

ABBREVIATION	MEANING	EXAMPLE	CONDITION
XX	Female	46,XX	Normal female karyotype
XY	Male	46,XY	Normal male karyotype
[##]	Number [#] of cells	46,XY[12]/47,XXY[10]	Number of cells in each clone, typically inside brackets Mosaicism in Klinefelter syndrome with 12 normal cells and 10 cells with an extra X chromosome
cen	Centromere		
del	Deletion	46,XY,del(5p)	Male with deletion of chromosome 5 short arm
der	Derivative	46,XX,der(2),t(2p12;7q13)	Female with a structurally rearranged chromosome 2 that resulted from a translocation between chromosomes 2 (short arm) and 7 (long arm)
dup	Duplication	46,XY,dup(15)(q11-q13)	Male with interstitial duplication in the long arm of chromosome 15 in the Prader-Willi/Angelman syndrome region
ins	Insertion	46,XY,ins(3)(p13q21q26)	Male with an insertion within chromosome 3 A piece between q21 and q26 has reinserted on p13
inv	Inversion	46,XY,inv(2)(p21q31)	Male with pericentric inversion of chromosome 2 with breakpoints at bands p21 and q31
ish	Metaphase FISH	46,XX.ish del(7)(q11.23q11.23)	Female with deletion in the Williams syndrome region detected by in situ hybridization
nuc ish	Interphase FISH	nuc ish(DXZ1 × 3)	Interphase in situ hybridization showing three signals for the X chromosome centromeric region
mar	Marker	47,XY,+mar	Male with extra, unidentified chromosome material
mos	Mosaic	mos 45,X[14]/46,XX[16]	Turner syndrome mosaicism (analysis of 30 cells showed that 14 cells were 45,X and 16 cells were 46,XX)
p	Short arm	46,XY,del(5)(p12)	Male with a deletion on the short arm of chromosome 5, band p12 (short nomenclature)
q	Long arm	46,XY,del(5)(q14)	Male with a deletion on the long arm of chromosome 5, band 14
r	Ring chromosome	46,X,r(X)(p21q27)	Female with one normal X chromosome and a ring X chromosome
t	Translocation	t(2;8)(q33;q24.1)	Interchange of material between chromosomes 2 and 8 with breakpoints at bands 2q33 and 8q24.1
ter	Terminal	46,XY,del(5)(p12-pter)	Male with a deletion of chromosome 5 between p12 and the end of the short arm (long nomenclature)
/	Slash	45,X/46,XY	Separate lines or clones Mosaicism for monosomy X and a male cell line
+	Gain of	47,XX,+21	Female with trisomy 21
−	Loss of	45,XY,−21	Male with monosomy 21

FISH, Fluorescence in situ hybridization.

99.2 Abnormalities of Chromosome Number

Carlos A. Bacino and Brendan Lee

ANEUPLOIDY AND POLYPLOIDY

Typical human cells contain 46 chromosomes, which is a multiple of 23 chromosomes. Haploid cells contain 23 chromosomes (n=23, typically in the ovum or sperm). If a cell's chromosomes are an exact multiple of 23 (46, 69, 92 in humans), those cells are referred to as **euploid**. **Polyploid** cells are euploid cells with more than the normal **diploid** number of 46 (2n) chromosomes, such as 3n, 4n. Polyploid conceptions are usually not viable, but the presence of mosaicism with a karyotypically normal cell line can allow survival. **Mosaicism** is an abnormality defined as the presence of two or more different cell lines in a single individual. **Polyploidy** is a common abnormality seen in first-trimester pregnancy losses.

Triploid cells are those with three haploid sets of chromosomes (3n) and are only viable in a mosaic form. Nonmosaic triploid infants can be liveborn but typically die shortly after birth. **Triploidy** is often the result of fertilization of an egg by two sperm (dispermy). Failure of one of the meiotic divisions, resulting in a diploid egg or sperm, can also result in triploidy. The phenotype of a triploid conception depends on the origin of the extra chromosome set. If the extra set is of **paternal** origin, it results in a partial *hydatidiform mole* (excessive placental growth) with poor embryonic development, but triploid conceptions that have an extra set of **maternal** chromosomes result in severe embryonic restriction with a small, fibrotic placenta (insufficient placental development) that is typically spontaneously aborted.

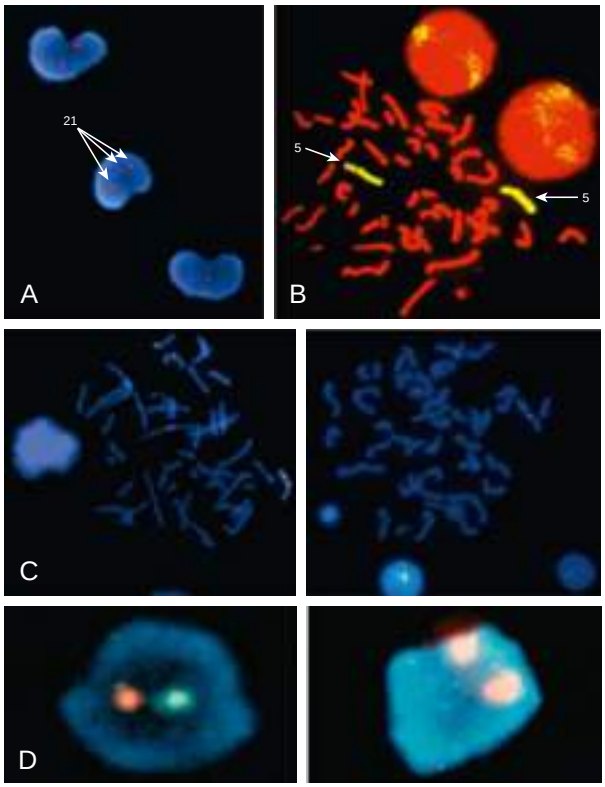

Fig. 99.4 A, Fluorescence in situ hybridization (FISH) analysis of interphase peripheral blood cells from a patient with Down syndrome using a chromosome 21–specific probe. The three *red signals* mark the presence of three chromosomes 21. B, FISH analysis of a metaphase chromosome spread from a clinically normal individual using a whole chromosome paint specific for chromosome 5. Both chromosome 5s are completely labeled *(yellow)* along their entire length. C, FISH on metaphase cells using a unique sequence probe that hybridizes to the elastin gene on chromosome 7q11.23, inside the Williams syndrome critical region. The elastin probe is labeled in *red*, and a control probe on chromosome 7 is labeled in *green*. The *left* image shows normal hybridization to chromosome 7, with two signals for the elastin region and two for the control probe. The *right* image shows a normal chromosome on the right with control and elastin signals and a deleted chromosome 7 on the left, evidenced by a single signal for the control probe. This image corresponds to a patient with a Williams syndrome region deletion. D, FISH in interphase cells using DNA probes that hybridize to repetitive α-satellite sequences in the pericentromeric region for the sex chromosomes. *Left,* interphase cells with two signals, one labeled in *red* for the X chromosome and *green* for the Y chromosome, consistent with a normal male chromosome complement. *Right,* interphase cell showing two *red* signals for the X chromosome, compatible with a normal female chromosome complement.

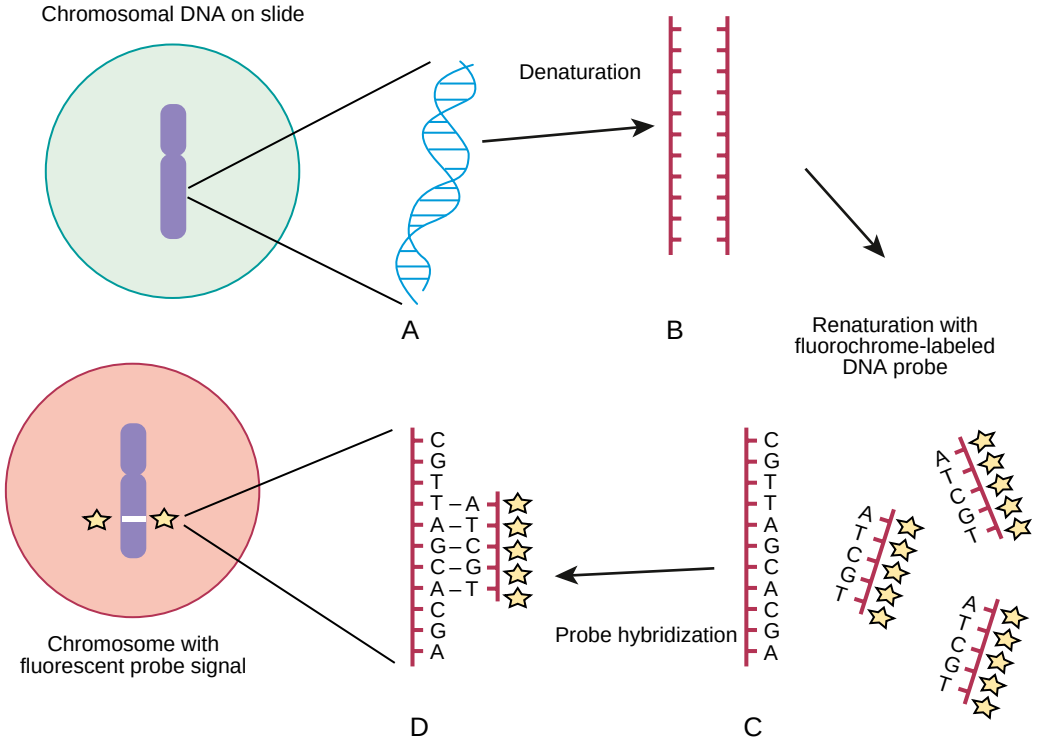

Fig. 99.5 FISH involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations (A) into single-stranded DNA (B). The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base-pair sequence or probe (C). The probe anneals or "hybridizes" to sites of complementary DNA sequence (D) within the chromosomal genome. Probe signal is visualized and imaged on the chromosome by fluorescent microscopy. *(From Lin RL, Cherry AM, Bangs CD, et al. FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In: Hyme HE, Greydanus D, eds, Genetic Disorders in Adolescents: State of the art reviews. Adolescent medicine. Philadelphia: Hanley and Belfus; 2002: pp. 305–313.)*

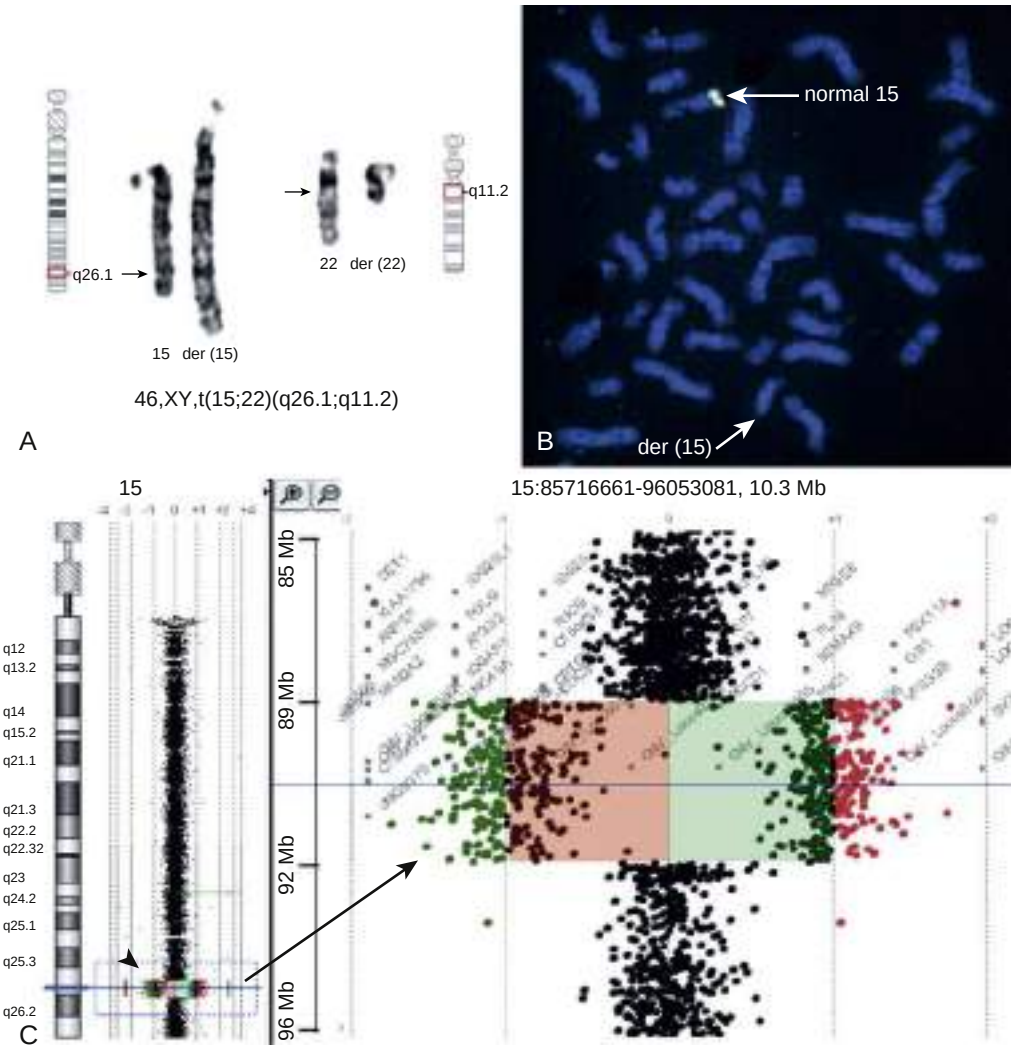

Fig. 99.6 Example of a cryptic microdeletion at a translocation breakpoint of an apparently balanced translocation in a patient with developmental delay (dd) and growth defect. **A,** Partial karyotype shows t(15;22)(q26.1;q11.2). **B,** Fluorescence in situ hybridization (FISH) with clones 2O19 *(top arrow)* and 354M14 *(bottom arrow)* at 15q26.1; *arrows* indicate signals only present on the normal chromosome 15, suggesting a deletion on the der(15). **C,** Two-color array comparative genomic hybridization (aCGH) with dye swap with 244 K oligo probes; *arrowhead* indicates a 3.3-Mbp deletion at chromosome 15q26.1-q26.2; *arrow* points to the close-up view of the deletion. *(From Li MM, Andersson HC. Clinical application of microarray-based molecular cytogenetics: an emerging new era of genomic medicine. J Pediatr. 2009;155:311–317, with permission of the authors and publisher.)*

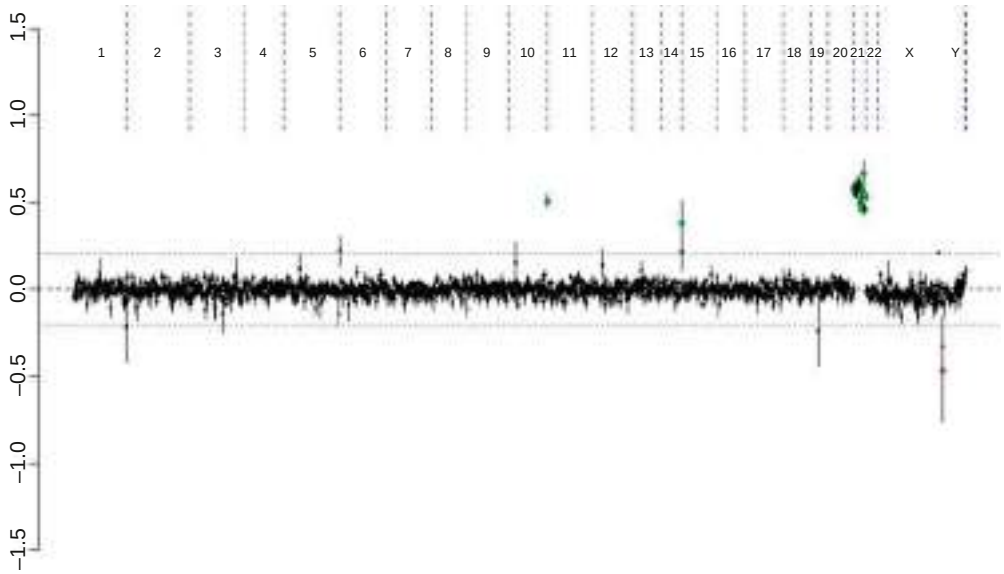

Fig. 99.7 Array comparative genomichybridization (aCGH) in a female patient with Down syndrome. Each *black dot* represents a piece of DNA segment specific for different chromosome location. Most of the dots displayed between the 0.0 and 0.2 axis are considered within normal range. Exceptions are often a result of polymorphic variations. A group of dots colored in *green* clusters on chromosome 21 and above 0.5. These represent a *gain* in copy number of DNA segments for chromosome 21, as seen in Down syndrome and consistent with trisomy 21.

Table 99.3 Chromosomal Trisomies and Their Clinical Findings*

SYNDROME	INCIDENCE	CLINICAL MANIFESTATIONS
Trisomy 13, Patau syndrome	1/10,000 births	Cleft lip often midline; flexed fingers with postaxial polydactyly; ocular hypotelorism, bulbous nose; low-set, malformed ears; microcephaly; cerebral malformation, especially holoprosencephaly; microphthalmia, cardiac malformations; scalp defects; hypoplastic or absent ribs; visceral and genital anomalies Early lethality in most cases, with a median survival of 12 days; ~80% die by 1 year; 10-year survival ~13%; survivors have significant neurodevelopmental delay
Trisomy 18, Edwards syndrome	1/6,000 births	Low birthweight, closed fists with index finger overlapping the third digit and the fifth digit overlapping the fourth, narrow hips with limited abduction, short sternum, rocker-bottom feet, microcephaly, prominent occiput, micrognathia, cardiac and renal malformations, intellectual disability ~88% of children die in the first year; 10-year survival ~10%; survivors have significant neurodevelopmental delay
Trisomy 8, mosaicism	1/20,000 births	Long face; high, prominent forehead; wide, upturned nose; thick, everted lower lip; microretrognathia; low-set ears; high-arched, sometimes cleft, palate; osteoarticular anomalies common (camptodactyly of second through fifth digits, small patella); deep plantar and palmar creases; moderate intellectual disability

*For trisomy 21, see Chapter 57.

Abnormal cells that do not contain a multiple of haploid number of chromosomes are termed **aneuploid** cells. **Aneuploidy** is the most common and clinically significant type of human chromosome abnormality, occurring in at least 3–4% of all clinically recognized pregnancies. **Monosomies** occur when only one, instead of the normal pair (two), of a given chromosome is present in an otherwise diploid cell. In humans, most autosomal monosomies appear to be lethal early in development, and survival is possible in **mosaic forms** or by means of chromosome rescue (restoration of the normal number by duplication of single monosomic chromosome, also known as monosomy rescue). An exception to this rule is monosomy for the X chromosome (45,X), seen in Turner syndrome; nonetheless, the majority of 45,X conceptuses are believed to be lost early in pregnancy for as yet unexplained reasons.

The most common cause of aneuploidy is **nondisjunction**, the failure of chromosomes to disjoin normally during meiosis (see Fig. 99.1). Nondisjunction can occur during meiosis I or II or during mitosis, although maternal meiosis I is the most common nondisjunction in aneuploidies (e.g., Down syndrome, trisomy 18). After meiotic nondisjunction, the resulting gamete either lacks a chromosome or has two copies instead of one normal copy, resulting in a monosomic or trisomic zygote, respectively.

Trisomy is characterized by the presence of three chromosomes, instead of the normal pair (two), of any particular chromosome. Trisomy is the most common form of aneuploidy. Trisomy can occur in all cells, or it may be mosaic. Most individuals with a trisomy exhibit a consistent and specific phenotype depending on the chromosome involved.

FISH is a technique that can be used for rapid diagnosis in the prenatal detection of common fetal aneuploidies, including chromosomes 13, 18, and 21, as well as sex chromosomes (see Fig. 99.4C and D). Direct detection of cell-free fetal DNA (trophoblastic or placental origin) in maternal plasma for fetal trisomy detection is a safe and highly effective screening test for fetal aneuploidy. The most common numerical abnormalities in liveborn children include trisomy 21 (Down syndrome) (see Chapter 57); trisomy 18 (Edwards syndrome); trisomy 13 (Patau syndrome); and sex chromosomal aneuploidies, such as Turner syndrome (usually 45,X), Klinefelter syndrome (47,XXY), 47,XXX, and 47,XYY. By far the most common type of trisomy in liveborn infants is trisomy 21 (47,XX,+21 or 47,XY,+21) (see Table 99.1). Trisomy 18 and trisomy 13 are relatively less common and are associated with a characteristic set of congenital anomalies and severe intellectual disability (Table 99.3). The occurrence of trisomy 21 and other trisomies increases with advanced maternal age (≥35 years). Because of this increased risk, women who are ≥35 years old at delivery should be offered genetic counseling and prenatal diagnosis (including serum screening, ultrasonography, and cell-free DNA detection, amniocentesis, or chorionic villus sampling; see Chapter 117).

99.3 Abnormalities of Chromosome Structure

Carlos A. Bacino and Brendan Lee

TRANSLOCATIONS

Translocations, which involve the transfer of material from one chromosome to another, occur with a frequency of 1 in 500 liveborn human infants. They may be inherited from a carrier parent or appear de novo, with no other affected family member. Translocations are usually reciprocal or Robertsonian, involving two chromosomes (Fig. 99.8).

Reciprocal translocations are the result of breaks in nonhomologous chromosomes, with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but are at an increased risk for miscarriage caused by transmission of unbalanced reciprocal translocations and for bearing chromosomally abnormal offspring. Unbalanced translocations are the result of abnormalities in the segregation or crossover of the translocation carrier chromosomes in the germ cells.

Robertsonian translocations involve two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) that fuse near the centromeric region with a subsequent loss of the short arms. Because the short arms of all five pairs of acrocentric chromosomes have multiple copies of genes encoding for ribosomal RNA, loss of the short arms of acrocentric chromosomes has no deleterious effect. The resulting karyotype has only 45 chromosomes, including the translocated chromosome, which consists of the long arms of the two fused chromosomes. Carriers of Robertsonian translocations are usually phenotypically normal. However, they are at increased risk for miscarriage and unbalanced translocations in phenotypically abnormal offspring.

In some rare instances, translocations can involve three or more chromosomes, as seen in complex rearrangements. Another less

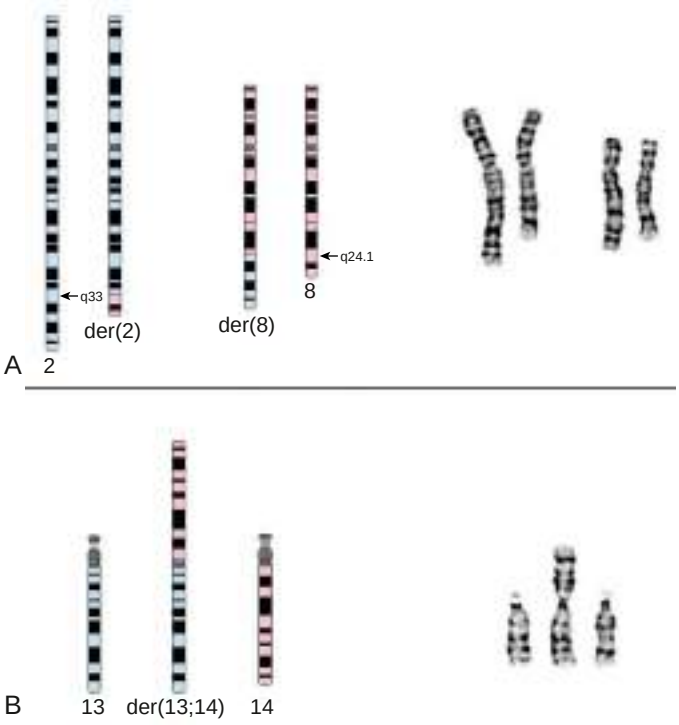

Fig. 99.8 A, Schematic diagram *(left)* and partial G-banded karyotype *(right)* of a reciprocal translocation between chromosome two *(blue)* and chromosome eight *(pink)*. The breakpoints are on the long *(q)* arm of both chromosomes at bands 2q33 and 8q24.1, with the reciprocal exchange of material between the derivative *(der)* chromosomes 2 and 8. This translocation is balanced, with no net gain or loss of material. The nomenclature for this exchange is t(2;8)(q33:q24.1). B, Schematic diagram *(left)* and partial G-banded karyotype *(right)* of a Robertsonian translocation between chromosomes 13 *(blue)* and 14 *(pink)*. The breakpoints are at the centromere (band q10) of both chromosomes, with fusion of the long arms into a single derivative chromosome and loss of the short *(p)* arm material. The nomenclature for this exchange is der(13;14)(q10;q10).

common type is the insertional translocation. **Insertional translocations** result from a piece of chromosome material that breaks away and later is reinserted within the same chromosome at a different site or inserted into another chromosome.

INVERSIONS

An inversion requires that a single chromosome breaks at two points; the broken piece is then inverted and joined into the same chromosome. Inversions occur in 1 in 100 live births. There are two types of inversions, pericentric and paracentric. In **pericentric inversions** the breaks are in the two opposite arms of the chromosome and include the centromere. They are usually discovered because they change the position of the centromere. The breaks in **paracentric inversions** occur in only one arm. Carriers of inversions are usually phenotypically normal, but they are at increased risk for miscarriages, typically in paracentric inversions, and chromosomally abnormal offspring in pericentric inversions.

DELETIONS AND DUPLICATIONS

Deletions involve loss of chromosome material and, depending on their location, can be classified as **terminal** (at the end of chromosomes) or **interstitial** (within the arm of a chromosome). They may be isolated or may occur along with a duplication of another chromosome segment. The latter typically occurs in unbalanced reciprocal chromosomal translocation secondary to abnormal crossover or segregation in a translocation or inversion carrier.

A carrier of a deletion is monosomic for the genetic information of the missing segment. Deletions are usually associated with intellectual disability and malformations. The most commonly observed deletions in routine chromosome preparations include 1p–, 4p–, 5p–, 9p–, 11p–, 13q–, 18p–, 18q–, and 21q– (Table 99.4 and Fig. 99.9), all distal or terminal deletions of the short or the long arms of chromosomes. Deletions may be observed in routine chromosome preparations, and deletions and translocations larger than 5-10 Mbp are usually visible microscopically.

High-resolution banding techniques, FISH, and molecular studies such as CMA can reveal deletions that are too small to be seen in ordinary or routine chromosome spreads (see Fig. 99.7). **Microdeletions** involve loss of small chromosome regions, the largest of which are detectable only with prophase chromosome studies and molecular methods. For submicroscopic deletions, the missing piece can only be detected using molecular methodologies such as DNA-based studies (e.g., CMA, FISH). The presence of extra genetic material from the same chromosome is referred to as **duplication**. Duplications can also

Table 99.4 Common Deletions and Their Clinical Manifestations

DELETION	CLINICAL ABNORMALITIES
4p–	Wolf-Hirschhorn syndrome. The main features are a typical "Greek helmet" facies secondary to ocular hypertelorism, prominent glabella, frontal bossing, microcephaly, dolichocephaly, hypoplasia of the orbits, ptosis, strabismus, nystagmus, bilateral epicanthic folds, cleft lip and palate, beaked nose with prominent bridge, hypospadias, cardiac malformations, and intellectual disability.
5p–	Cri du chat syndrome. The main features are hypotonia, short stature, characteristic shrill cry in the first few weeks of life (also called cat's cry syndrome), microcephaly with protruding metopic suture, hypertelorism, bilateral epicanthic folds, high arched palate, wide and flat nasal bridge, and intellectual disability.
9p–	The main features are craniofacial dysmorphic features with trigonocephaly, slanted palpebral fissures, discrete exophthalmos secondary to supraorbital hypoplasia, arched eyebrows, flat and wide nasal bridge, short neck with low hairline, genital anomalies, long fingers and toes with extra flexion creases, cardiac malformations, and intellectual disability.
13q–	The main features are low birthweight, failure to thrive, microcephaly, and severe intellectual disability. Facial features include high, wide nasal bridge; hypertelorism; ptosis; and micrognathia. Ocular malformations are common (retinoblastoma). The hands have hypoplastic or absent thumbs and syndactyly.
18p–	A few patients (15%) are severely affected and have cephalic and ocular malformations: holoprosencephaly, cleft lip and palate, ptosis, epicanthal folds, and varying degrees of intellectual disability. Most (80%) have only minor malformations and mild intellectual disability.
18q–	The main features are growth deficiency and hypotonia with a "froglike" position with the legs flexed, externally rotated, and in hyperabduction. The face is characteristic, with depressed midface and apparent protrusion of the mandible, deep-set eyes, short upper lip, and everted lower lip ("carplike" mouth); antihelix of the ears is very prominent. Varying degrees of intellectual disability and belligerent personality are present. Myelination abnormalities occur in the central nervous system.

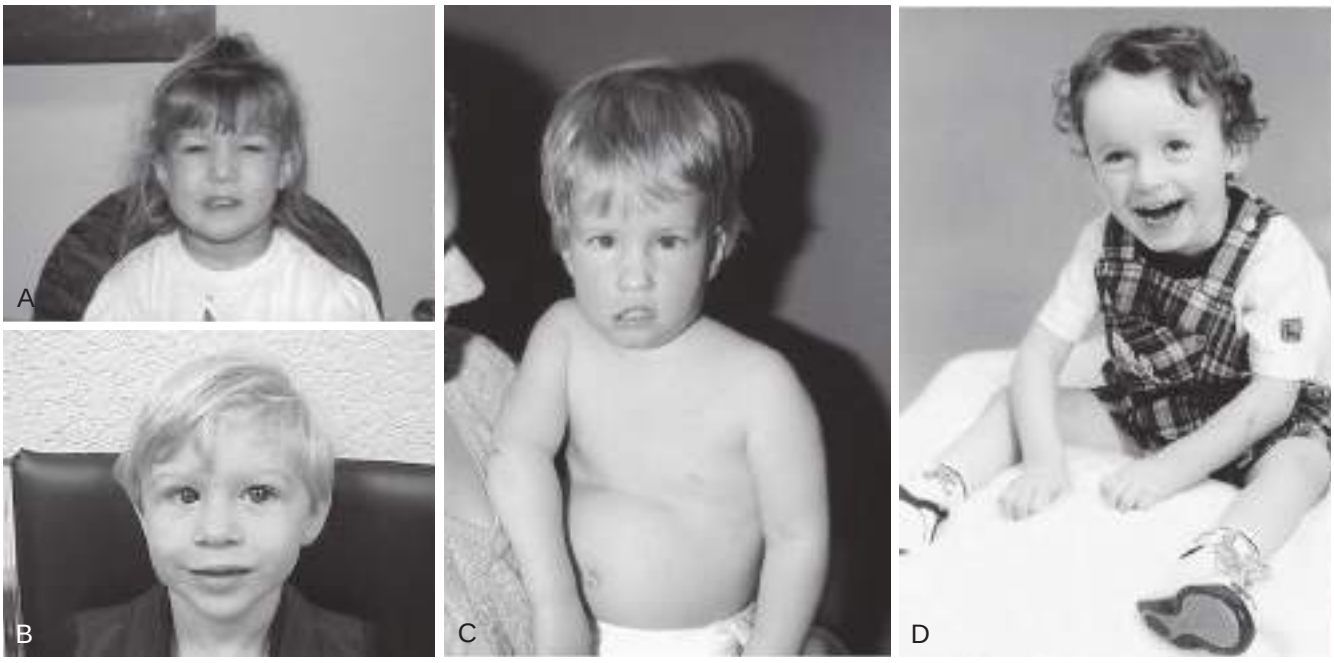

Fig. 99.9 **A,** Child with velocardiofacial syndrome (deletion 22q11.2). **B,** Child with Williams syndrome (deletion 7q11.23). **C,** Child with Prader-Willi syndrome (deletion 15q11-13). **D,** Child with Angelman syndrome (deletion 15q11-13). *(From Lin RL, Cherry AM, Bangs CD, et al. Adolescent medicine. Philadelphia: Hanley and Belfus; 2002: pp. 305–313.)*

Table 99.5 Microdeletion and Contiguous Gene Syndromes and Their Clinical Manifestations

DELETION	SYNDROME	CLINICAL MANIFESTATIONS
1p36	1p deletion	Growth restriction, dysmorphic features with midface hypoplasia, straight thin eyebrows, pointy chin, sensorineural hearing loss, progressive cardiomyopathy, hypothyroidism, seizures, intellectual disability
5q35	Sotos (50% are deletions of *NSD1* gene in Asians but only 6% in Whites)	Overgrowth, macrocephaly, prominent forehead, prominence of extraaxial fluid spaces on brain imaging, large hands and feet, hypotonia, clumsiness, mental disabilities
6p25	Axenfeld-Rieger	Axenfeld-Rieger malformation, hearing loss, congenital heart defects, dental anomalies, developmental delays, facial dysmorphism
7q11.23	Williams	Round face with full cheeks and lips, long philtrum, stellate pattern in iris, strabismus, supravalvular aortic stenosis and other cardiac malformations, varying degrees of intellectual disability, friendly personality
8p11	8p11	Kallmann syndrome type 2 (hypogonadotropic hypogonadism and anosmia), spherocytosis (deletions of ankyrin 1), multiple congenital anomalies, intellectual disability
8q24.1-q24.13	Langer-Giedion or trichorhinophalangeal type II	Sparse hair, multiple cone-shaped epiphyses, multiple cartilaginous exostoses, bulbous nasal tip, thickened alar cartilage, upturned nares, prominent philtrum, large protruding ears, mild intellectual disability
9q22	Gorlin	Multiple basal cell carcinomas, odontogenic keratocysts, palmoplantar pits, calcification falx cerebri
9q34	9q34 deletion	Distinct face with synophrys, anteverted nares, tented upper lip, protruding tongue, midface hypoplasia, conotruncal heart defects, intellectual disability
10p12-p13	DiGeorge type 2	Many of the DiGeorge type 1 and velocardiofacial type 1 features (conotruncal defects, immunodeficiency, hypoparathyroidism, dysmorphic features)
11p11.2	Potocki-Shaffer	Multiple exostoses, parietal foramina, craniosynostosis, facial dysmorphism, syndactyly, intellectual disability
11p13	WAGR	Hypernephroma (Wilms tumor), aniridia, male genital hypoplasia of varying degrees, gonadoblastoma, long face, upward-slanting palpebral fissures, ptosis, beaked nose, low-set poorly formed auricles, intellectual disability (retardation)
11q24.1-11qter	Jacobsen	Growth restriction, intellectual disability, cardiac and digit anomalies, thrombocytopenia
15q11-q13 (paternal)	Prader-Willi	Severe hypotonia and feeding difficulties at birth, voracious appetite and obesity in infancy, short stature (responsive to growth hormone), small hands and feet, hypogonadism, intellectual disability

DD, Developmental delay; FTT, failure to thrive; GH, growth hormone; ID, intellectual disability.

be sporadic or result from abnormal segregation in translocation or inversion carriers.

Microdeletions and microduplications usually involve regions that include several genes, so the affected individuals can have a distinctive phenotype depending on the number of genes involved. When such a deletion involves more than a single gene, the condition is referred to as a **contiguous gene deletion syndrome** (Table 99.5). With the advent of chromosome microarray, a large number of microduplications, have been uncovered. Many of those **microduplication syndromes** are the reciprocal duplications of the known deletions or microdeletion counterparts and have distinctive clinical features (Table 99.6).

Subtelomeric regions are often involved in chromosome rearrangements that cannot be visualized using routine cytogenetics. *Telomeres,* which are the distal ends of the chromosomes, are gene-rich regions. The distal repetitive sequence structure of telomeres is essentially common to all chromosomes, but proximal to these are unique regions known as *subtelomeres,* which typically are involved in deletions and other chromosome rearrangements. Small subtelomeric deletions, duplications, or rearrangements (translocations, inversions) may be relatively common in children with nonspecific intellectual disability and minor anomalies. Subtelomeric rearrangements have been found in 3–7% of children with moderate to severe intellectual disability and 0.5% of those with mild intellectual disability and can be detected by CMA studies.

Pathogenic variants affecting telomere function and length have been associated with dyskeratosis congenita and other aplastic anemia syndromes, as well as pulmonary or hepatic fibrosis. Both the subtelomeric rearrangements and the microdeletion and microduplication syndromes are typically diagnosed by molecular techniques like CMA and multiple ligation-dependent probe amplification (MLPA) studies. CMA can detect 14–18% of abnormalities in patients who previously had normal cytogenetic studies.

INSERTIONS

Insertions occur when a piece of a chromosome broken at two points is incorporated into a break of a chromosome in another location. A total of three breakpoints are then required, and they can occur between two or within one chromosome. A form of nonreciprocal translocation, insertions are rare. Insertion carriers are at risk of having offspring with deletions or duplications of the inserted segment.

ISOCHROMOSOMES

Isochromosomes consist of two copies of the same chromosome arm joined through a single centromere and forming mirror images of one another. The most commonly reported autosomal isochromosomes tend to involve chromosomes with small arms. Some of the more common chromosome arms involved in this formation include 5p, 8p, 9p, 12p, 18p, and 18q. There is also a common isochromosome abnormality seen in long arm of the X chromosome and associated with Turner syndrome. Individuals who have one isochromosome X within 46 chromosomes are monosomic for genes in the lost short arm and trisomic for the genes present in the long arm of the X chromosome.

MARKER AND RING CHROMOSOMES

Marker chromosomes are rare and are usually chromosome fragments that are too small to be identified by conventional cytogenetics; they usually occur in addition to the normal complement of 46 chromosomes. Most are sporadic (70%); mosaicism is often (50%) noted because of the mitotic instability of the marker chromosomes. The incidence in newborn infants is 1 in 3,300, and the incidence in persons with intellectual disability is 1 in 300. The associated phenotype ranges from normal to severely abnormal, depending on the amount of chromosome material and number of genes included in the fragment.

Ring chromosomes, which are found for all human chromosomes, are rare. A ring chromosome is formed when both ends of a chromosome are deleted and the ends are then joined to form a ring. Depending on the amount of chromosome material that is lacking or in excess (if the ring has duplicated chromosomal material), a patient with a ring chromosome can appear normal or can have different degrees of intellectual disability and/or multiple congenital anomalies.

Marker and ring chromosomes can be found in the cells of solid tumors of children. Some of these markers can be the result of tumor-specific rearrangements, such as translocations, deletions, and duplications, ultimately leading to gene fusions and tumor gene amplifications.

99.4 Sex Chromosome Aneuploidy

Carlos A. Bacino and Brendan Lee

About 1 in 400 males and 1 in 650 females have some form of sex chromosome abnormality. Considered together, sex chromosome abnormalities are the most common chromosome abnormalities seen in liveborn infants, children, and adults. Sex chromosome abnormalities can be either structural or numerical and can be present in all cells or in a mosaic form. Those affected with these abnormalities might have few or no physical or developmental problems (Table 99.7).

TURNER SYNDROME

Turner syndrome is a condition characterized by complete or partial monosomy of the X chromosome and defined by a combination of phenotypic features (see Table 99.7 and Table 99.8). Half the patients with Turner syndrome have a 45,X chromosome complement. The other half exhibit mosaicism and varied structural abnormalities of the X or Y chromosome. Maternal age is not a predisposing factor for children with 45,X. Turner syndrome occurs in approximately 1

Table 99.7 Sex Chromosome Abnormalities

DISORDER	KARYOTYPE	APPROXIMATE INCIDENCE
Klinefelter syndrome	47,XXY	1/580 males
	48,XXXY	1/50,000-1/80,000 male births
	Other (48,XXYY; 49,XXXYY; mosaics)	
XYY syndrome	47,XYY	1/800-1,000 males
Other X or Y chromosome abnormalities		1/1,500 males
XX males	46,XX	1/20,000 males
Turner syndrome	45,X	1/2,500-1/5,000 females
	Variants and mosaics	
Trisomy X	47,XXX	1/1,000 females
	48,XXXX and 49,XXXXX	Rare
Other X chromosome abnormalities		1/3,000 females
XY females	46,XY	1/20,000 females

Table 99.8 Signs Associated with Turner Syndrome

Short stature
Congenital lymphedema
Horseshoe kidneys
Patella dislocation
Increased carrying angle of elbow (cubitus valgus)
Madelung deformity (chondrodysplasia of distal radial epiphysis)
Congenital hip dislocation
Scoliosis
Widespread nipples
Shield chest
Redundant nuchal skin (in utero cystic hygroma)
Low posterior hairline
Coarctation of aorta
Bicuspid aortic valve
Cardiac conduction abnormalities
Hypoplastic left heart syndrome and other left-sided heart abnormalities
Gonadal dysgenesis (infertility, primary amenorrhea)
Gonadoblastoma (increased risk if Y chromosome material is present)
Learning disabilities (nonverbal perceptual motor and visuospatial skills) (in 70%)
Developmental delay (in 10%)
Social awkwardness
Hypothyroidism (acquired in 15–30%)
Type 2 diabetes mellitus (insulin resistance)
Strabismus
Cataracts
Red-green color blindness (as in males)
Recurrent otitis media
Sensorineural hearing loss
Inflammatory bowel disease
Celiac disease (increased incidence)

in 5,000 female live births. In 75% of patients, the lost sex chromosome is of paternal origin (whether an X or a Y). 45,X is one of the chromosome abnormalities most often associated with spontaneous pregnancy losses. It has been estimated that 95–99% of 45,X conceptions are miscarried.

Clinical findings in the newborns can include small size for gestational age, webbing of the neck, protruding ears, and lymphedema of the hands and feet, although many newborns are phenotypically normal (Fig. 99.10). Older children and adults have short stature and exhibit variable dysmorphic features. Congenital heart defects (40%) and structural renal anomalies (60%) are common. The most common heart defects are bicuspid aortic valves, coarctation of the aorta, aortic stenosis, and mitral valve prolapse. The gonads are generally streaks of fibrous tissue **(gonadal dysgenesis)** (see Chapter 626). There is primary amenorrhea and lack of secondary sex characteristics. These children should receive regular endocrinologic testing.

Patients with **45,X/46,XY mosaicism** can have Turner syndrome, although this form of mosaicism can also be associated with male pseudohermaphroditism, male or female genitalia in association with mixed gonadal dysgenesis, or a normal male phenotype. This variant is estimated to represent approximately 6% of patients with mosaic Turner syndrome. Some of the patients with Turner syndrome phenotype and a Y cell line exhibit masculinization. Phenotypic females with 45,X/46,XY mosaicism have a 15–30% risk of developing **gonadoblastoma**. The risk for the patients with a male phenotype and external testes is not so high, but tumor surveillance is nevertheless recommended. The American Academy of Pediatrics (AAP) has recommended the use of FISH analysis to look for Y chromosome mosaicism in all 45,X patients. If Y chromosome material is identified, laparoscopic gonadectomy is recommended.

Noonan syndrome (see Chapter 101.1) shares many clinical features with Turner syndrome and was formerly called *pseudo-Turner syndrome*, although it is an autosomal dominant disorder resulting from pathogenic variants in several genes involved in the RAS-MAPK pathway. In contrast to Turner syndrome, Noonan syndrome affects both sexes and has a different pattern of congenital heart disease, typically involving right-sided heart lesions.

KLINEFELTER SYNDROME

Persons with Klinefelter syndrome are phenotypically male. This syndrome is the most common cause of hypogonadism and infertility in males and the most common sex chromosome aneuploidy in humans (see Chapter 623). Eighty percent of children with Klinefelter syndrome have a male karyotype with an extra chromosome X-47,XXY. The remaining 20% have multiple sex chromosome aneuploidies (48,XXXY; 48,XXYY; 49,XXXXY), mosaicism (46,XY/47,XXY), or structurally abnormal X chromosomes; the greater the aneuploidy, the more severe the mental impairment and dysmorphism. The prevalence of 47,XXY is 1 in 580 liveborn males. Errors in paternal nondisjunction in meiosis I account for ~50% of the cases.

47,XYY

The incidence of 47,XYY is approximately 1 in 800-1,000 males, with many cases remaining undiagnosed, because most affected individuals have a normal appearance and normal fertility. The extra Y is the result of nondisjunction at paternal meiosis II. Those with this abnormality have normal intelligence but are at risk for learning disabilities. Behavioral abnormalities, including hyperactive behavior, pervasive developmental disorder, and aggressive behavior, have been reported. Early reports that assigned stigmata of criminality to this disorder have long been disproved.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

99.5 Mosaicism

Carlos A. Bacino and Brendan Lee

Mosaicism describes an individual or tissue that contains ≥2 genetically different cell lines typically derived from a single zygote. Genetic differences can result from mitotic nondisjunction (see Fig. 99.1; Table 99.9) or sporadic variant. Study of placental tissue from chorionic villus samples collected at or before the 10th week of gestation has shown that ≥2% of all conceptions are mosaic for a chromosome abnormality. With the exception of chromosomes 13, 18, and 21, complete autosomal trisomies are usually nonviable, and the contribution of a normal cell line might allow these other trisomic conceptions to survive to term. Depending on the point at which the new cell line arises during early embryogenesis, mosaicism may be present in some tissues but not in others. **Germline mosaicism**, which refers to the presence of mosaicism in the germ cells of the gonad, may be associated with an increased risk for recurrence of an affected child if the germ cells are affected with a chromosomal abnormality or with a specific gene pathogenic variant.

PALLISTER-KILLIAN SYNDROME

Pallister-Killian syndrome is characterized by coarse facies (prominent full cheeks), abnormal ear lobes, localized alopecia (sparse hair

Fig. 99.10 Physical manifestations associated with Turner syndrome. **A,** This newborn shows a webbed neck with low hairline, shield chest with widespread nipples, abnormal ears, and micrognathia. **B,** The low-set posterior hairline can be better appreciated in this older child, who also has protruding ears. **C,** In this frontal view, mild webbing of the neck and small, widely spaced nipples are evident, along with a midline scar from prior cardiac surgery. The ears are low-set and prominent, protruding forward. **D** and **E,** The newborn shown in **A** also has prominent lymphedema of the hands and feet. *(From Madan-Khetarpal S, Arnold G. Genetic disorders and dysmorphic conditions. In: Zitelli BJ, McIntire SC, Nowalk AJ, eds, Zitelli and Davis' Atlas of Pediatric Physical Diagnosis, 6th ed. Philadelphia: Elsevier; 2012: Fig. 1.25.)*

in the temporal regions), pigmentary skin anomalies, diaphragmatic hernia, cardiovascular anomalies, supernumerary nipples, seizures, and profound intellectual disability. The syndrome is caused by mosaicism for an isochromosome of the short chromosome of 12 (12p). The presence of the isochromosome 12p in cells gives four functional copies for the short arm of chromosome 12 in the affected cells. The isochromosome 12p is preferentially cultured from fibroblasts that can be readily obtained from a skin punch biopsy and is seldom present in lymphocytes. A CMA obtained from a buccal swab can be another tool to detect this disorder. The abnormalities seen in affected persons probably reflect the presence of abnormal cells during early embryogenesis.

HYPOMELANOSIS OF ITO

Hypomelanosis of Ito is characterized by unilateral or bilateral macular hypo- or hyperpigmented whorls, streaks, and patches (see Chapter 694). Sometimes these pigmentary defects follow the lines of Blaschko that represent areas of early epidermal cell migration. Hair and tooth anomalies are common. Abnormalities of the eyes, musculoskeletal system (growth asymmetry, syndactyly, polydactyly, clinodactyly), and central nervous system (microcephaly, seizures, intellectual disability) may also be present. Patients with hypomelanosis of Ito might have two genetically distinct cell lines. The mosaic chromosome anomalies that have been observed involve both autosomes and sex chromosomes and have been demonstrated in about

Table 99.9 Other Rare Mosaic Aneuploidy Syndromes

DISORDER	KARYOTYPE	CLINICAL MANIFESTATIONS
Trisomy 8	47,XX/XY,+8	Variable growth and intellectual deficiency The majority of patients are mosaic Deep palmar and plantar furrows Joint contractures
Trisomy 9	47,XX/XY,+9	The majority of patients are mosaic Craniofacial (high forehead, microphthalmia, low-set malformed ears, bulbous nose) Skeletal (joint contractures) Heart defects (60%)
Trisomy 16	47,XX/XY,+16	The most commonly observed autosomal aneuploidy in spontaneous abortion Recurrence risk negligible
Tetrasomy 12p	46,XX[12]/46,XX, +i(12p)[8] (mosaicism for an isochromosome 12p)	Pallister-Killian syndrome Sparse anterior scalp hair (more so temporal region), eyebrows, and eyelashes; prominent forehead; full cheeks; long philtrum with thin upper lip and cupid-bow configuration; polydactyly; streaks of hyper- and hypopigmentation

50% of clinically affected patients. The mosaicism might not be visible in lymphocyte-derived chromosome studies; it is more likely to be found when chromosomes are analyzed from skin fibroblasts. The distinct cell lines might not always be caused by observable chromosomal anomalies but might result from single-gene pathogenic variants or other mechanisms.

99.6 Chromosome Instability Syndromes

Carlos A. Bacino and Brendan Lee

Chromosome instability syndromes, formerly known as *chromosome breakage syndromes,* are characterized by an increased risk of malignancy and specific phenotypes. They display autosomal recessive inheritance and have an increased frequency of chromosome breakage and/or rearrangement, either spontaneous or induced. Chromosome instability syndromes result from specific defects in DNA repair, cell cycle control, and apoptosis. The resulting chromosomal instability leads to the increased risk of developing neoplasms. The classic chromosome instability syndromes are Fanconi anemia, ataxia telangiectasia, Nijmegen syndrome, ICF (immunodeficiency, centromere instability, facial anomalies) syndrome, Roberts syndrome, and Bloom syndrome (Table 99.10).

99.7 Uniparental Disomy and Imprinting

Carlos A. Bacino and Brendan Lee

UNIPARENTAL DISOMY

Uniparental disomy **(UPD)** occurs when both chromosomes of a pair or areas from one chromosome in any individual have been inherited from a single parent. UPD can be of two types, uniparental *iso*disomy or uniparental *hetero*disomy. **Uniparental isodisomy** means that both chromosomes or chromosomal regions are identical (typically the result of monosomy rescue by duplication). **Uniparental heterodisomy** means that the two chromosomes are different members of a pair, both of which were still inherited from one parent. This results from a trisomy that is later reduced to disomy, leaving two copies from one parent. The phenotypic result of UPD varies according to the chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: those related to imprinted genes (i.e., the absence of a gene that is normally expressed only when inherited from a parent of a specific sex), those related to the uncovering of autosomal recessive disorders, and those related to a vestigial aneuploidy producing mosaicism (see Chapter 97).

In **uniparental isodisomy**, both chromosomes or regions (and thus the genes) in the pair are identical. This is particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has UPD with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in two copies, and the phenotype will be that of the autosomal recessive disorder; the child has an autosomal recessive disorder even though only one parent is a carrier of that recessive disorder. It is estimated that all humans carry approximately 20 abnormal autosomal recessive genes. Some autosomal recessive disorders, such as spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, α- and β-thalassemias, and Bloom syndrome, have been reported in cases of UPD. The possibility of uniparental isodisomy should also be considered when a person is affected with >1 recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a *rare* cause of recessively inherited disorders. Uniparental isodisomies can also be detected by SNP microarrays.

Maternal UPD involving chromosomes 2, 7, 14, and 15 and **paternal UPD** involving chromosomes 6, 11, 15, and 20 are associated with phenotypic abnormalities of growth and behavior. UPD of maternal chromosome 7 is associated with Russell-Silver syndrome with intrauterine growth restriction. These phenotypic effects may be related to imprinting (see later) (Fig. 99.11).

Although microdeletions cause the majority of cases, UPD for chromosome 15 is seen in some instances of Prader-Willi syndrome and Angelman syndrome. In **Prader-Willi syndrome**, approximately 25–29% of cases have maternal UPD (missing the paternal chromosome 15) (Fig. 99.12). In **Angelman syndrome**, paternal UPD of chromosome 15 is only observed in approximately 5% of the cases (missing the maternal chromosome 15). The phenotype for Prader-Willi syndrome and Angelman syndrome in cases of UPD is thought to result from the lack of specific parental contributions from chromosome 15. In Prader-Willi syndrome the paternal contribution is missing, and the maternal contribution is missing in Angelman syndrome. Prader-Willi syndrome may be caused by paternal deficiency of a cluster of small nucleolar RNAs (snoRNAs).

Table 99.10 Chromosome Instability Syndromes

SYNDROME	LABORATORY FINDINGS AND GENES INVOLVED	CLINICAL FINDINGS
Fanconi anemia (FA)	Chromosome breakage induced by diepoxybutane and mitomycin C There are least 21 FA genes, most are autosomal recessive, only one is X linked	Short stature, microcephaly in 1/3 of cases, radial ray defects including thumb anomalies, pancytopenia, skeletal anomalies, renal anomalies, café-au-lait macules, ear abnormalities and hearing loss
Ataxia telangiectasia	Chromosome instability with rearrangements between chromosomes 7 and 14 in lymphocytes often involving the T-cell receptors in those chromosomes Decreased IgA levels Pathogenic variants in the *ATM* gene. Autosomal recessive	Progressive cerebellar ataxia with later development of conjunctival telangiectasias, choreoathetosis, and dystonia Sinopulmonary infections Predisposition to malignancies like B-cell lymphomas, T-cell leukemias and solid tumors
Nijmegen syndrome	Translocations involving chromosomes 7 and 14 in up to 50% of cells Pathogenic variants in the *NBN* gene (autosomal recessive)	IUGR, short stature, progressive microcephaly, and intellectual disability, recurrent sinopulmonary infections Susceptibility to malignancies before age 20 years like T- and B-cell lymphomas, medulloblastomas, gliomas, rhabdomyosarcoma
ICF (immunodeficiency, centromere instability, facial anomalies) syndrome, types I and II	Pericentromeric chromosomal instability on PHA-stimulated metaphases in chromosomes 1, 9, and 16 Decrease of IgG and IgE in type I, IgM and IgE in type II Low T cells, like NK cells. Pathogenic variants in *DNMT3B* and ZBTB24 genes in types I and II, respectively Autosomal recessive	Immunodeficiency, recurrent infections, intellectual disability, facial dysmorphic features
Roberts-SC phocomelia syndrome	Premature chromosome separation with chromatid/centromere repulsion in prophase or early metaphase easily detected using C-banding Pathogenic variants in *ESCO2* gene Autosomal recessive	Prenatal growth deficiency, absent or hypoplastic arms typically symmetric with reduction of digits' length including thumbs that are usually more affected than lower extremities, bilateral cleft lip and palate, dysmorphic features, cardiac anomalies, renal anomalies, and intellectual disability
Bloom syndrome	Marked chromosomal increase of sister chromatid exchange in the presence of BrdU and increased spontaneous chromosome breakage Decreased IgG, IgA, IgM Pathogenic variants in the *RECQL3* gene. Autosomal recessive	Severe prenatal and postnatal growth deficiency, microcephaly (average intelligence), sensitivity to sunlight (butterfly distribution over the face), cafe-au-lait macules, insulin resistance, predisposition to malignancies: lymphomas, leukemias, squamous cell carcinoma and solid tumors Hypersensitivity to chemotherapy
Werner syndrome	"Variegated translocation mosaicism": chromosomal aberrations, including translocations, inversions, and deletions Telomere loss Pathogenic variants in *RECQL2* Autosomal recessive	Short stature, premature aging appearance, and predisposition to malignancies Loss and graying of hair, hoarseness, scleroderma-like changes in the 20s Cataracts, type II diabetes, osteoporosis, hypogonadism in the 30s Neoplasms in >40% of cases including sarcomas, melanomas, and thyroid cancer Myocardial infarction and malignancies are cause of early death

IUGR, Intrauterine growth restriction; PHA, phytohemagglutinin; NK, natural killer.

These findings suggest that there are differences in function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father. Angelman syndrome is caused by absent function of the maternal gene *UBE3A* and can be the result of maternal deletion, maternal *UBE3A* pathogenic variant, paternal UPD, and abnormalities in the maternal imprinting center on chromosome 15q11-13 region.

UPD most frequently arises when a pregnancy starts off as a **trisomic conception** followed by **trisomy rescue.** Because most trisomies are lethal, the fetus can only survive if a cell line loses one of the extra chromosomes to revert to the disomic state. One third of the time, the disomic cell line is uniparental. This is the typical mechanism for Prader-Willi syndrome, and it is often associated with advanced maternal age. The embryo starts off as trisomy 15 secondary to maternal meiosis I nondisjunction, followed by random loss of the paternal chromosome. In this case the disomic cell line becomes the more viable one and outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether UPD has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities (i.e., chromosome involved in UPD containing imprinted genes). There must always be concern that some residual cells that are trisomic are present in some tissues, leading to malformations or dysfunction. The

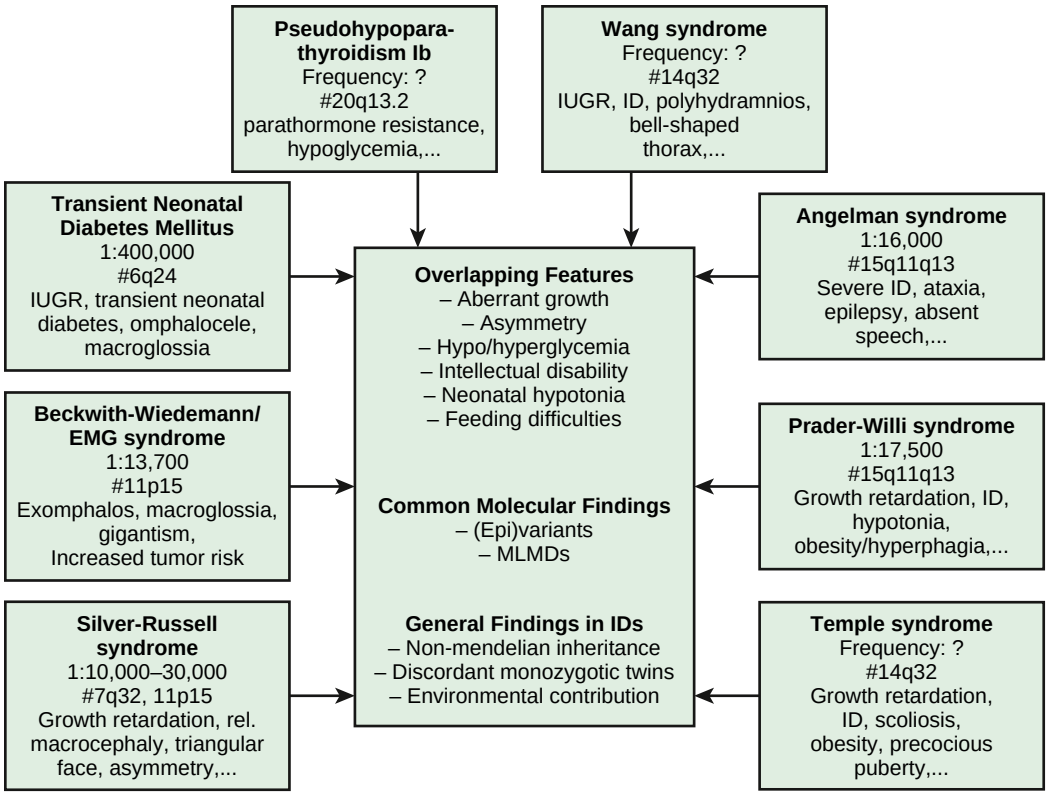

Fig. 99.11 Overview of the common clinical and molecular findings in the eight known imprinting disorders, including specific features, frequencies, and major chromosomal localization. #6q24, Chromosome 6q24; EMG, exomphalos-macroglossia-gigantism; IUGR, intrauterine growth restriction; ID, intellectual disability; MLMDs, multilocus methylation defects. *(From Eggermann T, Elbracht M, Schröder C, et al. Congenital imprinting disorders: a novel mechanism linking seemingly unrelated disorders. J Pediatr. 2013;163:1204.)*

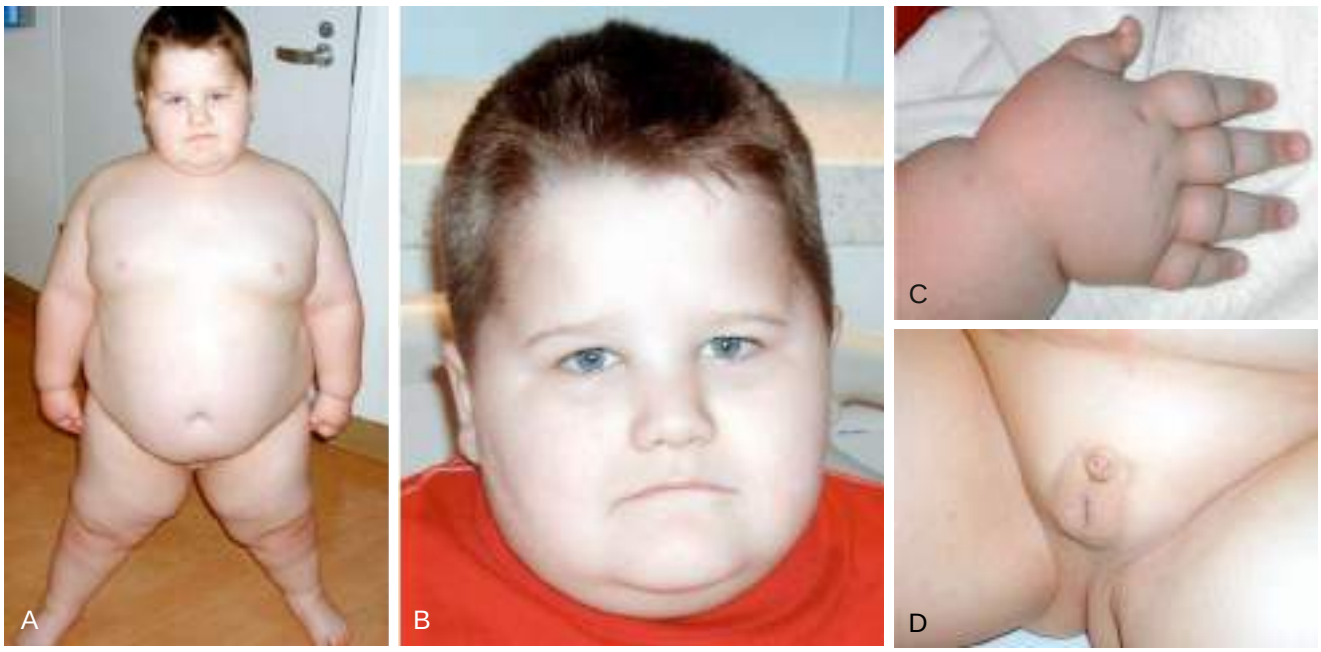

Fig. 99.12 Prader-Willi phenotype. A and B, Individual showing morbid obesity with facial features as shown. C, Upper extremities are notable for small hands relative to body size. D, External genitalia after laparoscopic orchiopexy at 13 months. Parental informed consent, as approved by the Baylor College of Medicine Institutional Review Board, was obtained to publish the photographs. *(From Sahoo T, del Gaudio D, German JR, et al. Prader-Willi phenotype caused by paternal deficiency for the HBII-85 C/D box small nucleolar RNA cluster. Nat Genet. 2008;40:719–721.)*

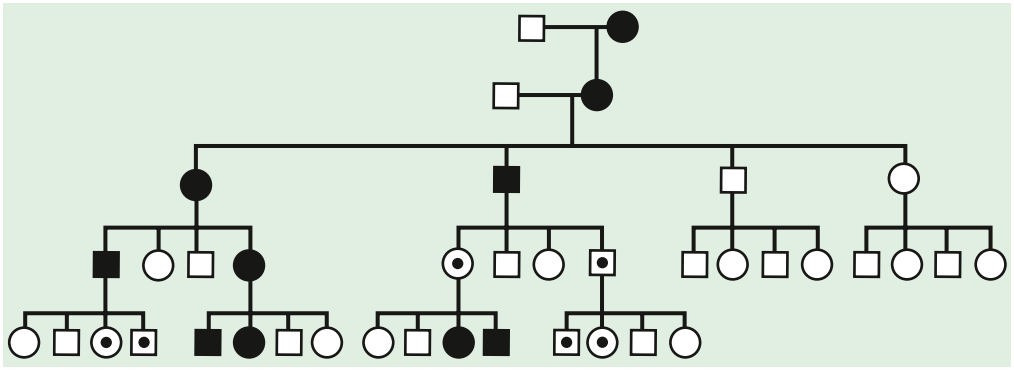

Fig. 99.13 In this hypothetical pedigree suggestive of imprinting, phenotypic effects occur only when the mutated gene is transmitted from the mother, but not when it is transmitted from the father, that is, maternal deficiency. Equal numbers of males and females can be affected and not affected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; that is, in maternal deficiency disorders (also termed *paternal imprinting*), there are "skipped" nonmanifesting females. This is theoretical, because in most clinical scenarios of maternal deficiency, such as Angelman syndrome, affected persons do not reproduce.

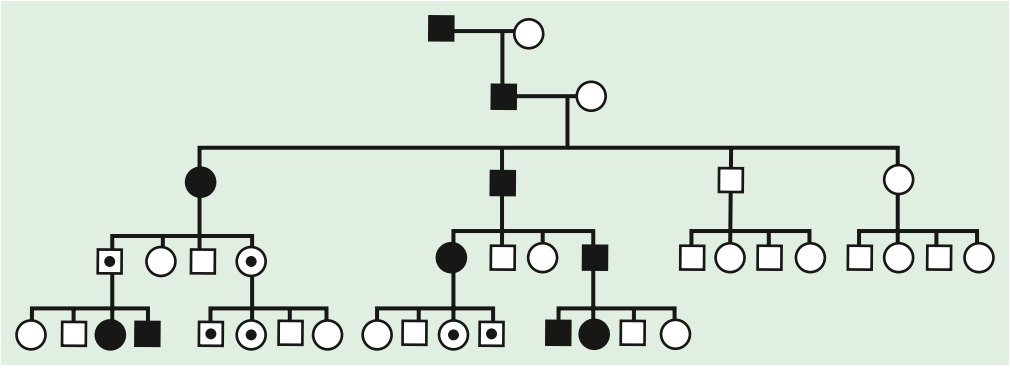

Fig. 99.14 In theoretical pedigrees suggestive of paternal deficiency (maternal imprinting), phenotypic effects occur only when the mutated gene is transmitted from the father but not when transmitted from the mother. Equal numbers of males and females can be affected and not affected phenotypically in each generation. In a theoretical situation, a nonmanifesting transmitter gives a clue to the sex of the parent who passes on the expressed genetic information; that is, in paternal deficiency (also known as *maternal imprinting*), there are "skipped" nonmanifesting males. In real-life clinical cases of Prader-Willi syndrome, affected persons do not reproduce.

Table 99.11 Consensus Diagnostic Criteria for Prader-Willi Syndrome

	MAJOR CRITERIA (1 POINT EACH)	MINOR CRITERIA (1/2 POINT EACH)
1	Neonatal/infantile hypotonia	Decreased fetal movement and infantile lethargy
2	Feeding problems and failure to thrive as an infant	Typical behavior problems
3	Weight gain at 1-6 years; obesity; hyperphagia	Sleep apnea
4	Characteristic dysmorphic facial features	Short stature for family by 15 years
5	Small genitalia; pubertal delay and insufficiency	Hypopigmentation for the family
6	Developmental delay/intellectual disability	Small hands and feet for height
7		Narrow hands, straight ulnar border
8		Esotropia, myopia
9		Thick, viscous saliva
10		Speech articulation defects
11		Skin picking

Table 99.12 Nutritional Phases in Prader-Willi Syndrome

PHASE	MEDIAN AGES	CLINICAL CHARACTERISTICS
0	Prenatal to birth	Decreased fetal movements and lower birthweight than siblings
1a	0-9 mo	Hypotonia with difficulty feeding and decreased appetite
1b	9-25 mo	Improved feeding and appetite and growing appropriately
2a	2.1-4.5 yr	Weight increasing without appetite increase or excess calories
2b	4.5-8 yr	Increased appetite and calories, but can feel full
3	8 yr to adulthood	Hyperphagic, rarely feels full
4	Adulthood	Appetite is no longer insatiable

Table 99.13 Molecular Mechanisms Causing Prader-Willi and Angelman Syndromes

	PRADER-WILLI SYNDROME	ANGELMAN SYNDROME
15q11-q13 deletion	~70% (paternal)	~70% (maternal)
Uniparental disomy	~30% (maternal)	~5% (paternal)
Single-gene pathogenic variants	None detected	*UBE3A* gene encoding the E6-AP ubiquitin-protein ligase (11% of total but mostly in familial cases)
Imprinting center pathogenic variants	5%	1%
Unidentified	<1%	10–15%

Data from Nicholls RD, Knepper JL. Genome organization, function and imprinting in Prader-Willi and Angelman syndromes. *Annu Rev Genomics Hum Genet.* 2001;2:153–175; and Horsthemke B, Buiting K. Imprinting defects on human chromosome 15. *Cytogenet Genome Res.* 2006;113:292–299.

presence of aggregates of trisomic cells might account for the spectrum of abnormalities seen in persons with some UPDs.

IMPRINTING

Genomic imprinting occurs when the phenotypic expression of a gene depends on the *parent of origin* for certain genes or chromosome regions. Whether the genetic material is expressed or not depends on the sex of the parent from whom it was derived. Genomic imprinting can be suspected in some cases on the basis of a pedigree. In these pedigrees the disease is always transmitted from the same sex and could be passed on silently for several generations by the opposite sex (Figs. 99.13 and 99.14). Imprinting probably occurs in many different parts of the human genome and is thought to be particularly important in gene expression related to development, growth, cancer, and behavior; >60 genes have been classified as imprintable. Imprinting disorders may arise from UPD, deletions or duplications, epigenetic aberrant methylation patterns, or single nucleotide pathogenic variants in a specific gene.

A classic example of imprinting disorder is seen in **Prader-Willi syndrome** and **Angelman syndrome**, two very different clinical conditions. These syndromes are both commonly caused by a deletion of the same region in the proximal long arm of chromosome 15. A deletion of the paternally derived chromosome causes Prader-Willi syndrome, in which the maternally derived copy is still intact, for which some of the imprinted genes within this region normally remain silent. Prader-Willi syndrome can be diagnosed clinically (Table 99.11) and confirmed with genetic testing. Additional clinical features and issues of weight gain are noted in Table 99.12. The weight gain is difficult to control, but treatment with growth hormone has resulted in improvements in height, lean body mass, decreased adipose tissue, and improvement in cognitive function.

A maternal deletion of the same region as in Prader-Willi syndrome causes Angelman syndrome, leaving intact the paternal copy that in this case has genes that are also normally silent. In other situations, UPD can lead to the same diagnosis (Table 99.13). Many other disorders are associated with this type of parent-of-origin effect, as in some cases of Beckwith-Wiedemann syndrome (see Chapter 598.1), Russell-Silver syndrome, and neonatal diabetes.

Chapter 100

Dysmorphology, Phenotyping, and Sequences

Anne M. Slavotinek

Dysmorphology is the study of differences in human form and the mechanisms that cause them. It has been estimated that 1 in 40 newborns, or 2.5%, have a recognizable birth defect or pattern of malformations at birth; ~50% of these newborns have a single, isolated malformation, whereas in the other half, multiple malformations are present. About 20–30% of infant deaths and 30–50% of deaths after the neonatal period are caused by congenital abnormalities (http://www.marchofdimes.com/peristats/). In 2021, birth defects accounted for ~1 in 5 infant deaths in the United States, with a rate of 108.2 deaths per 100,000 live births, which was higher than other causes of mortality, such as preterm/low birthweight (80.4/100,000), sudden infant death syndrome (39.8/100,000), maternal complications of pregnancy (33.4/100,000), and unintentional injury (33.5/100,000).

CLASSIFICATION OF BIRTH DEFECTS

Birth defects can be subdivided into isolated (single) defects or multiple defects, typically described as multiple congenital anomalies (MCAs). An isolated primary defect can be classified, according to the presumed cause of the defect, as a malformation, dysplasia, deformation, or disruption (Table 100.1 and Fig. 100.1). Most birth defects are malformations, a term used interchangeably with anomalies. A malformation is a structural defect arising from a *localized* error in morphogenesis that results in the abnormal formation of a tissue or organ. Dysplasia refers to the *abnormal organization of cells* into tissues. Malformations and dysplasias can both affect the intrinsic structure of tissues and organs. In contrast, a deformation is an *alteration* in the shape or form of a structure or organ that has previously developed or differentiated normally. A disruption is a defect resulting from the *destruction* of a structure that had formed normally before the insult.

Most human disorders with altered morphogenesis display multiple anomalies or malformations rather than an isolated birth defect. When several malformations coexist in a single individual, they can be classified as a syndrome, sequence, or an association. A **syndrome** is defined as a pattern comprising multiple anomalies that are related by pathophysiology, resulting from a single, defined etiology. **Sequences** consist of multiple anomalies that are caused by a single event, although the sequence itself can have different etiologies. An **association** refers to a nonrandom grouping of anomalies in which there is an unclear, or unknown, relationship among the anomalies, such that they do not fit the criteria for a syndrome or sequence.

Malformations and Dysplasias

Human anomalies and dysplasias can be caused by pathogenic gene variants, chromosome aberrations and copy number variants, environmental factors, or interactions between genetic and environmental factors (Table 100.2). Some malformations are caused by deleterious sequence variants in single genes, whereas other anomalies arise because of deleterious sequence variants in multiple genes acting in combination, termed *digenic* or *oligogenic* inheritance. In the past, it was thought that malformations were caused by monogenic pathogenic variants in 7.5% of patients; chromosomal anomalies in 6%; multigenic pathogenic variants in 20%; and known environmental factors, such as maternal diseases, infections, and teratogens, in 6–7% (Table 100.3). In the remaining 60–70% of patients, malformations were classified as having an unknown etiology. Currently, the percentages have increased for all of the possible genetic etiologies of malformations due to improved cytogenetic and molecular genetic methods, including microarrays and single nucleotide polymorphism (SNP) arrays for detecting copy number variants, and next-generation sequencing (NGS) technologies, such as exome or genome sequencing, for identifying novel genes and pathogenic sequence variants.

Many developmental abnormalities caused by *pathogenic sequence variants* in a single gene display characteristic of mendelian patterns of inheritance such as autosomal dominant, autosomal recessive, and X-linked inheritance. Genes that cause birth defects or MCA syndromes are often transcription factors, part of evolutionarily conserved signal transduction pathways, or regulatory proteins required for key developmental events (see Chapters 101 and 102 and Table 100.2).

In addition, syndromes with MCA can be caused by chromosomal aberrations or copy number variants and teratogens (see Tables 100.2 and 100.3). **Down syndrome** typically results from an extra copy of an entire chromosome 21 or, less frequently, an extra copy of the Down syndrome critical region on chromosome 21. Chromosome 21 is a small chromosome that contains an estimated 250 genes, and thus individuals with Down syndrome typically have an increased dosage

Table 100.1 Mechanisms, Terminology, and Definitions of Dysmorphology

TERMINOLOGY	DEFINITION	EXAMPLE
Sequence	Single error in morphogenesis that results in a series of subsequent defects	Pierre-Robin sequence, in which a small jaw results in glossoptosis and cleft palate 22q11 deletion sequence of primary fourth brachial arch and third and fourth pharyngeal pouch defects, leading to aplasia or hypoplasia of the thymus and parathyroid glands, aortic arch anomalies, and micrognathia
22q11 deletion	Mechanical (uterine) force that alters structure of intrinsically normal tissue	Oligohydramnios produces deformations by in utero compression of limbs (e.g., dislocated hips, equinovarus foot deformity), crumpled ears, or small thorax
Disruption sequence	In utero tissue destruction after a period of normal morphogenesis	Amnionic membrane rupture sequence, leading to amputation of fingers/toes, tissue fibrosis, and tissue bands
Dysplasia sequence	Atypical organization of cells into tissues or organs	Neurocutaneous melanosis sequence, with atypical migration of melanocyte precursor cells from the neural crest to the periphery, manifesting as melanocytic hamartomas of skin and meninges
Malformation syndrome	Appearance of multiple malformations in unrelated tissues that have a known, unifying cause	Trisomy 21 Teratogens Numerous multiple congenital anomaly syndromes as described above

From Kliegman RM, Greenbaum LA, Lye PS, eds. *Practical Strategies in Pediatric Diagnosis and Therapy,* 2nd ed. Philadelphia: Elsevier; 2004.

Fig. 100.1 Four major types of problems in morphogenesis: malformation, deformation, disruption, and dysplasia. **A,** Infant with campomelic dysplasia syndrome, which results in multiple anomalies caused by a pathogenic variant in *SOX9*. **B,** Infant with oligohydramnios deformation sequence caused by premature rupture of membranes from 17 weeks' gestation until birth at 36 weeks; the infant was delivered from a persistent transverse lie. **C,** Fetus with early amnion rupture sequence with attachment of the placenta to the head and resultant disruption of craniofacial structures with distal limb contractures. **D,** Infant with diastrophic dysplasia caused by biallelic pathogenic variants in a sulfate transporter protein. *(From Graham Jr JM. Smith's Recognizable Patterns of Human Deformation, 3rd ed. Philadelphia: Saunders; 2007, Fig. 1-1, p. 4.)*

for the genes encoded by this chromosome that causes their physical differences (see Chapter 57).

Neural tube defects (NTDs) are an example of a birth defect that typically displays multifactorial inheritance. NTDs and other birth defects, such as cleft lip and palate, can recur in families, but inheritance for the majority of affected individuals does not follow a straightforward, mendelian inheritance pattern, and multiple genes and environmental factors acting together likely contribute to the pathogenesis (see Table 100.2). Many of the genes involved in NTDs are unknown, so one cannot predict with certainty the mode of inheritance or a precise recurrence risk for an individual case. Empirical recurrence risks can be provided on the basis of population studies and the presence of single or multiple family members with the same malformation. However, one important gene/environment interaction has been identified for NTDs (see Chapter 631.1). **Folic acid deficiency** is associated with NTDs and can result from a combination of dietary factors and increased utilization during pregnancy. A common variant in the gene for an enzyme in the folate recycling pathway, 5,10-methylene-tetrahydrofolate reductase *(MTHFR)*, that makes this enzyme less stable, may also be important in folic acid status. Several teratogenic causes of birth defects have been described (see Tables 100.2 and 100.3). **Ethanol** causes a recognizable pattern of anomalies that is variably called fetal alcohol syndrome (FAS), fetal alcohol spectrum disorder (FASD), or fetal alcohol effects (FAE) (see Chapter 146). Children who were exposed to ethanol during the pregnancy can display microcephaly, developmental delays, hyperactivity, and facial anomalies. Ethanol, which is toxic to the developing central nervous system (CNS), causes cell death in developing neurons.

Deformations

Many deformations involve the musculoskeletal system (Fig. 100.2). Fetal movement is required for the proper development of the musculoskeletal system, and restriction of fetal movement can result in musculoskeletal deformations, such as clubfoot, or talipes. Two major intrinsic etiologies of deformations are **primary neuromuscular disorders** and **oligohydramnios**, or decreased amniotic fluid, which can be caused by fetal renal defects. Both primary neuromuscular disorders and oligohydramnios can compromise fetal movements. The major extrinsic causes of deformations are those that result in fetal crowding and restriction of fetal movement. Examples of extrinsic causes include oligohydramnios resulting from chronic leakage of amniotic fluid, and abnormal shape of the amniotic cavity. When a fetus is in the breech position (Fig. 100.3), the incidence of deformations is increased 10-fold. The shape of the amniotic cavity also has a profound effect on the shape of the fetus and is influenced by many factors, including uterine shape and the volume of amniotic fluid (Fig. 100.4).

It is important to determine whether deformations result from intrinsic or extrinsic causes. Most children with deformations from *extrinsic* causes are otherwise completely normal, and their prognosis is usually excellent. Correction typically occurs spontaneously. Deformations caused by *intrinsic* factors, such as multiple joint contractures resulting from CNS or peripheral nervous system defects, have a different prognosis and may be much more significant for the child (Fig. 100.5).

Disruptions

Disruptions are caused by destruction of a previously normally formed organ or body part. At least two mechanisms are known to produce disruptions. One involves entanglement followed by tearing apart, or amputation, of a normally developed structure, usually a digit or limb, by strands of amnion floating within amniotic fluid that are termed amniotic bands (Fig. 100.6). The other mechanism involves interruption to the blood supply to a developing body part, which can lead to infarction, necrosis, and resorption of structures distal to the insult. If interruption to the blood supply occurs early in gestation, the disruptive defect typically involves **atresia,** or absence of a body part. Genetic factors have been considered to play a minor role in the pathogenesis of disruptions, as most occur as sporadic events in otherwise healthy individuals, but little is known regarding etiology. The prognosis for a disruptive defect is determined entirely by the extent and location of the tissue loss.

Multiple Anomalies: Sequences, Associations, and Syndromes

The pattern of multiple anomalies that occurs when a single primary defect in early development produces multiple anomalies because of a cascade of secondary and tertiary developmental effects is called a *sequence* (Fig. 100.7). When evaluating a child with MCAs, the physician must differentiate between multiple anomalies that are caused by a single localized error in morphogenesis (a sequence) from syndromes with multiple anomalies. In the former, recurrence risk counseling for the multiple anomalies depends entirely on the risk of recurrence for the single, localized malformation. **Pierre-Robin sequence** is a pattern of multiple anomalies produced by mandibular hypoplasia. Because the tongue is relatively large for the oral cavity, it drops back (glossoptosis), blocking closure of the posterior palatal shelves and causing a U-shaped cleft palate. There are numerous causes of mandibular hypoplasia, all of which can result in the characteristic features of Pierre-Robin sequence.

VATER association was first defined as the nonrandom occurrence of a combination of congenital anomalies comprising vertebral defects,

Table 100.2 Examples of Malformations with Distinct Causes, Clinical Features, and Pathogenesis

DISORDER	CAUSE/INHERITANCE	SELECTED CLINICAL FEATURES	PATHOGENESIS
Spondylocostal dysostosis syndrome	Mendelian; autosomal recessive	Abnormal vertebral and rib segmentation	Deleterious sequence variants in *DLL3* and other genes
Rubinstein-Taybi syndrome	Autosomal dominant	Intellectual disability Broad thumbs and halluces; valgus deviation of these digits Hypoplastic maxillae Prominent nose and columella Congenital heart disease	Deleterious sequence variants in *CBP* and *EP300*
X-linked lissencephaly	X-linked	Male: severe intellectual disability, seizures Female: variable	Deleterious sequence variants in *DCX*
Aniridia	Autosomal dominant	Absent iris or iris/foveal hypoplasia	Deleterious sequence variants in *PAX6*
Waardenburg syndrome, type I	Autosomal dominant	Deafness White forelock Wide-spaced eyes Iris heterochromia and/or pale skin pigmentation	Deleterious sequence variants in *PAX3*
Holoprosencephaly	Loss of function or haploinsufficiency for multiple genes	Microcephaly Cyclopia Single central incisor	*SHH,* multiple other genes
Velocardiofacial syndrome	Microdeletion 22q11.2	Congenital heart disease, including conotruncal defects Cleft palate T-cell defects Facial anomalies	*TBX1* haploinsufficiency/ pathogenic variants; haploinsufficiency for other genes in the deleted interval also contributes to the phenotype
Down syndrome	Additional copy of chromosome 21 (trisomy 21)	Intellectual disability Characteristic facial anomalies Congenital heart disease Increased risk of leukemia Alzheimer disease	Increase in dosage of an estimated 250 genes on chromosome 21
Neural tube defects	Multifactorial	Meningomyelocele	Defects in folate sensitive enzymes or folic acid uptake
Fetal alcohol syndrome	Teratogenic	Microcephaly Developmental delay Facial anomalies Behavioral abnormalities	Ethanol toxicity to developing brain
Retinoic acid embryopathy	Teratogenic	Microtia Congenital heart disease	Isotretinoin effects on neural crest and branchial arch development

anal atresia, tracheoesophageal fistula (TEF) with esophageal atresia, radial anomalies, and renal dysplasia. The association was expanded to include cardiac anomalies (C) and limb anomalies (L), leading to the longer acronym, **VACTERL**. Although there are still no definitively established diagnostic criteria, most clinicians consider that a minimum of three of the seven component features must be present for the diagnosis. In addition, the designation of VATER/VACTERL association is typically one of exclusion; *growth and developmental delays as well as facial anomalies are atypical and should prompt the consideration of alternative diagnoses.* Anorectal defects and TEF are considered more characteristic of VATER/VACTERL association than some of the other components, such as cardiac anomalies. A single umbilical artery is a common finding. The estimated incidence of VATER/VACTERL has ranged from 1 in 10,000 to 1 in 40,000 infants. VACTERL with hydrocephalus, also known as VACTERL-H, is a separate condition.

VATER/VACTERL association has so far defied the identification of a simple mendelian etiology. Many cases are sporadic, although there are rare reports of familial inheritance and first-degree relatives with clinical findings in the component systems of VATER/VACTERL association. Hedgehog signaling has been postulated to be important, as mouse models with defective Hedgehog and/or ciliary signaling manifest the clinical findings observed in VATER/VACTERL. However, cytogenetic studies have not demonstrated chromosome aberrations or copy number variants. Exome sequencing (ES) has not identified a single causative gene or gene family, although nonrecurrent variants have been described in mendelian disease genes, most typically in patients with renal involvement. Clinical overlap has led to the identification of pathogenic variants in the *SALL1*, *SALL4,* and *MID1* genes in patients with anorectal malformations.

Pathogenic variants in several autosomal recessive genes in the **kynurenine pathway**, including *KYNU*, *HAAO,* and *NADSYN1*, have been associated with a spectrum of anomalies that overlap with VATER/VACTERL association, including vertebral defects, cardiac anomalies, renal malformations, and limb defects of variable severity. Biallelic variants in these genes perturb the synthesis of nicotinamide adenine dinucleotide (NAD) synthesis; these conditions have been grouped together as **congenital NAD deficiency disorders.** The overall contribution of these genes to the pathogenesis of VATER/VACTERL association appears to be small in terms of the entire group of patients but remains an important diagnostic consideration. Interestingly, studies in mice with biallelic

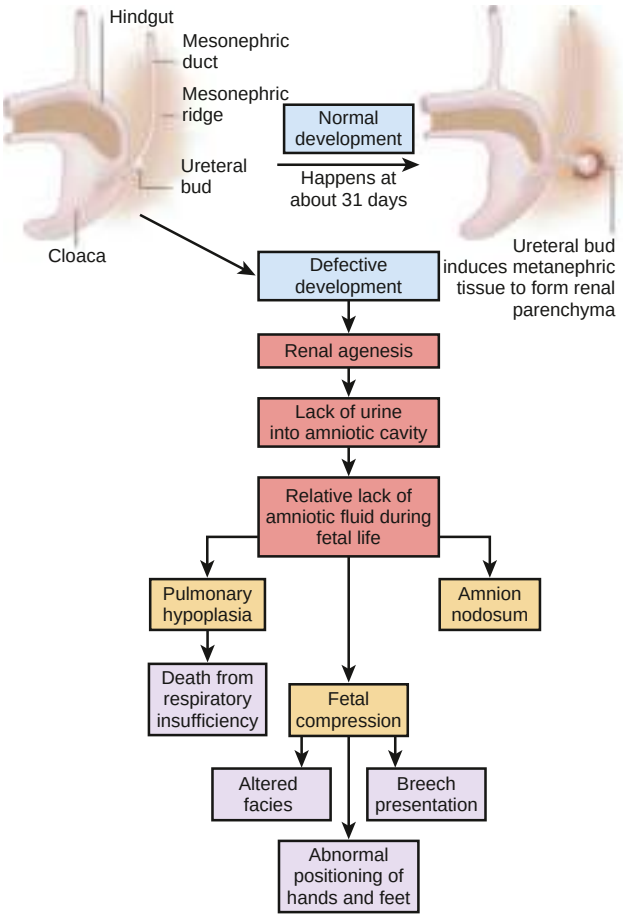
Fig. 100.3 Breech deformation sequence.

loss-of-function variants in *Haao* and *Kynu* that were provided with niacin in their diet showed that the vitamin can overcome the metabolic block associated with loss-of-function for these genes. Niacin enters the NAD biosynthesis pathway downstream to *Haao* and *Kynu*, and this finding implies that the availability of niacin and other components of the kynurenine pathway can influence NAD levels during pregnancy and consequently the clinical severity resulting from the variants affecting some of the genes involved in NAD synthesis. These conditions outline the importance of considering the influence of environmental factors on the phenotype caused by genetic variation.

MOLECULAR MECHANISMS OF MALFORMATIONS

Inborn Errors of Development

Genes that cause malformation syndromes, as well as genes whose expression is disrupted by environmental agents or teratogens, can participate in numerous cellular processes, including signal transduction, transcription, or the regulation of genes and proteins required for key developmental events. When anomalies are viewed as alterations resulting from disturbances to important developmental pathways, this provides a molecular framework for understanding the birth defects (see Chapter 101).



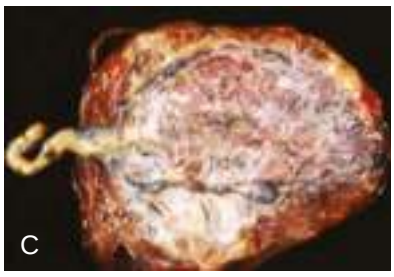


Fig. 100.4 A, Consequences of renal agenesis. B, Multiple deformational defects. C, Defects in amnion nodosum; brown-yellow granules from vernix have been ribbed into defects of the amniotic surface. *(From Jones KL, Jones MC, Del Campo M, eds. Smith's Recognizable Patterns of Human Malformation, 7th ed. Philadelphia: Elsevier; 2013: p. 821.)*

It is important to consider MCA syndromes as members of a group based on shared or overlapping clinical findings and related causative genes that act in the same developmental or metabolic pathway. See Chapter 101 for the Sonic Hedgehog disorders, RASopathies, craniosynostoses, and chromatin regulatory disorders as examples; disruption of specific steps in this pathway result in a variety of related developmental disorders and anomalies (see Fig. 100.2).

Cytogenetic Aberrations and Chromosomal Imbalance

Cytogenetic imbalances resulting from an additional copy of a whole human chromosome can result in characteristic and recognizable

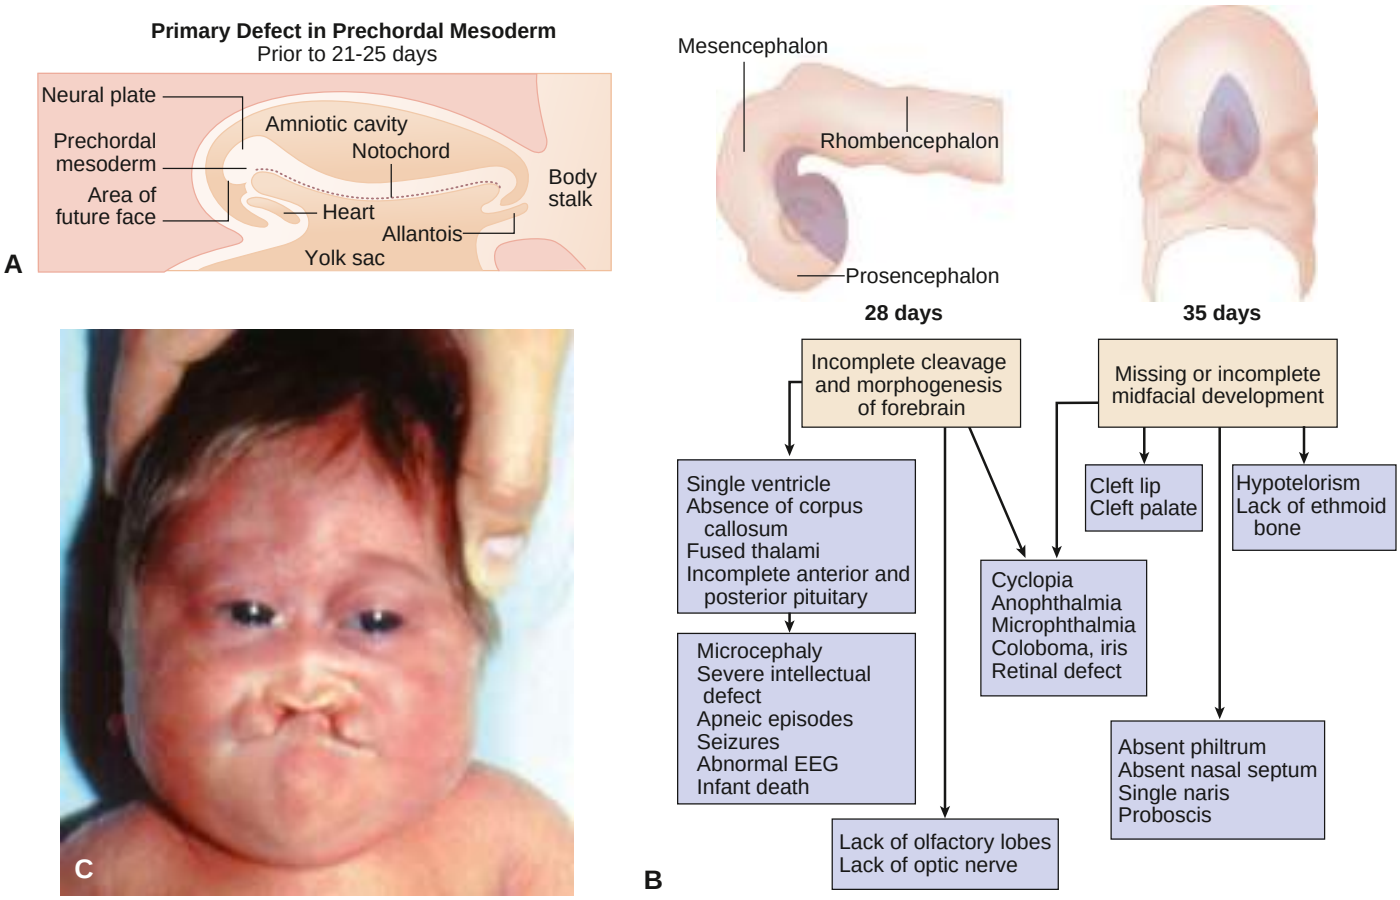

Fig. 100.7 Holoprosencephaly sequence. **A**, Schematic longitudinal section of 21-day embryo. **B**, Developmental pathogenesis of the sequence. **C**, Affected individual. *(From Jones KL, Jones MC, Del Campo M, eds.* Smith's Recognizable Patterns of Human Malformation*, 7th ed. Philadelphia: Elsevier; 2013: pp. 802–803.)*

syndromes. An additional copy of chromosome 21 results in **Down syndrome** (see Chapter 57); loss of one of the X chromosomes results in **Turner syndrome** (see Chapter 99.2 for discussion of syndromes with whole chromosomal imbalances). With the advent of high-resolution cytogenetic techniques, such as fluorescence in situ hybridization (FISH), array comparative genomic hybridization (array CGH), and SNP arrays, it has become straightforward to identify **submicroscopic chromosome deletions and duplications**. Several recurrent chromosome deletions and duplications have been identified as the cause of characteristic and recognizable syndromes (see Table 100.6 and Chapter 99), including **Williams syndrome** (deletion of chromosome 7q11.23), **Miller-Dieker syndrome** (deletion of chromosome 17p13.3), **Smith-Magenis syndrome** (deletion of chromosome 17p11.2), and 22q11 deletion syndrome (deletion of chromosome 22q11.2, also known as **velocardiofacial syndrome**). Collectively, chromosome microarrays (CMAs) and genetic sequencing have made it possible to uncover rare microdeletions, microduplications, and single nucleotide pathogenic variants associated with birth defects, intellectual disability, and neuropsychiatric disorders. The sensitivity and specificity of microarrays made them a standard starting point for the evaluation of a child with MCAs and intellectual disabilities, but exome, genome, and gene panel testing have been preferred due to higher diagnostic yield. It is important to note that unaffected individuals may carry small microdeletions and microduplications as part of familial variation. Therefore it is important to compare copy number variants that are identified in children with birth defects or developmental delays with their parents' chromosome analyses and with databases of normal variants detected in individuals without such birth defects.

APPROACH TO THE CHILD WITH FACIAL ANOMALIES

One approach to the child with facial anomalies is the *pattern recognition* approach, which compares the physical differences in the patient against a broad and memorized (or computerized) knowledge of human disorders. This approach can be appropriate for experienced dysmorphologists and clinical geneticists. In conjunction, a systematic *genetic mechanism* approach can also be effective for clinicians who are not dysmorphology experts. By gathering and analyzing the clinical data, the general pediatrician can diagnose the patient in a straightforward case or initiate a referral to an appropriate specialist.

Medical History

The history for a patient with birth defects includes elements related to etiologic factors. The family history, or *pedigree*, is necessary to assess the inheritance pattern, or lack thereof, for a disorder. For disorders that have a simple mendelian inheritance pattern, recognition of the mode of inheritance can be critical for narrowing the differential diagnosis, then prioritizing common genes with the appropriate inheritance pattern that could cause the patient's clinical features. Many common birth defects have a complex, or multifactorial, genetic etiology, such as isolated cleft palate and spina bifida or NTDs. The recognition of a close relative affected with a birth defect similar to the proband's findings can be useful. Typically, a three-generation pedigree is sufficient for this purpose (see Chapter 97).

The perinatal history is also an essential component of the history. It includes the pregnancy history of the mother, which can be useful for recognition of recurrent miscarriages that may be indicative of a chromosomal disorder, factors that may relate to deformations or disruptions such as oligohydramnios, and maternal exposures to teratogenic drugs or chemicals, including isotretinoin and ethanol, that are potential causes of microcephaly.

Another component of the history that is often useful is the natural history of the **phenotype**. MCA syndromes caused by chromosomal aberrations and single-gene disorders are frequently *static*, meaning that, although the patients can experience new complications over

Table 100.4 Definitions of Common Clinical Signs of Syndromes with Facial Anomalies

SIGN	DEFINITION
Brachycephaly	A condition in which head shape is shortened from front to back along the sagittal plane; typically the back of the skull (occiput) and face are flatter than normal.
Brachydactyly	Short digits.
Brushfield spots	Speckled white spots or rings about two-thirds of the distance to the periphery of the iris of the eye.
Camptodactyly	Permanent flexion of one or more fingers that can be associated with missing interphalangeal creases.
Clinodactyly	A medial or lateral curving of the fingers or toes; usually refers to incurving of the fifth finger.
Hypoplastic or small nail	A small nail on a digit.
Low-set ears	This designation is made when the helix meets the cranium at a level below a horizontal plane that is an extension of a line through both inner canthi.
Melia	A suffix meaning "limb" (e.g., amelia, missing limb; brachymelia, short limb).
Wide-set eyes	Increased distance between the center of the pupils of the two eyes; can be measured as an *increased interpupillary distance* (IPD).
Plagiocephaly	A condition in which head shape is asymmetric in the sagittal or coronal plane; can result from asymmetry in cranial suture closure, asymmetry of brain growth, or deformation of the skull.
Posterior hair whorl	A single hair whorl occurs to the right or left of midline and is within 2 cm anterior to the posterior fontanel in 95% of cases.
Postaxial polydactyly	Extra finger or toe present on the lateral side of the hand or foot.
Preaxial polydactyly	Extra finger or toe present on the medial side of the hand or foot.
Prominent lateral palatine ridges	Relative overgrowth of the lateral palatine ridges that can be caused by a deficit of tongue thrust into the hard palate.
Scaphocephaly	A condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic; also termed *dolichocephaly*.
Shawl scrotum	The scrotal skin joins around the superior aspect of the penis and represents a mild deficit in full migration of the labial-scrotal folds.
Short palpebral fissures	Decreased horizontal distance of the eyelid folds based on measurements from the inner canthus to the outer canthus.
Syndactyly	Incomplete separation of the fingers or toes. It most commonly occurs between the third and fourth fingers and between the second and third toes.
Synophrys	Eyebrows that meet in the midline.
Telecanthus	Lateral displacement of the inner canthi. The inner canthal distance (ICD) is increased, but the IPD is normal.
Widow's peak	V-shaped midline, downward projection of the scalp hair in the frontal region. It represents an upper forehead intersection of the bilateral fields of periocular hair growth suppression. A widow's peak can occur together with wide-spaced eyes.

time, the phenotype is typically not progressive. In contrast, disorders that cause facial anomalies because of metabolic perturbations, for example, Hunter syndrome or Sanfilippo syndrome, can be mild or may not be apparent at birth, but can progress, causing deterioration of patient status over time.

Physical Examination

The physical examination is very important for identifying anomalies that can aid a genetic diagnosis. The essential element of the physical evaluation is an assessment of the patient's clinical findings, with the clinician performing an organized evaluation of the size and formation of various body structures. Familiarity with the terminology typically used to describe anomalies is helpful (Table 100.4). The size and shape of the head is relevant; for example, many children with Down syndrome have mild microcephaly and a shortened anteroposterior dimension of skull, termed brachycephaly. Eye position, shape, and the slant of the palpebral fissures are useful signs for many disorders. Reference standards are available with which physical measurements (e.g., interpupillary distance) can be compared. It can be useful to categorize anomalies as "major" or "minor" birth defects. Major defects either cause significant dysfunction or require surgical correction (see Table 100.5), and minor defects neither cause significant dysfunction nor require surgical correction (e.g., clinodactyly) (Table 100.6 and Fig. 100.8). By cataloging physical parameters, the clinician may be able to identify a characteristic pattern of anomalies and recognize the diagnosis. Facial recognition software has been helpful in identifying the etiology of patients with facial dysmorphology (Fig. 100.9).

Imaging Studies

Imaging studies can be critical in diagnosing an underlying genetic etiology. If short stature or disproportionate stature (e.g., long trunk and short limbs) is noted, a full skeletal survey with radiographs should be performed. The skeletal survey can detect anomalies in bone number, structure, and formation that can be used to narrow the differential diagnosis. When there are abnormal neurologic signs or symptoms, such as hypotonia, and an abnormal head size, such as microcephaly, brain imaging can be indicated. Other studies and examinations, such as echocardiography, renal ultrasonography, and hearing and ophthalmology evaluation, can also be useful to identify additional major or minor anomalies that may serve as diagnostic clues.

Diagnosis

The examining physician should gather data on the patient's pedigree and perinatal and pediatric history and should have an appreciation for the natural history of the clinical findings. At this point, the physician has examined the child, identified atypical physical features, and obtained appropriate imaging studies.

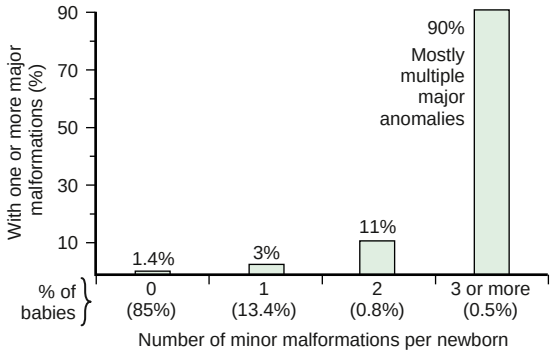

Fig. 100.8 Frequency of major malformations in relation to the number of minor anomalies detected in a given newborn baby. *(From Jones KJ. Smith's Recognizable Patterns of Human Malformation, 6th ed. Philadelphia: Saunders; 2006.)*

The clinician should now attempt to organize the findings to elucidate potential developmental processes. An assessment based on **specificity** can be helpful for this process. If a child has multiple findings, such as a patent ductus arteriosus (PDA), mild growth restriction, mild microcephaly, and holoprosencephaly, micropenis, and ptosis, a selection of the rarer or pathognomonic findings may be prioritized. The PDA, ptosis, mild growth restriction, and mild microcephaly are considered *nonspecific findings*, as they are present in many disorders or often present as isolated features that are not part of a syndrome. However, holoprosencephaly and micropenis are present in fewer syndromes and are not considered part of normal variation. The clinician can therefore search for disorders that include both holoprosencephaly and micropenis. The search can be performed manually using the features index of a textbook such as *Smith's Recognizable Patterns of Human Malformation* or a computerized database such as Online Mendelian Inheritance in Man (OMIM). Searching for both holoprosencephaly and micropenis returns a list of diagnostic possibilities, and the physician can then return to the patient to examine for additional features of the leading possible candidate disorders. Appropriate genetic testing can then be undertaken to confirm the clinician's hypothesis and verify the diagnosis. Alternatively, broad genetic testing can be undertaken if the patient's clinical findings are nonspecific.

Laboratory Studies and Genetic Testing

The laboratory evaluation of a child with anomalies can be critical to reach or confirm the correct diagnosis, particularly for metabolic conditions. Array CGH and SNP arrays enable the detection of chromosome abnormalities and copy number variants and, in the case of SNP arrays, evaluation for loss of heterozygosity. Chromosome deletion syndromes may also be identified with specific and sensitive FISH analysis, although this technology has been largely replaced by chromosome arrays and NGS sequencing. Cytogenetic studies with Giemsa-banded (G-banded) chromosome analysis are still useful for the diagnosis of Down syndrome and balanced translocations (Table 100.7). These tests are sensitive methods for the detection of cytogenetic alterations associated with birth defects and MCAs. Cytogenetic alterations can also be detected by whole genome sequencing that is becoming increasingly utilized.

Molecular testing for deleterious sequence variants that cause pleiotropic malformation syndromes is also available for many disorders as clinical testing. In most cases, however, such testing should not be performed indiscriminately; instead, it should be ordered thoughtfully after a differential diagnosis has been considered. *NGS with ES and whole genome sequencing has led to the identification of innumerable novel genes and revolutionized the testing that is available for patients and families with intellectual disability, birth defects, and other genetic diseases.* A strong suspicion of a genetic diagnosis warrants consideration of testing to confirm the diagnosis, facilitate patient treatment and anticipatory guidance, clarify recurrence risks, and enable carrier testing for additional family members. Single genes can still be tested by *Sanger sequencing* that targets single or multiple exons. However,

for diagnoses that have substantial genetic heterogeneity (e.g., hearing loss), *panel testing* often using NGS, in which multiple relevant genes can be interrogated for single nucleotide variants and gene deletions and duplications, is more expeditious than single-gene testing. Panel tests also frequently have the advantage of providing high coverage for the genes on the panel compared with the coverage for the same genes that can be obtained by ES. However, in situations with diagnostic uncertainty, such as the investigation of a child with intellectual disability and facial anomalies for which there is no clearly recognizable pattern, **exome** or **genome sequencing (GS)** may be most useful as a broad testing approach. ES examines approximately 200,000 exons, or the 1–2% of the DNA that comprises the coding regions of the genome. ES is typically performed with a *trio* approach, in which the patient and both biological parents are tested simultaneously, so that the inheritance pattern, or segregation, of deleterious sequence variants can be determined, thus simplifying analysis. Trio sequencing has resulted in higher diagnostic yields than proband-only sequencing and can approach 30–40% for indications such as intellectual disability. In contrast, GS examines the entire DNA content, including noncoding regions, and increasingly enables analysis for cytogenetic rearrangements in addition to copy number loss or gain. ES and GS are applicable to a wide range of birth defects and genetic diseases and can discover causative variants in known or novel genes associated with a particular condition.

Management and Counseling

Management and genetic counseling are essential aspects of the approach to a patient with a genetic disorder. For example, children with Down syndrome have a high incidence of hypothyroidism, and children with achondroplasia have a high incidence of cervicomedullary

junction abnormalities and monitoring for both is appropriate. One of the many benefits of an early and accurate diagnosis is that **anticipatory guidance and medical monitoring** of patients for syndrome-specific medical risks can improve their quality of life and prolong it. When a diagnosis is made, the treating physicians can access published information on the natural history and management of the disorder through the medical literature, genetics reference texts, and databases. Providing access to disorder-specific patient support groups can also provide immense benefit to patients and families.

The second major benefit of an accurate diagnosis is that it provides data for **recurrence risk** estimates. Genetic disorders may have direct effects on only one member of the family, but the diagnosis of the condition can have implications for the entire family. One or both parents may be carriers, and siblings may be carriers or may want to know their genetic status when they reach their reproductive years. Recurrence risk provision is an important component of genetic counseling and should be included in all evaluations for families affected with birth defects or other inherited disorders (see Chapter 98).

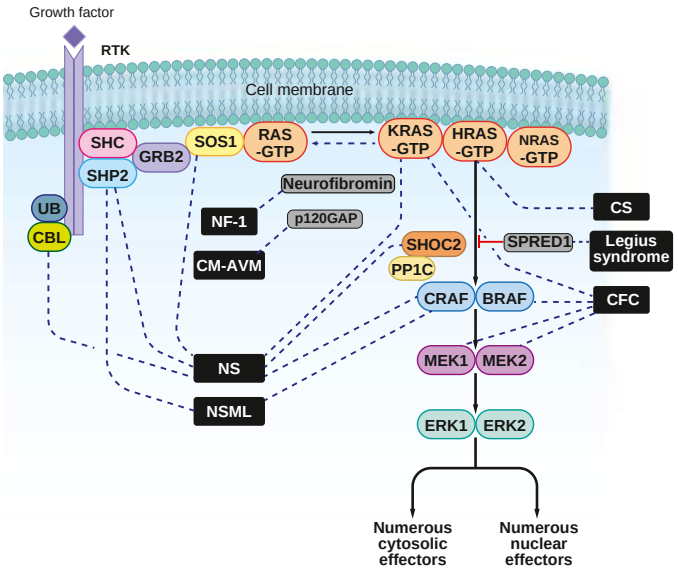

Fig. 101.1 The RAS/MAPK signal transduction pathway. The MAPK signaling pathway of protein kinases is critically involved in cellular proliferation, differentiation, motility, apoptosis, and senescence. The RASopathies are patterns of anomalies caused by pathogenic variants in genes that encode components or regulators of the RAS/MAPK pathway (indicated by *dashed lines*). These disorders include neurofibromatosis type one (NF1), Noonan syndrome (NS), Noonan syndrome with multiple lentigines (NSML), capillary malformation–arteriovenous malformation syndrome (CM-AVM), Costello syndrome (CS), cardiofaciocutaneous syndrome (CFC), and Legius syndrome. RAS/MAPK, RAS protein family/mitogen-activated protein kinase. (*From Rauen KA. The RASopathies. Annu Rev Genom Hum Genet. 2013;14:355–369.*)

Chapter 101

Signaling Pathway Disorders

Chad R. Haldeman-Englert and Anne M. Slavotinek

An increasing number of defined molecular genetic etiologies explain many multiple congenital anomaly (MCA) syndromes. Several themes have emerged: (1) many clinical disorders that were believed to represent a single entity have multiple genetic etiologies, often within genes that are functionally related; (2) many disorders believed to be distinct have common underlying genetic bases; and (3) teratogens and genetic disorders with similar clinical features can often be understood in the context of shared underlying pathology.

It is useful to consider MCA syndromes as members of a group of disorders based on shared or overlapping clinical findings and related causative genes that act in the same developmental or metabolic pathway.

101.1 RAS/MAPK Pathway

Chad R. Haldeman-Englert and Anne M. Slavotinek

The RASopathies comprise a clinically defined group of conditions caused by germline pathogenic variants in genes encoding the components or regulators of the renin-angiotensin system (RAS)/mitogen-activated protein kinase (MAPK) pathway. This pathway is one of the most important signaling pathways in human development (Fig. 101.1). Signaling is initiated when one of several growth factors or cytokines binds extracellularly to a transmembrane receptor tyrosine kinase (RTK), which transmits the signal to activate of one of several intracellular RAS proteins, such as HRAS, KRAS, or NRAS. Phosphorylation then occurs in a stepwise manner to one or more RAF proteins (ARAF, BRAF, and/or CRAF), and subsequently to MEK1 and/or MEK2, and then ERK1 and/or ERK2. Activation of ERK1/2 has downstream targets including transcription factors, membrane proteins, and other protein kinases that direct cellular growth and differentiation.

More than 20 genes implicated in RAS/MAPK signaling have been implicated in human disorders, most with some degree of clinical overlap. Common RASopathies include **Noonan syndrome (NS),** NS with multiple lentigines, Costello syndrome, cardiofaciocutaneous (CFC) syndrome, neurofibromatosis type one (NF1), Legius syndrome, and capillary malformation–arteriovenous malformation syndrome (Table 101.1).

NS represents the canonical RASopathy and is an autosomal dominant disorder resulting from pathogenic variants in several genes in the RAS/MAPK pathway. NS occurs in an estimated 1 in 1,000-2,500 live births. Approximately 30–75% of the cases are familial, and the condition typically exhibits autosomal dominant inheritance, although the *LZTR1* gene can be associated with autosomal dominant or autosomal recessive inheritance. Pathogenic variants in RAS/MAPK genes are found in ~70% of individuals with NS, with missense variants activating the *PTPN11* gene that encodes the nonreceptor protein tyrosine phosphatase SHP-2; this is observed in 50% of affected individuals. Pathogenic variants involving *SOS1* occur in 10–13% of affected individuals; variants in *RAF1* and *RIT1* each occur in 5% of patients, and variants in *KRAS*, *BRAF*, *MAP2K1, LZTR1,* and *NRAS* and duplications of the 12q24 region containing the *PTPN11* gene are rare. The strong clinical overlap between NS and other RASopathies, such as CFC syndrome, is due to the involvement of the same pathway and often identical genes in pathogenesis.

Common features in NS comprise short stature, a characteristic pattern of facial anomalies including ptosis, wide-spaced eyes with down-slanting palpebral fissures, epicanthal folds, anomalous and low-set ears and micrognathia, congenital heart disease, chest deformities with pectus excavatum and/or pectus carinatum, a short or wide neck with a low posterior hairline, and cryptorchidism

Table 101.1 Genes and Features of the RAS/MAPK Pathway

SYNDROME	RAS/MAPK PATHWAY GENE	PROTEIN	PROTEIN FUNCTION	CLINICAL PHENOTYPE
Noonan syndrome	*PTPN11* *SOS1* *RAF1* *KRAS* *NRAS* *SHOC2* *CBL* *RIT1*	SHP2 SOS1 CRAF KRAS NRAS SHOC2 CBL RIT1	Phosphatase RasGEF Kinase GTPase GTPase Scaffolding E3 ubiquitin ligase GTPase	Craniofacial dysmorphic features, including a broad forehead, hypertelorism, down-slanting palpebral fissures, ptosis, a high-arched palate, and low-set, posteriorly rotated ears; congenital heart defects; short stature; undescended testicles; ophthalmologic abnormalities; bleeding disorders; normal neurocognitive function or mild impairment; predisposition to cancer
Noonan syndrome with multiple lentigines	*PTPN11* *RAF1*	SHP2 RAF1/CRAF	Phosphatase Kinase	Same as Noonan syndrome, but with possible development of multiple skin lentigines as individuals age; unclear predisposition to cancer
Capillary malformation–arteriovenous malformation	*RASA1*	p120-RasGAP	RasGAP	Multifocal capillary malformations, which may be associated with arteriovenous malformations and fistulae; unclear predisposition to cancer
Costello syndrome	*HRAS*	HRAS	GTPase	Craniofacial features similar to those of Noonan syndrome but potentially more coarse; congenital heart defects; failure to thrive; short stature; ophthalmologic abnormalities; multiple skin manifestations, including papilloma; normal neurocognitive function or mild impairment; hypotonia; predisposition to cancer
Cardiofaciocutaneous syndrome	*BRAF* *MAP2K1* *MAP2K2* *KRAS*	BRAF MEK1 MEK2 KRAS	Kinase Kinase Kinase GTPase	Craniofacial features similar to those of Noonan syndrome; congenital heart defects; failure to thrive; short stature; ophthalmologic abnormalities; multiple skin manifestations, including progressive formation of nevi; normal neurocognitive function or mild impairment; hypotonia; unclear predisposition to cancer
Neurofibromatosis type 1	*NF1*	Neurofibromin	RasGAP	Café-au-lait maculae; intertriginous freckling; neurofibromas and plexiform neurofibromas; iris Lisch nodules; osseous dysplasia; optic pathway glioma; normal neurocognitive function or mild impairment; predisposition to other cancers
Legius syndrome	*SPRED1*	SPRED1	SPROUTY-related, EVH1 domain–containing protein 1	Café-au-lait maculae; intertriginous freckling; macrocephaly; normal neurocognitive function or mild impairment; no apparent predisposition to cancer

Modified from Rauen KA. The RASopathies. *Annu Rev Genom Hum Genet*. 2013;14:355–369. Table 3.

(Table 101.2 and Fig. 101.2). The pattern of congenital heart disease typically involves right-sided lesions, most frequently presenting with pulmonary valvular stenosis and hypertrophic cardiomyopathy, but atrial and ventricular septal defects, branch pulmonary artery stenosis, tetralogy of Fallot, and coarctation of the aorta have all been described. Children with NS can manifest developmental delays in association with hypotonia and may have challenges with articulation and coordination. High-frequency sensorineural hearing loss is common and should be considered in patients with language delays. Hepatosplenomegaly, low levels of clotting factors XI and XII, and primary lymphatic anomalies have also been noted; patients may rarely develop acute lymphoblastic leukemia or juvenile myelomonocytic leukemia (JMML). Puberty may be delayed, and an adult height that reaches the lower limit of the typical range can be achieved by the end of the second decade. Other distinctive phenotypes include NS-like disorder with loose anagen hair caused by *SHOC2* variants and NS-like disorder with or without JMML caused by *CBL* variants.

DIAGNOSIS

Initial suspicion of a RASopathy generally depends on recognition of one or more characteristic features associated with the various conditions. Genetic testing includes a panel of genes including those in the RAS/MAPK pathway. Multigene panel testing is preferred over single-gene analysis due to the many overlapping symptoms seen in RASopathy disorders. Genetic testing can often be performed on blood, saliva, or a buccal swab. If a gene in the RAS/MAPK pathway is found to have a pathogenic or likely pathogenic variant, this would provide molecular confirmation of the clinical diagnosis.

TREATMENT

Management of NS is noted in Table 101.3. Human growth hormone will improve growth velocity in many individuals with NS and short stature; it is recommended for those who fall below the third percentile for height. MEK inhibitors, such as trametinib, have been used to treat refractory lymphedema or chylous effusions and possibly severe cardiac hypertrophy.

Table 101.2	Clinical Findings Associated with Noonan Syndrome
Short stature	
Failure to thrive (use of specific Noonan syndrome growth curves is recommended)	
Tall forehead	
Epicanthal folds	
Ptosis	
Blue-green irides	
Wide-spaced eyes	
Low nasal bridge, upturned nose	
Down-slanting palpebral fissures	
Low-set and posteriorly rotated ears	
Dental malocclusion	
Low posterior hairline	
Pectus excavatum	
Pectus carinatum superiorly	
Scoliosis	
Pigmented villonodular synovitis (polyarticular)	
Cubitus valgus	
Pulmonary valve stenosis (dysplastic valve)	
Hypertrophic cardiomyopathy	
Atrial septal defect, ventricular septal defect	
Lymphedema	
Nevi, lentigines, café-au-lait spots	
Cryptorchidism	
Small penis	
Delayed puberty	
Bleeding disorders, including thrombocytopenia and coagulation factor deficiencies	
Leukemia, myeloproliferative disorders, other malignancies	
Cognitive delay	

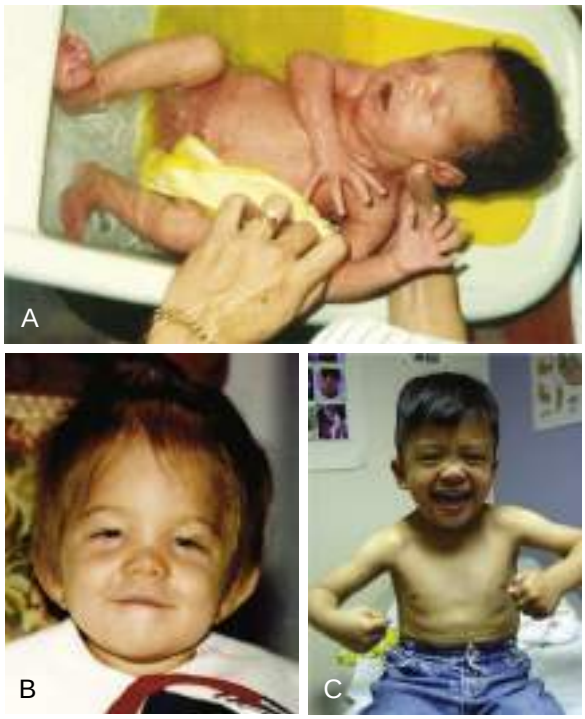

Fig. 101.2 Noonan syndrome. **A**, Newborn. **B**, Toddler. **C**, Affected male. Note the down-slanting palpebral fissures, low-set ears, elevated left shoulder secondary to scoliosis, and wide-spaced nipples. (*From Jones KL, Jones MC, Del Campo M, eds. Smith's Recognizable Patterns of Human Malformation, 8th ed. Philadelphia: Elsevier; 2022: Fig. 1AC, p. 150 and Fig. 2A, p. 151; **A** and **B** courtesy Dr. Jacqueline Noonan, University of Kentucky, Lexington, Kentucky.*)

NEUROFIBROMATOSIS

NF1 is a multisystem disorder that primarily abstractly involves the skin and peripheral nervous system (see Chapter 636.1). NF1 is associated with marked clinical variability. NF1 is inherited in an autosomal dominant manner. The disorder is caused by pathogenic variants in the *NF1* gene, which encodes neurofibromin and functions as a regulator of RAS signaling (see Table 101.1 and Fig. 101.1).

LEGIUS SYNDROME

Legius syndrome is a RASopathy caused by pathogenic variants in *SPRED1,* which encodes an HRAS regulator. Individuals with Legius syndrome present with typical multiple café-au-lait macules inherited as an autosomal dominant trait but do not develop the serious medical complications of NF1.

101.2 Sonic Hedgehog Pathway

Chad R. Haldeman-Englert

The Hedgehog signaling pathway plays numerous tissue-specific critical roles during embryogenesis and postnatal life. Disruption of specific steps in this pathway result in a variety of related developmental disorders and anomalies (Fig. 101.3). Activation of this pathway in the child or adult may lead to abnormal cellular proliferation and cancer. Three genes, Sonic (SHH), Indian (IHH), and Desert (DHH), comprise the hedgehog family, with SHH being the most widely expressed. These genes encode secreted signaling molecules important in cellular differentiation, proliferation, and survival. Secreted SHH acts as a *ligand* for specific cellular receptors to have a signal transduced by other components of the pathway to regulate downstream gene transcription. The SHH ligand is expressed in the embryo in regions important for development of the brain, face, limbs, and the gut.

Deleterious sequence variants in *SHH* can cause **holoprosencephaly** (see Fig. 100.7), a variably severe, midline defect associated with clinical effects ranging from cyclopia to a single maxillary incisor with close spacing of the ocular orbits. The SHH protein is processed by proteolytic cleavage to an active N-terminal form, which is then further modified by the addition of cholesterol. The steroidal alkaloid cyclopamine exerts a teratogenic effect by inhibiting cholesterol modification of SHH and can result in holoprosencephaly in sheep. In humans, a defect in cholesterol biosynthesis involving the recessive delta-7-dehydrocholesterol reductase gene *(DHCR7)* results in **Smith-Lemli-Opitz syndrome** (SLOS) (see Chapter 106).

In addition to microcephaly and holoprosencephaly, patients with SLOS (see Fig. 101.3) display syndactyly, classically of the second and third toes, postaxial polydactyly of the hands and feet, an upturned or anteverted nose, ptosis, and cryptorchidism.

The cholesterol-modified active form of SHH binds to its transmembrane receptor Patched (PTCH1). This SHH-PTCH1 complex then inhibits the activity of the transmembrane protein Smoothened (SMO). Because SMO normally acts to suppress downstream targets, the GLI family of transcription factors, inhibition of SMO by PTCH1 results in activation of GLI1, GLI2, and GLI3. Pathogenic variants resulting in activation of *SMO* can be oncogenic, particularly in basal cell carcinomas and medulloblastomas. In addition, *PTCH1* and its orthologue, *PTCH2*, act as tumor suppressors, and somatic, inactivating sequence variants can be associated with loss of tumor suppressor function. Relatedly, germline inactivating variants in *PTCH1* result in **Gorlin syndrome** (see Fig. 101.3), an autosomal dominant disorder characterized by a broad face, dental anomalies, rib defects and shortened

Table 101.3 Management of Noonan Syndrome

	AT DIAGNOSIS	AFTER DIAGNOSIS	IF SYMPTOMATIC
General	Complete physical and neurologic examination; medical genetics consultation to confirm diagnosis, consider molecular genetic testing and genetic counseling	Yearly complete physical and neurologic examination; return to geneticist if genotype negative or for multisystem assessment; genetic counseling at adolescence or when a young adult	Orchiopexy by age 1 year for cryptorchidism; if lymphoedema, refer to specialty clinic; brain and cervical spine MRI if intracranial pressure increases; electroencephalogram and referral to neurologist if seizures suspected
Developmental	Multidisciplinary developmental assessment	Developmental screening yearly for children age 5-18 years	Neuropsychologist testing if screening abnormal; referral to early intervention if delays detected before age 3 years; individual education plan for children age 5-18 years with delays
Dental	First dental assessment between age 1 year and 2 years	Yearly dental assessment	—
Growth and feeding	Plot growth on curves for Noonan syndrome	Plot growth on curves for Noonan syndrome 3 times per year until age 3 years, then yearly	Refer to gastroenterologist for feeding problems or recurrent vomiting, or if evidence of growth failure without comorbid cause exists; thyroid function tests if signs or symptoms of hypothyroidism
Cardiovascular	Cardiac examination, electrocardiogram, echocardiogram	Follow up on the basis of initial findings. If initial assessment normal, repeat every 5 years	—
Ophthalmologic	Baseline eye examination Baseline audiology examination	Repeat every 2 years, sooner if indicated	—
Audiologic	Baseline audiology examination	Repeat if recurrent otitis media or speech delay	Refer to ear, nose, and throat specialist for recurrent otitis media or serous otitis; hearing aids or classroom interventions for hearing loss
Hematologic	Complete blood cell count with differential, and prothrombin time or activated partial thromboplastin time	Repeat complete blood cell count with differential and prothrombin time or activated partial thromboplastin time if age 6-12 months at initial screen Preoperatively: complete blood cell count with differential and prothrombin time or activated partial thromboplastin time, second tier (in consultation with hematologist) factor IX, XI, and XII concentrations, von Willebrand factor, platelet aggregation	Prothrombin time or activated partial thromboplastin time if bleeding abnormal or persistent, refer to hematologist; complete blood cell count with differential for splenomegaly; complete blood cell count with differential and liver function studies for hepatosplenomegaly
Renal	Kidney ultrasound	—	—
Skeletal	Clinical assessment of spine with radiology if indicated by examination	Repeat spinal examination yearly through adolescence; radiology and referral to orthopaedic specialist if abnormal	—

From Roberts AE, Allanson JE, Tartaglia M, Gelb BD. Noonan syndrome. *Lancet*. 2013;381:333–342.

metacarpals; basal cell nevi that can undergo malignant transformation; and an increased risk of cancers, including medulloblastomas and rhabdomyosarcomas. *GLI1* amplification has been found in several human tumors, including glioblastoma, osteosarcoma, rhabdomyosarcoma, and B-cell lymphomas. Likewise, pathogenic variants in *GLI3* can cause **Greig cephalopolysyndactyly syndrome** (GCPS), **Pallister-Hall syndrome** (PHS), postaxial polydactyly type A (and A/B), and preaxial polydactyly type IV (see Fig. 101.3). GCPS consists of wide-spaced eyes, syndactyly, additional digits on the radial border of the hand or inner aspect of the foot, termed preaxial polydactyly, and broad thumbs and halluces. PHS is an autosomal dominant disorder characterized by postaxial polydactyly, syndactyly, hypothalamic hamartomas, imperforate anus, and occasionally holoprosencephaly. GLI3 binds to CBP, the protein that is haploinsufficient in **Rubinstein-Taybi syndrome**.

Disorders that are caused by pathogenic variants in genes that function together in a developmental pathway typically have overlapping clinical manifestations. The overlapping features result from the embryonic tissues in which SHH is important for development, including the brain, face, limbs, and gut as previously noted. Brain defects are present in holoprosencephaly (see Fig. 100.7), SLOS, and PHS. Facial anomalies are found in holoprosencephaly, SLOS, Gorlin syndrome, GCPS, and PHS. Limb defects occur in SLOS, Gorlin syndrome, GCPS, PHS, and the polydactyly syndromes. Overexpression, or activating sequence variants, affecting the SHH pathway results in cancer,

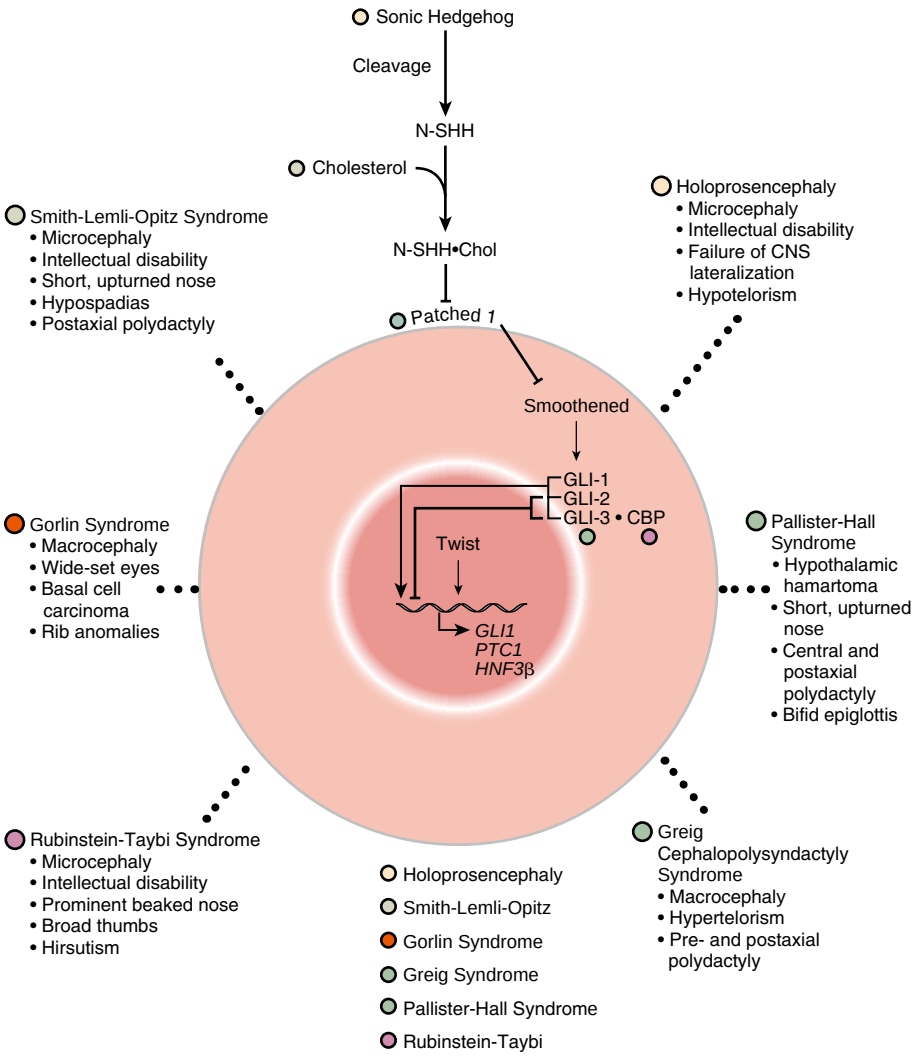

Fig. 101.3 Signaling components and clinical features of the sonic hedgehog (SHH) signaling pathway. Deleterious sequence variants in genes that function together in a developmental pathway typically have overlapping clinical manifestations. Several components of the SHH pathway have been identified and their relationships elucidated. Pathogenic variants in several members of this pathway result in phenotypes with facial anomalies, as seen in holoprosencephaly, Smith-Lemli-Opitz syndrome, Gorlin syndrome, Greig cephalopolysyndactyly syndrome, Pallister-Hall syndrome, and Rubinstein-Taybi syndrome. CNS, Central nervous system.

including basal cell carcinomas, medulloblastomas, glioblastomas, and rhabdomyosarcomas.

101.3 Ciliopathies

Chad R. Haldeman-Englert

Cilia are microtubule-containing organelles that project from the surface of most human cells. Three types of cilia exist in humans: motile cilia, nodal cilia, and primary cilia. Motile cilia typically contain a sweeping motion and play important roles in the respiratory epithelium (see Chapter 455 for discussion of structure of cilia and their role in primary ciliary dyskinesia and respiratory disorders). Nodal cilia play a very brief role during embryonic development, and their whirling flow in the Henson's node during gastrulation is central in determining the left-right body axis. Defects in this process manifest as alterations in body orientation, including situs inversus and heterotaxy (see Chapter 480.11).

Primary cilia are nonmotile and are present in nearly all cells. The membrane of each cilium is continuous with the plasma membrane. There are unique differences in its membrane that allow cilia to detect changes in the extracellular environment to function as mechanoreceptors, osmosensors, and chemosensors and convey this information via various intracellular signaling pathways to regulate diverse cellular processes (proliferation, polarity, nerve growth, differentiation, and tissue maintenance). These pathways may include Hedgehog (HH), G-protein–coupled receptors (GPCRs), Wingless and Int-1 (WNT), RTKs, and transforming growth factor β (TGF-β).

Pathogenic changes to genes that control the function and signaling within the cilia give rise to conditions called *ciliopathies*. Given the extent of cilia located throughout the human body, symptoms associated with ciliopathies can be variable and extensive. Defects can occur to many different organs during fetal development through adulthood. Organ systems generally affected in ciliopathies include the brain, eyes, liver, kidneys, and skeleton (Fig. 101.4). There are many well-described ciliopathy effects, including retinitis pigmentosa, hearing loss, infertility, primary ciliary dyskinesia, polycystic kidney disease, and nephronophthisis, as well as a number of syndromes including Joubert, Bardet-Biedl, Meckel-Gruber, and orofaciodigital syndromes (Table 101.4).

The diagnosis of a ciliopathy is generally based on recognition of the clinical features followed by either targeted gene testing, a multigene panel, or exome/genome sequencing. If a diagnosis is established with molecular testing, additional studies may be indicated to evaluate for additional medical and developmental concerns. Surveillance for potential changes to the kidneys, liver, and eyes should be routinely performed.

101.4 Craniosynostoses

Chad R. Haldeman-Englert

To permit appropriate brain growth, the cranial sutures do not completely fuse until adulthood. Growth of the skull occurs perpendicular to the direction of each suture. Craniosynostosis arises when one or more cranial sutures prematurely ossify, which usually becomes apparent between the third trimester of pregnancy and the first year of life (see Chapter 631.10). The shape of the skull is often the clue to the affected suture (Fig. 101.5). Most patients with craniosynostosis do not have additional syndromic features; this may depend on the sutures involved. Patients with bicoronal or multisuture craniosynostosis often have an associated genetic syndrome, whereas patients with isolated sagittal craniosynostosis do not have features of an identifiable genetic cause.

Craniosynostosis can result from reduced intrinsic factors (poor brain growth), increased extrinsic forces (primiparity, multiple pregnancy, fetal position, high birth weight), or genetic abnormalities leading to uncontrolled cranial bone growth. Genes commonly associated with syndromic craniosynostosis include three fibroblast growth factor receptor genes *(FGFR1*, *FGFR2*, *FGFR3)*, *TWIST1*, and *EFNB1*. *FGFR1*, *FGFR2*, and *FGFR3* are associated with recognizable conditions such as Crouzon, Pfeiffer, Apert, and Muenke syndromes; *TWIST1* with Saethre-Chotzen syndrome; and *EFNB1* with craniofrontonasal syndrome. Distinguishing between the FGFR-related craniosynostosis syndromes can often be made based on additional features, particularly of the hands and feet (see Chapter 631.10).

Other pathogenic gene variants have been identified in patients with syndromic and nonsyndromic craniosynostosis (Table 101.5). Given the overlap of clinical features of many of the craniosynostosis conditions, appropriate genetic testing for patients with craniosynostosis could include either a multigene panel or exome/genome sequencing. The diagnosis is made based on the genetic abnormality and clinical features.

Management of patients with craniosynostosis is often complex and performed with a multidisciplinary team of various specialists, including audiology, dentistry, genetics, neurosurgery, ophthalmology, orthodontics, otolaryngology, pediatrics, plastic surgery, and speech therapy (see Chapter 631.10).

Table 101.5 Core Genes For Which Specific Types of Variants Are Associated with Craniosynostosis in More Than Half of Affected Individuals

GENE (MIM#)	INHERITANCE PATTERN	CLINICAL DISORDER (MIM#)	PREVALENCE (%)	TYPICAL SUTURE FUSION	MAJOR PHENOTYPIC FEATURES
ASXL1 (612990)	AD (n)	Bohring-Opitz syndrome (605039)	—	Metopic	Forehead nevus flammeus, ulnar deviation and flexion of wrists and metacarpophalangeal joints, severe intellectual disability
CDC45 (603465)	AR	—	—	Coronal	Thin eyebrows, small ears, variable short stature
COLEC11 (612502)	AR	3MC syndrome 2 (265050)	—	Metopic	Hypertelorism, blepharoptosis, arched eyebrows, cleft lip/palate, hearing loss, radioulnar synostosis, genital and vesicorenal anomalies
EFNB1 (300035)	XLD (male sparing)	Craniofrontonasal syndrome (304110)	0.8	Coronal	Hypertelorism, notched nasal tip, chest anomalies, longitudinal splitting of nails; heterozygous females more severely affected than hemizygous males
ERF (611888)	AD	ERF-related craniosynostosis (600775)	1.1	Multisuture	Exorbitism, midface hypoplasia, Chiari type I malformation, postnatal onset of craniosynostosis
FGFR1 (136350)	AD	Pfeiffer syndrome (101600)	—	Coronal	Mild craniofacial features, broad medially deviated thumbs and halluces, cutaneous syndactyly, specific amino acid substitution p.Pro252Arg
FGFR1	AD (n)	Osteoglophonic dysplasia (166250)	—	Multisuture	Prominent brow ridges, depressed nasal bridge, rhizomelic dwarfism, localized lytic lesions of metaphyses
FGFR2 (176943)	AD (n)	Apert syndrome (101200)	3.6	Coronal, multisuture	Midface hypoplasia, dilated cerebral ventricles, complex syndactyly of the hands and feet
FGFR2	AD (n)	Beare-Stevenson syndrome (123790)	*	Multisuture	Choanal atresia, prominent umbilical stump, furrowed scalp/neck skin, acanthosis nigricans in survivors
FGFR2	AD	Crouzon syndrome (123500)	2.4	Multisuture, coronal, sagittal	Exorbitism, midface hypoplasia, beaked nose ("crouzonoid" facies), clinically normal hands and feet
FGFR2	AD (n)	Pfeiffer syndrome (101600)	0.8	Multisuture	Broad thumbs and halluces; in severe cases, cloverleaf skull, brain anomalies, tracheal sleeve, fused elbows
FGFR2	AD (n)	Bent bone dysplasia (614592)	*	Coronal	Osteopenia, reduced mineralization of the calvaria, bent long bones; perinatal lethal
FGFR3 (134934)	AD	Muenke syndrome (602849)	4.0	Coronal	Defined by specific amino acid substitution p.Pro250Arg; may include sensorineural hearing loss, mild brachydactyly, cone-shaped epiphyses
	AD (n)	Crouzon/acanthosis nigricans (612247)	0.4	Multisuture	Crouzonoid facies, choanal stenosis, hydrocephalus, acanthosis nigricans; specific amino acid substitution p.Ala391Glu
	AD (n)	Thanatophoric dysplasia II (187601)	*	Multisuture	Lethal skeletal dysplasia, micromelic limb shortening, straight femora; specific amino acid substitution p.Lys650Glu
IHH (600726)	AD	Philadelphia craniosynostosis (185900)	—	Sagittal	Cutaneous and osseous syndactyly

Table 101.5 Core Genes For Which Specific Types of Variants Are Associated with Craniosynostosis in More Than Half of Affected Individuals—cont'd

GENE (MIM#)	INHERITANCE PATTERN	CLINICAL DISORDER (MIM#)	PREVALENCE (%)	TYPICAL SUTURE FUSION	MAJOR PHENOTYPIC FEATURES
IL11RA(600939)	AR	Craniosynostosis and dental anomalies (614188)	—	Multisuture	Maxillary hypoplasia, delayed tooth eruption, supernumerary teeth, minor digit abnormalities, conductive hearing loss
MEGF8(604267)	AR	Carpenter syndrome 2 (614796)	—	Metopic	Hypertelorism, arched eyebrows, lateralization defects, brachydactyly, syndactyly, preaxial polydactyly
MSX2(123101)	AD	Boston craniosynostosis (604757)	—	Sagittal, coronal, multisuture	None diagnostic; syndrome defined by specific amino acid substitutions p.Pro148His, p.Pro148Leu
POR(124015)	AR	Antley-Bixler syndrome (201750)	—	Bicoronal, multisuture	Choanal stenosis, radiohumeral synostosis, bowed femora, multiple joint contractures, genital abnormalities; abnormal steroidogenesis
RAB23(606144)	AR	Carpenter syndrome 1 (201000)	—	Multisuture	Obesity, cardiac defects, polysyndactyly, brachydactyly, genu valgum, hypogenitalism, umbilical hernia, learning disability
RUNX2(600211)	AD (n)	—	—	Multisuture	None diagnostic; syndrome defined by specific gene duplication
SKI(164780)	AD (n)	Shprintzen-Goldberg syndrome (182212)	—	Sagittal, multisuture	Hypertelorism, micrognathia, high-arched palate, arachnodactyly, joint contractures, pectus deformity, aortic root aneurysm, mitral valve prolapse, learning disability
TCF12(600480)	AD	TCF12-related craniosynostosis (615314)	1.3	Coronal	Resembles mild Saethre-Chotzen syndrome; diagnosis defined by presence of mutations in the gene, ~50% nonpenetrance
TWIST1(601622)	AD	Saethre-Chotzen syndrome (101400)	3.6	Coronal	Low frontal hairline, hypertelorism, eyelid ptosis, down-slanting palpebral fissures, blocked tear ducts, small ears with prominent crus helicis
WDR35(613602)	AR	Cranioectodermal dysplasia 2 (613610)	—	Sagittal	Facial dysmorphism, narrow thorax, short long bones, brachydactyly, sparse hair, hypoplastic teeth, cystic kidneys, hepatic fibrosis
ZIC1(600470)	AD (n)	ZIC1-related craniosynostosis	0.2	Coronal	Severe learning disability

The prevalence figures are for percent total craniosynostosis cases with specified mutation, from the cohort attending the Craniofacial Unit, Oxford, born between 1998 and 2008 (n = 531) and surgically treated before end of 2013.
*Usually lethal at birth.
AD, Autosomal dominant; AR, autosomal recessive; XLD, X-linked dominant; (n), usually arises by new mutation.

Chapter 102

Chromatin Regulatory Disorders

Kosuke Izumi

Pathogenic variants in genes that encode chromatin proteins that orchestrate gene expression in a range of human tissues frequently cause pediatric developmental disorders that include developmental delay/intellectual disability and facial dysmorphisms.

KABUKI SYNDROME

Kabuki syndrome (MIM: 147920 and 300867) is a genetic disorder characterized by facial features, mild to moderate intellectual disability, growth deficiency, and skeletal anomalies. Kabuki syndrome was originally named "Kabuki make-up syndrome" due to patients' facial features, suggestive of those of Kabuki actors (Fig. 102.1). Approximately 1:32,000 to 1:86,000 individuals are estimated to have Kabuki syndrome.

Molecular Etiology

Heterozygous *KMT2D* pathogenic variants (~90%), and hemizygous (in males) or heterozygous (in females) *KDM6A* pathogenic variants (~10%) cause classic Kabuki syndrome; *KMT2D* encodes a histone methyltransferase and *KDM6A* encodes a histone demethylase. Both of these histone modification enzymes regulate histone codes to orchestrate global gene expression. Most genetic changes causing Kabuki syndrome are due to de novo changes. However, because *KDM6A* locates on the X chromosome, its inheritance pattern can be complex, with most *KDM6A* pathogenic variants being de novo, but maternal transmission of pathogenic *KDM6A* variants has been seen. Kabuki-like syndromes share many clinical features but do not have pathogenic variants in *KMT2D* or *KDM6A*.

Clinical Features of Kabuki Syndrome (Table 102.1)

Physical features: Common features of Kabuki syndrome include long palpebral fissures with eversion of the lateral third of the lower eyelid, arched broad eyebrows, a short columella, depressed nasal tip, large, prominent or cupped ears, and persistent fingertip pads (see Fig. 102.1). Dental anomalies such as widely spaced teeth and hypodontia are commonly seen.

Growth and feeding: Individuals with Kabuki syndrome often have short stature and feeding difficulties. The degree of difficulty with feeding and growth varies, but it is not uncommon for infants or children with Kabuki syndrome to require feeding tubes.

Development and behavior: Global developmental delay is commonly seen in children with Kabuki syndrome, and individuals with Kabuki syndrome typically have mild to moderate intellectual disability. Most individuals speak and ambulate independently. Although infrequent, autism is seen in Kabuki syndrome.

Neurology: Hypotonia is a common feature. Structural brain differences are typically not seen, but individuals with Kabuki syndrome have an ~30% risk for seizures.

Congenital heart disease: Approximately 70% of children with Kabuki syndrome have a structural heart defect. The most common types include coarctation of the aorta and septal defects, although complex congenital heart disease is also seen.

Gastrointestinal: In addition to feeding difficulties, structural anomalies such as anal atresia, congenital diaphragmatic hernia (CDH), and cholestasis can be seen.

Endocrinology: Hypoglycemia or hyperinsulinemia can be seen, and some females with Kabuki syndrome have early premature thelarche.

Ophthalmology: The common everted lower eyelid seen in Kabuki can lead to excessive tearing. Other eye differences can include ptosis, cataracts, corneal differences, blue sclerae, or strabismus.

Ear, nose, and throat: Hearing loss, mainly conductive hearing loss, and more rarely sensorineural hearing loss, is seen in up to 50% of individuals with Kabuki syndrome. Chronic otitis media is a major cause of conductive hearing loss. Individuals with Kabuki syndrome can also have cleft lip and/or palate.

Genitourinary: Kidney and urinary tract disorders occur in more than 25% and can include abnormal renal location, duplicated collecting system, hypospadias and cryptorchidism in males, and hypoplastic labia in females.

Musculoskeletal: Many individuals have joint hypermobility that can manifest with scoliosis. Spinal abnormalities such as sagittal clefts and hemivertebrae can be seen in individuals with Kabuki syndrome.

Immunology and hematology: Frequent and recurrent infections including sinopulmonary infections and otitis media are common in children with Kabuki syndrome. Some can have hypogammaglobulinemia and immune dysfunction, with some needing regular intravenous immunoglobulin injection. Autoimmune disorders such as vitiligo, immune thrombocytopenia, hemolytic anemia, and coagulopathy are also common.

Molecular diagnosis of Kabuki syndrome: This is often made using sequencing and deletion/duplication analyses of *KMT2D* and *KDM6A* following clinical suspicion or by exome sequencing. Often, parental testing is performed to determine whether the identified variant is de novo. In addition, a DNA methylation profile has been identified for Kabuki syndrome caused by *KMT2D* and *KDM6A* variants, and a matching profile can support the diagnosis in the context of uncertain pathogenicity of identified *KMT2D* or *KDM6A* variants.

Fig. 102.1 Physical features of Kabuki syndrome. A, Patient with *KMT2D* c.10201C>T, p.Gln3401* pathogenic variant. Dysmorphic features include long and up-slanted palpebral fissures and large prominent ears. B, Patient with *KDM6A* c.3717G>A; p.Trp1239* pathogenic variant. Dysmorphic features include long and up-slanted palpebral fissures.

RUBINSTEIN-TAYBI SYNDROME

Rubinstein-Taybi syndrome (RSTS; MIM 180849 and 613684) is characterized by down-slanted palpebral fissures, broad thumb and first toe, developmental delay/intellectual disability, and short stature (Fig. 102.2). It occurs in ~1 in 125,000 births.

Molecular Etiology

RSTS is caused by heterozygous pathogenic variants in *CREBBP* and *EP300* genes. These genes encode transcriptional co-activators as histone lysine acetyltransferases. RSTS is caused by pathogenic variants, typically de novo in *CREBBP* in 55% and in *EP300* in ~8%. *CREBBP* pathogenic variants tend to result in more typical RSTS features, with *EP300* alterations resulting in a wider, often milder, phenotypic spectrum.

Table 102.1 Kabuki Phenotype Scoring List

CLINICAL FEATURES	POSSIBLE SCORE	FEATURES
Facial features	0-5 points (0-3 features = 1 point; 4-6 = 2 point; 7-9 = 3 point; 10-12 = 4 point; 13-15 = 5 point)	Long palpebral fissures; everted lower eyelids; large dysplastic ears; arched eyebrows, sparse lateral one third; flat nasal tip; abnormal dentition; high/cleft palate; strabismus; blue sclera; micrognathia; ptosis; broad nasal root; oligodontia; thin upper and full lower lip; lip nodules
Limb/extremity features	Up to 1 point (0-1 features = 0 point; 2-4 = 1 point)	Persistent fetal pads; brachy- or clinodactyly; lax joints; hip dislocation
Microcephaly	1 point	
Short stature	1 point	
Heart	1 point	
Kidney	1 point	
Sum	0-10	

From Wang YR, Xu NX, Wang J, Wang XM. Kabuki syndrome: review of the clinical features, diagnosis and epigenetic mechanisms. *World J Pediatr*. 2019;15:528–535. Table 1.

Fig. 102.2 Rubinstein-Taybi syndrome. A, A 21-month-old child. Note the hirsutism, down-slanting palpebral fissures, maxillary hypoplasia, prominent nose with nasal septum extending below alae nasi, and low, posteriorly rotated ears. B, Broad thumbs with radial angulation and persistent fingertip pads. *(A courtesy Dr. Marilyn C. Jones, Children's Hospital, San Diego, California; from Jones KL, Jones MC, Del Campo M, eds.* Smith's Recognizable Patterns of Human Malformation, *8th ed. Philadelphia: Elsevier; 2022, Fig. 1C, p. 108 and Fig. 2C, p. 109.)*

Clinical Features of RSTS

Physical features: Characteristic facial features include arched eyebrows, down-slanting palpebral fissures, low-hanging columella, and grimacing smile. Individuals often have broad thumbs and/or halluces.

Growth: Prenatal growth is usually normal, but most individuals have short stature caused by slow postnatal growth. Obesity may be seen during childhood or adolescence.

Development: Global developmental delay is typical with milder features often seen in individuals with *EP300* pathogenic variants. The average age of walking is 30 months and first words 25 months. Speech delay occurs in 90% of children and some remain nonverbal. Features of autism spectrum disorder, as well as impulsivity, distractibility, mood instability, and stereotypies can be seen.

Intellectual disability: This is in the moderate to severe range is typical for individuals with RSTS, with an IQ range of 25-79. Verbal ability is typically poorer than other skills.

Neurologic: Craniospinal and posterior fossa abnormalities, such as Chiari malformation or cervical cord compression, can be seen as well as seizures or abnormal electroencephalogram (EEG).

Eye findings: These can include refractory errors, ptosis, cataracts, coloboma, nystagmus, strabismus, and glaucoma.

Congenital heart defects: These are seen in ~30% of individuals with RSTS. Common defects include atrial septal defect, ventricular septal defect, patent ductus arteriosus, coarctation of the aorta, pulmonary stenosis, aortic stenosis, and vascular ring.

Respiratory: Obstructive sleep apnea is common.

Genitourinary: Kidney anomalies include hydronephrosis and duplications. Many males have cryptorchidism.

Gastrointestinal: Feeding problems due to gastroesophageal reflux and constipation are common.

Musculoskeletal: Joint laxity, scoliosis, and vertebral abnormalities can be seen. Hypotonia is common.

Molecular diagnosis: This can be made using a gene panel (sequencing and deletion/duplication analyses of *CREBBP* and *EP300*). For individuals with clinical features with atypical RSTS features, exome sequencing is recommended.

CORNELIA DE LANGE SYNDROME

Cornelia de Lange syndrome (CdLS; MIM 122470) is characterized by craniofacial features including synophrys, high-arched eyebrows and thin downturned upper lip, hirsutism, intellectual disability, microcephaly, growth retardation, limb anomalies, such as micromelia, phocomelia, and oligodactyly, and several other systemic abnormalities. Its population incidence is approximately 1 in 50,000.

Molecular Mechanism of CdLS

CdLS is caused by pathogenic variants in genes encoding the structural and regulatory components of the cohesin complex. Variants have been found in *NIPBL*, *HDAC8*, *RAD21*, *SMC1A,* and *SMC3* in CdLS. The cohesin complex is composed of SMC1A, SMC3, RAD21, and other subunits that comprise a ringlike structure that "embraces" chromatin. *NIPBL* encodes a protein that controls cohesin complex genome loading. The SMC3 component of the cohesin complex becomes acetylated once loaded onto the genome and is subsequently deacetylated by HDAC8 for cohesin protein recycling. Pathogenic variants in *BRD4* are an infrequent cause of CdLS. Cohesin has shown to play a key role in transcriptional regulation, and global transcriptional alterations due to cohesin dysfunction are thought to lead to the pathogenesis of CdLS.

NIPBL pathogenic variants are found in approximately 60% of the individuals with CdLS and are more likely to be identified in more severely (or "classically") affected individuals, with loss-of-function variants resulting in a more severe phenotype. Pathogenic variants in *SMC1A*, *SMC3, RAD21*, *HDAC8,* and *BRD4* can be found in 1–5% of the individuals with CdLS. Pathogenic variants in all related genes are typically acquired de novo, although instances of inherited variants from minimally affected mothers have been noted for the X-linked *HDAC8* and *SMC1A* genes.

Fig. 102.3 Physical features of Cornelia de Lange syndrome. **A**, Patient with *NIPBL* c.3100_3106del; p.K1034QfsX7 pathogenic variant. Dysmorphic features include synophrys, long eyelashes, upturned nasal tip with anteverted nares, long philtrum, and micrognathia. Severe reduction defects of upper extremities are also depicted. **B**, Patient with *SMC1A* c.2077C>G; p.R693G mutation. Dysmorphic features include mild synophrys.

Clinical Manifestations of CdLS

Facial features: Include synophrys with highly arched and/or thick eyebrows, long/thick eyelashes, short nasal bridge, upturned nasal tip with anteverted nares, long and/or smooth philtrum, thin vermilion of the upper lip, downturned corners of the mouth, highly arched palate with or without cleft palate, small widely spaced teeth, and micrognathia (Fig. 102.3).

Growth failure: Prenatal-onset growth failure and microcephaly are common.

Ophthalmologic: Common manifestations include ptosis, myopia, and nystagmus.

Otolaryngologic: Sensorineural hearing impairment is common, but conductive hearing loss can be seen.

Cardiovascular: Approximately 50% of individuals with CdLS have congenital heart disease. The most common abnormalities include pulmonic or peripheral pulmonic stenosis, ventricular septal defects, atrial septal defects, coarctation or hypoplastic aortic arch, aortic valve anomaly, tetralogy of Fallot, double-outlet right ventricle, and atrioventricular canal.

Gastrointestinal: Gastroesophageal reflux disease is present in nearly all instances, and some require a feeding tube during infancy/childhood. Other rare gastrointestinal abnormalities include pyloric stenosis (4%), intestinal malrotation (2%), and CDH (1%).

Genitourinary. Renal abnormalities such as vesicoureteral reflux and cryptorchidism are common.

Skeletal: Severe abnormalities of the upper extremities are seen in 25% of individuals with classical CdLS. Upper extremity deficiencies range from severe reduction defects such as complete absence of the forearms to mild fifth finger clinodactyly (see Fig. 102.3). Radioulnar synostosis is also common.

Skin: Hypertrichosis is common, and scalp hair, typically thick, can extend onto the temporal regions.

Developmental delay/intellectual disability: Most individuals with classical CdLS demonstrate global developmental delay. The overall range of IQ levels is broad, from below 30 to 85, with an average IQ of 53. Those affected individuals with classic features are more likely to have severe to profound intellectual disability. Fifty percent of children with CdLS walk by 24 months and 95% by 10 years old. A range of behavioral issues have been reported, and behavior problems are often directly related to frustration from an inability to communicate.

Neurologic: Approximately 25% of individuals with CdLS experience seizures.

Molecular Diagnosis of CdLS: Due to a relatively high frequency of mosaic variants not detected in blood, a next-generation sequencing panel of CdLS genes (*NIPBL, SMC1A, HDAC8, SMC3, RAD21,* and *BRD4*) performed on DNA extracted from buccal cells has been recommended as the most effective way of detecting causal variants. For individuals with atypical CdLS features, exome sequencing is recommended.

Fig. 102.4 Coffin-Siris syndrome. Note the coarse face and wide mouth with full lips (**A**), and hypoplastic fifth fingernails (**B**). *(From Jones KL, Jones MC, Del Campo M, eds.* Smith's Recognizable Patterns of Human Malformation, *8th ed. Philadelphia: Elsevier; 2022, Fig. 1A and 1D, p. 819.)*

COFFIN-SIRIS SYNDROME

Coffin-Siris syndrome (CSS) is characterized by thick eyebrows, periorbital fullness, wide mouth with full lips, and coarse facial features; fifth fingernail hypoplasia; absence of terminal phalanges; hypertrichosis; developmental delay/intellectual disability; and short stature (Fig. 102.4).

Molecular Mechanism of CSS

CSS is typically caused by de novo heterozygous germline pathogenic variants in genes encoding a component of BAF (BRG1/hBRM-associated factors) complex, which belongs to the SWI/SNF chromatin remodeler complex family. Pathogenic variants have been found in *ARID1A*, *ARID1B*, *SMARCA4*, *SMARCB1*, *SMARCE1,* and *SOX11*. Variants in one of these genes can be found in ~60–70% of the patients with CSS.

Clinical Features of CSS

Facial features: Characteristic facial features of CSS include wide mouth with thick, everted upper and lower lips, broad nasal bridge with broad nasal tip, thick eyebrows, and long eyelashes. Facial features typically coarsen over time.

Growth: Prenatal growth profile tends to be normal, but postnatal weight and height measurements are usually below the 50th percentile.

Development: Global developmental delay is common and variable; children sit around 12 months, walk at around 30 months, and say their first words at 24 months. Most individuals have intellectual disability, typically moderate to severe (IQ range: 40-69). Some individuals with CSS have behavioral concerns, aggression, or autistic features.

Neurologic: The majority of children with CSS have hypotonia. Structural brain malformations such as Dandy-Walker variant, and

agenesis of the corpus callosum may be seen. Seizures occur in up to 50% of individuals. Hearing impairment can occur.

Ophthalmology: Visual impairment is common, and ocular abnormalities include ptosis, strabismus and myopia.

Gastrointestinal: Feeding issues and slow growth are common.

Genitourinary: Renal malformation such as horseshoe kidney, and genitourinary malformation such as cryptorchidism and hypospadias have been noted.

Musculoskeletal: Fifth digit nail and distal phalanx hypoplasia or aplasia, a diagnostic criterion in the pre-exome era, is commonly seen. Brachydactyly of the fifth finger, joint laxity, and scoliosis are also frequent.

Cardiac: Congenital heart defects can be seen and include ventricular septal defects, atrial septal defects, and tetralogy of Fallot.

Skin: Hirsutism and hypertrichosis are typical.

Molecular Diagnosis of CSS

For those whom clinical diagnosis of CSS is strongly suspected, CSS gene sequencing and deletion/duplication panel is recommended. For those with atypical clinical features, comprehensive genetic testing such as exome sequencing is warranted.

OTHER CHROMATIN DISORDERS

An increasing number of genetic disorders, due to mutations in genes encoding chromatin transcriptional regulatory proteins, have been identified. These disorders include CHARGE syndrome due to *CHD7* pathogenic variants, Wiedemann-Steiner syndrome due to *KMT2A* pathogenic variants, Arboleda-Tham syndrome due to *KAT6A* pathogenic variants, and Say-Barber-Biesecker/Young-Simpson syndrome due to *KAT6B* pathogenic variants. CHD7 is a chromatin remodeler protein with a chromodomain histone-modification recognition motif. *KAT6A* and *KAT6B* encode histone modification enzymes. Common manifestations of genetic diagnoses due to these chromatin remodelers and histone modification enzyme defects include developmental delay, hypotonia, and facial dysmorphisms. Some of the clinical features enable astute clinicians to distinguish between typical cases of these syndromes. However, in their atypical presentations, a clinical diagnosis may not be feasible. Exome sequencing is recommended in any children with facial dysmorphisms as well as developmental delay to detect possible chromatin disorders.

Chapter 103

Genetics of Common Disorders

Neil A. Hanchard and Brendan Lee

Common pediatric diseases, like many common adult-onset diseases, are usually multifactorial. The combination of many genes and environmental factors contribute to a complex sequence of events leading to disease. The complexity of the combination of contributing factors increases the challenge of finding genetic variants that cause disease. Genetic tools include public databases of genetic variants and the human haplotype map. Genotyping has permitted very large numbers of common genetic variants (those with population frequencies >5%) to be efficiently tested in large numbers of patients. Genetic sequencing technologies are being used to investigate the role of rare coding sequence variants in common diseases. The incorporation of these tools into large, well-designed population studies has developed into the field of **genetic epidemiology**.

103.1 Major Genetic Approaches to the Study of Common Pediatric Disorders

Neil A. Hanchard and Brendan Lee

Millions of genetic variants are present in every person. Many of these variants have no known impact on health, while others have a measurable influence. Sometimes, sequence changes in a single gene consistently cause a disease, as seen with cystic fibrosis and sickle cell anemia; more often, specific genetic changes are insufficient to determine the manifestation of a specific medical condition by themselves. Rather, these changes can contribute indirectly or partially to the development of disease, and these are best conceptualized as *modifiers* of disease risk. Figure 103.1 demonstrates the relationship between variant frequency and the relative medical impact of the allele. The spectrum of variant impact ranges widely from a slightly increased risk of illness to predetermined, fully expressed disease. Studies aimed at discovering *rare* variants with strong health effects require only small sample populations to achieve statistical significance, whereas those studying *common* variants that contribute partially to the overall effect often require much larger sample sizes because of the small impact of multiple variants.

In many cases, genetic susceptibility is the result of the cumulative risk of many common variants. For common conditions, the genetic predisposition alone is not sufficient to cause disease. Everyone inherits a different degree of disease vulnerability, which is then augmented by exposure to certain environmental or other factors. Figure 103.2 is a model for the contribution of common genetic variants to individual health. One goal of medical genetics is to identify the genes that contribute to initial genetic susceptibility and help prevent the occurrence of disease, either by avoiding inciting environmental factors or by instituting interventions that reduce risk. For persons who cross the threshold of disease, the goal is to better understand the pathogenesis in the hope that this will suggest better approaches to treatment. Common genetic variation can also influence responses to medications and the risk of adverse drug reactions, as well as augments the impact of environmental exposures.

Complex traits may be inherently difficult to study if the precision of diagnosis **(phenotype)** is low, as often occurs with neurobehavioral traits. A starting point in the genetic analysis of a complex trait, therefore, is to obtain evidence in support of a genetic contribution and to estimate the relative strength of genetic and environmental factors. Complex traits typically exhibit familial clustering but are not transmitted in a distinct pattern as seen with classical mendelian autosomal dominant or recessive inheritance. Complex traits often show variation between groups of different ancestries, possibly reflecting the differences in frequency and/or effect of genetic variants within these groups.

Assessing the potential genetic contribution begins by determining whether the trait is seen among related individuals more often than in the general population. A common measure of **familiality** is the first-degree relative risk (usually designated by the symbol λ_s), which is equal to the ratio of the prevalence rate in siblings and/or parents to the prevalence rate in the general population. The λ_s for type 1 diabetes is about 15. The relative strength of genetic and nongenetic risk factors can be estimated by variance components analysis. The **heritability** of a trait is the estimate of the fraction of the total variance contributed by genetic factors (Fig. 103.3).

A minority of cases of common diseases such as diabetes may be caused by single-gene pathogenic variants (mendelian inheritance), chromosomal disorders, and other genomic disorders (see Chapter 629.4). However, these *unique* causes of the disease can provide important insight into the molecular pathways involved. Chromosomal regions with genes that might contribute to disease susceptibility have historically been located with **linkage mapping**, which locates regions

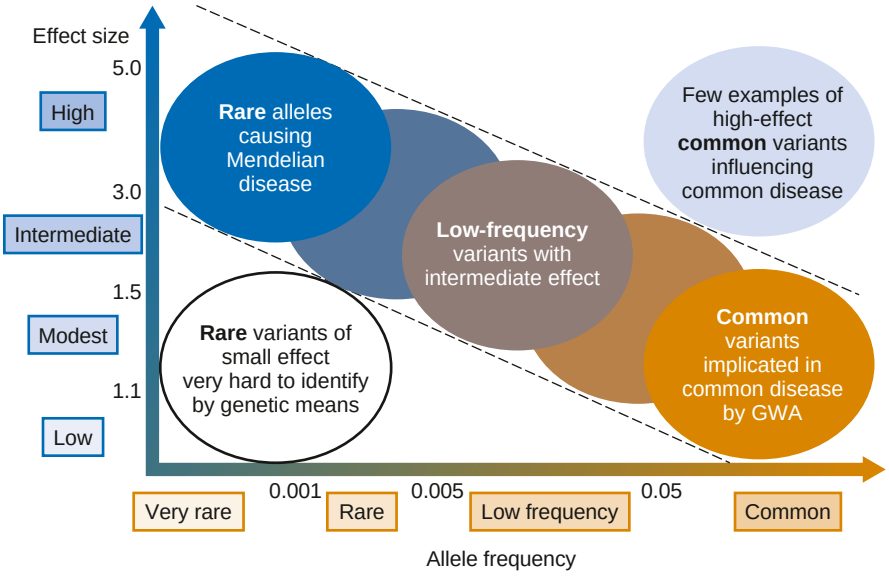

Fig. 103.1 Relationship between allele frequency and relative strength of genetic effect. Alleles with large effect tend to be very rare but can be studied with a small sample size because of the relative ease of allele detection when medical impact is high. Common variants tend to have a modest or low effect on health, requiring large datasets to visualize statistically small effects. The vast majority of disease-associated alleles identified to date have the characteristics shown within the *diagonal dotted lines*. GWA, Genome-wide association. *(Adapted from McCarthy MI, Abecasis GR, Cardon LR, et al. Genome-wide association studies for complex traits: consensus, uncertainty and challenges. Nat Rev Genet. 2008;9:356–369.)*

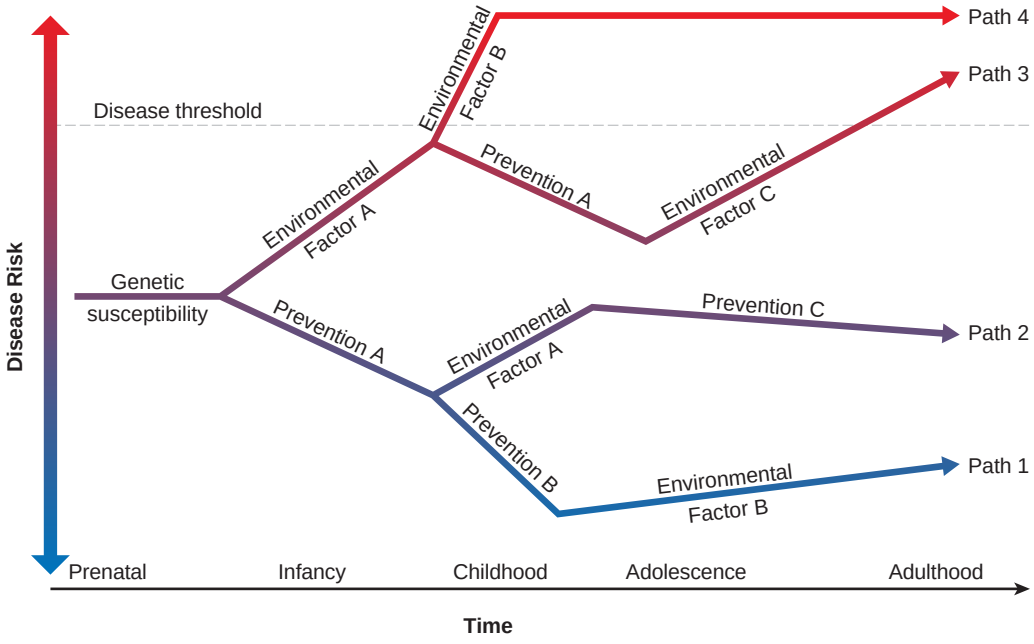

Fig. 103.2 Model for the influence of gene-environment interaction on genetic susceptibility to common diseases. Everyone inherits common variants that determine initial genetic liability for disease risk. For multifactorial disorders, the initial genetic susceptibility is insufficient to produce disease on its own. Over time, exposure to environmental factors increases the likelihood of a disease state. Identifying the gene variants responsible for risk can lead to prevention strategies or treatments.

Phenotypic variance		Genetic variance		Environmental variance		Measurement variance
V_P	=	V_G	+	V_E	+	V_M

$$h^2 = V_G / V_P$$

Heritability

Fig. 103.3 Heritability concept. The phenotypic variance of a particular trait can be partitioned between the contributions of the genetic variance, environmental variance, and measurement variance. This is usually empirically determined. Heritability is defined by the proportion of the phenotypic variance that is accounted for by the genetic variance. One can estimate the heritability from correlation of a quantitative trait between relatives.

of DNA that are inherited in families with the specific disease. In practical terms, however, this has become quite difficult for most complex traits either because of a dearth of families or because the effects of individual genetic loci are weak; thus linkage mapping is seldom used anymore.

Genetic **association studies** are a powerful way of identifying common gene variants (>5% in the population) that each have an effect on the risk of disease. Detection of the usually small to moderate effect of each variant alongside interactions with environmental factors requires well-powered studies that often include thousands of individuals. A number of parallel approaches for analyzing the aggregate effects of rare variants in genes have also been developed. Such rare variant association methods also require large sample sizes because the gene effects also appear to be relatively weak.

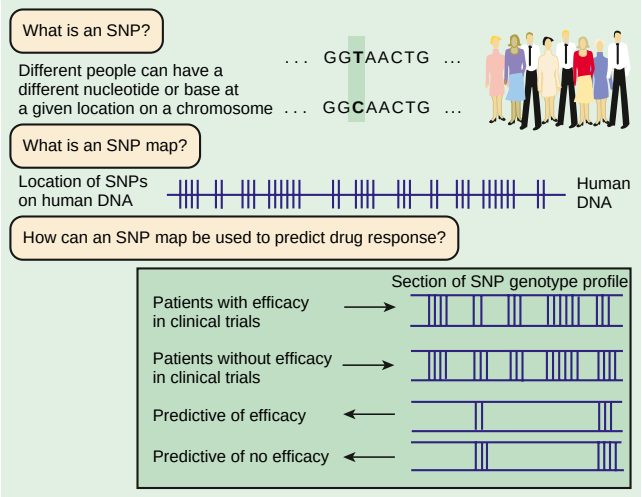

Fig. 103.4 Different combinations of single nucleotide polymorphisms (SNPs) are found in different individuals. The locations of these SNPs can be pinpointed on maps of human genes. Subsequently, they can be used to create profiles that are associated with difference in response to a drug, such as efficacy and nonefficacy. *(Adapted from Roses A. Pharmacogenetics and the practice of medicine. Nature. 2000;405:857–865.)*

Association studies require markers along the DNA that can be **genotyped** (ascertaining the combination of alleles at a locus in a diploid organism), typically with large-scale, high-throughput laboratory techniques. Markers that are typically used are **single nucleotide polymorphisms** (**SNPs**; Fig. 103.4). A sample of the same region of genome from 50 people will reveal that approximately 1 in every 200 bases varies between individuals. Catalogues of SNPs identified in thousands of individuals from multiple populations consist of tens of millions of SNPs across the genome (dbSNP; https://www.ncbi.nlm.nih.gov/snp/). Although most SNPs lack an obvious function, some will alter the amino acid sequence of the protein, and many have been shown to regulate the expression of nearby or distant genes (https://gtexportal.org/home/) or indirectly impact expression by altering the level of surrounding DNA methylation or the ability of proteins to act *(The ENCODE Project Consortium)*. Some of these functional alterations can directly affect susceptibility to disease.

A complex clinical **phenotype** can be defined by the presence or absence of a disease as a **dichotomous trait**, or by selection of a clinically meaningful continuous or **quantitative trait**, such as serum glucose in type 2 diabetes. Although it might not be possible to define subgroups of patients in advance based on disease mechanisms, the more uniform the phenotype, the more likely that a genetic study will be informative. **Locus heterogeneity** refers to the situation in which a similar trait results from alteration of different genes. **Allelic heterogeneity** is when more than one variant in a particular gene can contribute to different diseases. The development of a trait or disease from a nongenetic mechanism results in a **phenocopy**. These three factors often contribute to the difficulty in identifying individual disease susceptibility genes, because they reduce the effective size of the study population and thus require even larger sample sizes.

For genetic variants that directly lead to disease, a person bearing any variant or **allele** (inherited unit, DNA segment, or chromosome) in a gene has a given probability of being affected with a specific gene variant–associated disease. This is called the **penetrance**. Some diseases manifest signs only later in life **(age-related penetrance)**, which could lead to misclassifying children with the disease-producing variant to be classified as unaffected. Single-gene disorders are typically caused by pathogenic variants with relatively high penetrance. In contrast, most common variants have low penetrance because their overall contribution to the disease is small. Many such common variants can contribute to disease risk for a complex trait; for example, human height is influenced by >400 genes.

Ideally, important environmental exposures should be measured and accounted for in a population because there may be a dependent interaction between the environmental factor and specific genetic variant. An example is the likely requirement for a viral infection preceding onset of type 1 diabetes. Although **gene-environment interactions** are strongly suspected to play an important role in common diseases, it is difficult to identify and measure them. Very large studies with uniform collection of information about environmental exposures are rare, but are becoming more common with the expansion of large biorepositories that are integrated with electronic health records. Methods, such as genome-wide analyses of DNA methylation, sometimes referred to as epigenome-wide association studies, have been used to assess evidence for early environmental exposures that influence common diseases in later life. This apparent relationship between the environment and DNA methylation (and related genetic features) is being used to discover and validate other possible gene-environment interactions.

GENOME-WIDE APPROACHES TO ASSOCIATION

For multifactorial common diseases, association analyses have been used to identify disease-related genes. There are two types of association study: **direct association**, in which the risk-altering variant itself is tested to see whether its presence correlates with disease, and **indirect association**, in which markers that are physically close to the biologically important variant are used as proxies. The correlation of markers with other genetic variants in a small region of the genome is called **linkage disequilibrium**. Indirect association is enabled by the construction of linkage disequilibrium maps in continental reference populations (e.g., Europeans, Asians, West Africans) (International HapMap Project). SNPs that proxy most genetic variation have been identified across most of the genome and can be genotyped at low cost using specially designed microarrays that typically include 2-5 million genetic markers. This resolution provides a good proxy of genetic variation in relatively homogenous populations where linkage disequilibrium is generally high (such as Europeans), thus facilitating "genome-wide" testing of variants in those populations.

Three basic study designs are used for association testing:

1. **Case-control design:** the frequency of an allele in an affected group is compared with an unaffected group. This is the mostly commonly used framework for association testing, as it aligns with many more traditional epidemiologic study designs.
2. **Cohort design:** large numbers of people are ascertained and then followed for the onset of any number of diseases. Cohort analysis is very expensive, and there are few true cohort studies. However, investments in genomics of large-scale population-based cohorts in Iceland *(https://www.decode.com/)*, the United Kingdom *(https://www.ukbiobank.ac.uk/)*, and the United States *(https://allofus.nih.gov/)* include hundreds of thousands of individuals all tied to electronic health records and have begun to show unique insights to disease risk and pathogenesis.
3. **Family-based control design:** parents or siblings of an affected individual are used as the controls. Family-based control study designs are somewhat attractive for pediatric diseases because it is usually possible to enroll parents. These studies also solve a major problem in testing for association because the parents are perfectly matched for genetic background; however, family-based study designs are inherently less efficient to recruit than case-control studies and are used less commonly.

The success of any association analysis depends on the design of a well-powered study and an accurately measured trait to avoid phenotypic misclassification. In large, population-based studies, confounding by ethnicity or **population stratification,** could distort results. Variants more common in people from a particular ancestry group could cause an apparent association of a variant with a disease. This association would not be a true association between an allele and a disease, because the association would be confounded by genetic background. Methods for measuring subtle mismatching between cases and controls using many thousands of markers routinely genotyped

in genome-wide association studies allow researchers to account for this effect. The implementation of stringent thresholds for statistical significance replicate associations in other groups have helped make genome-wide association studies robust and reproducible.

Association studies are a powerful tool to find genetic variation that confers risk to an individual; however, the effect of any single genetic variant will be a small contribution to the overall risk and pathogenesis of disease. Hundreds of thousands of genetic associations between a variant or gene and disease, such as the *APOE*ε4 allele with an increased risk of Alzheimer disease, have now been observed for thousands of complex diseases and traits, including autoimmune disease, asthma, and bone density/fractures. Genetic variants that implicate a novel gene in a process drive research into systems and pathways that can alter disease outcome. With increasingly large datasets and advances in statistical analyses, all the genetic variants that impact common disease risk can also be combined to derive a composite genetic risk score. This score can then be integrated with known environmental risk factors to identify individuals at particularly high risk of disease who might require more urgent intervention or monitoring. In adults, this approach is being developed to identify individuals at high risk for coronary heart disease, although concerns about how well genetic risk scores work in different population groups are yet to be overcome.

Low-cost methods for sequencing the complete coding (exomes) *and* full DNA sequence (genomes) of individuals have facilitated comprehensive evaluation of a wider range of genetic variants involved in common diseases. Rare genetic variants, including small insertions or deletions, are important in pediatric diseases such as neurodevelopmental disorders, cardiovascular malformations, and other birth defects. Common traits such as height, obesity, diabetes, and autoimmune diseases are also affected by rare variants. In common severe disorders such as intellectual disability and complex heart malformations, de novo pathogenic variants (i.e., pathogenic variants not present in either parent) play an important role.

Metabolic Disorders

PART IX

Chapter 104

An Approach to Inborn Errors of Metabolism

Oleg A. Shchelochkov and Charles P. Venditti

Many childhood conditions are caused by single-gene pathogenic variants that encode specific proteins. These pathogenic variants can change the primary protein structure or the amount of protein synthesized. The function of a protein, whether it is an enzyme, receptor, transport vehicle, membrane component, transcriptional coregulator, or structural element, may be compromised or abolished. Hereditary diseases that disrupt normal biochemical processes are termed **inborn errors of metabolism** or **inherited metabolic diseases** (Fig. 104.1).

Most genetic changes are clinically inconsequential and represent *benign* variants. However, pathogenic variants produce diseases that range in severity of presentation and the time of onset. Severe metabolic disorders usually become clinically apparent in the newborn period or shortly thereafter, whereas milder forms may present later in childhood and even in adulthood. With some exceptions, the presenting symptoms of most metabolic conditions lack the specificity to enable a definitive diagnosis without further evaluation. The combination of *low specificity* of presenting symptoms and *low prevalence* of metabolic disorders makes specific diagnosis difficult. Progressive symptoms, the absence of a plausible nongenetic diagnosis after detailed evaluation, history of overlapping symptoms in a patient's relatives, or consanguinity should alert a pediatrician to seek a consultation with a geneticist and prompt metabolic testing early in the evaluation.

Correct diagnosis is often only the beginning of a long medical journey for most families affected by metabolic conditions (see Chapter 95). Although each inherited metabolic disorder is individually rare, improved diagnosis and increasing survival of patients with metabolic conditions virtually ensure that a pediatrician will encounter and provide care to affected patients. Pediatricians can play a critical role in establishing the continuity of care; managing some aspects of treatment; fostering adherence; and delivering routine pediatric interventions such as immunizations, referrals to specialists, and elements of genetic counseling (see Chapter 98.1).

The greater awareness of metabolic conditions, wider availability of biochemical laboratories, global metabolomic analysis, and routine application of exome and genome sequencing dramatically increased the detection rate of the known disorders and contributed to the discovery of new metabolic disorders. Nonetheless, collection and analysis of family history remain critical screening tests that a healthcare provider can use to identify an infant or child at risk for a metabolic disorder. The identification of consanguinity or a particular ethnic background with an unusually high incidence of inborn errors of metabolism can be important to direct further studies. For example, tyrosinemia type 1 is more common among French Canadians of Quebec, maple syrup urine disease is seen with higher frequency in the U.S. Amish population, and Canavan disease is more common in patients of the Ashkenazi Jewish ancestry.

NEWBORN SCREENING

The individual rarity of inborn errors of metabolism, the importance of early diagnosis, and the ensuing genetic counseling ramifications make a strong argument for the universal screening of all newborn infants. **Tandem mass spectrometry** of metabolites and **enzyme assays** form the foundation of first-tier newborn screening. Worldwide, newborn screening programs have begun incorporating reflex second-tier testing using **molecular analysis** of target genes. These methods require only a few drops of blood to be placed on a filter paper and delivered to a central laboratory for assay. Many genetic conditions can be identified by these methods, and the list of disorders continues to grow (Tables 104.1 and 104.2). Pediatricians need to be aware of the general screening procedure and limitations of screening. As a screening method, a positive result may require a repeat newborn screen or confirmatory testing to secure the diagnosis. The time required to return the results varies from country to country and even within states in the same country. Some metabolic conditions can be severe enough to cause clinical manifestations before the results of the newborn screening become available. Conversely, diagnostic metabolites in milder forms of screened disorders may not reach a set threshold to trigger secondary studies, thus leading to negative newborn screen results and delayed diagnosis. *Therefore negative newborn screening in a patient with symptoms suggestive of a metabolic disorder warrants a referral to a genetics specialist for further evaluation.*

Universal newborn screening may also identify mild forms of inherited metabolic conditions, some of which may never cause clinical manifestations in the lifetime of the individual. For example, short-chain acyl-CoA dehydrogenase deficiency has been identified with unexpectedly high frequency in screening programs using tandem mass spectrometry, but most of these children have remained asymptomatic. This highlights the need for an ongoing evaluation of metabolite cutoff values and approaches to confirmatory testing to maximize the diagnostic yield and minimize potential psychosocial and economic implications of such findings. Premature infants represent a special population in whom the incidence of false-positive or false-negative test results can be especially high.

With the advent of genetic therapy for spinal muscular atrophy (SMA) and enzyme replacement therapy for some lysosomal storage diseases (e.g., Pompe disease, Fabry disease, Gaucher disease, and mucopolysaccharidosis type 1), most state newborn screening programs include screening for SMA and lysosomal storage disorders.

CLINICAL MANIFESTATIONS OF GENETIC METABOLIC DISEASES

Physicians and other healthcare providers who care for children should familiarize themselves with early manifestations of inborn errors of metabolism, because (1) severe forms of some of these conditions may cause symptoms before the results of screening studies become available and (2) the current screening methods, although quite extensive, identify a small number of all inherited metabolic conditions. In the newborn period, the clinical findings are usually nonspecific and similar to those seen in infants with sepsis. An inborn error of metabolism should be considered in the differential diagnosis of a severely ill newborn infant, and special studies should be undertaken if the index of suspicion is high (see Fig. 104.1).

Signs and symptoms such as lethargy, hypotonia, hypothermia, convulsions (Table 104.3), poor feeding, and vomiting may develop as early as a few hours after birth. Occasionally, vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it may occur simultaneously in some infants.

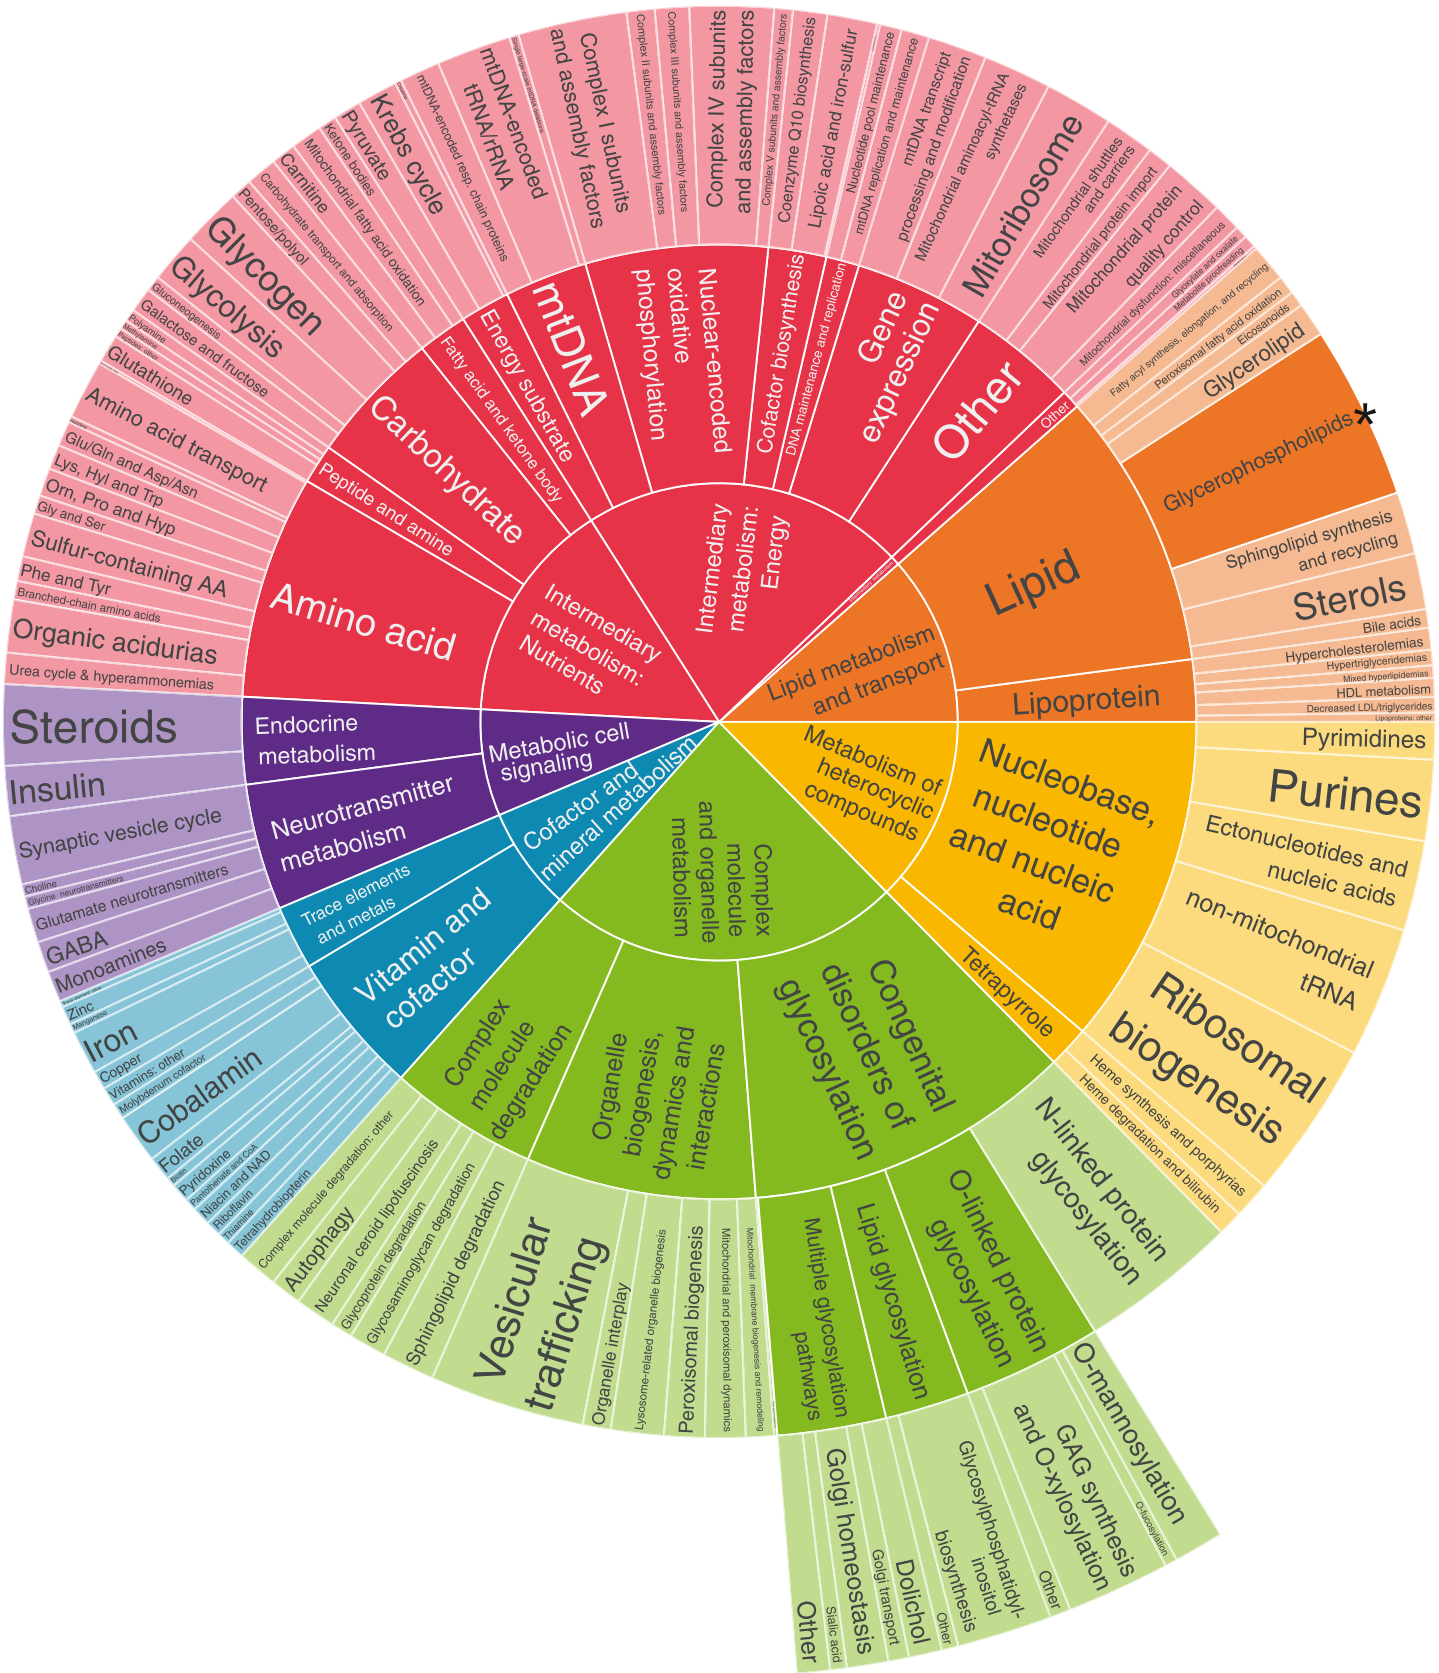

Fig. 104.1 Sunburst chart depicting the hierarchical nature of the International Classification of Inherited Metabolic Disorders. The size of each section of the chart is directly proportional to the number of disorders in that group. *Including phosphatidylinositol (with lesser numbers for ether lipids and lesser still for phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine) (*From Ferreira CR, Rahman S, Keller M, et al. An international classification of inherited metabolic disorders [ICIMD]. J Inherit Metab Dis. 2021;44:164–177, Fig. 1.*)

Table 104.1 Core Conditions on the Recommended Uniform Screening Panel by the Advisory Committee on Heritable Disorders in Newborns and Children of the U.S. Health Resources & Services Administration*

DISORDERS OF ORGANIC ACID METABOLISM
Propionic acidemia
Methylmalonic acidemia (methylmalonyl-CoA mutase)
Methylmalonic acidemia (cobalamin disorders)
Isovaleric acidemia
3-Methylcrotonyl-CoA carboxylase deficiency
3-Hydroxy-3-methyglutaric aciduria
Holocarboxylase synthase deficiency
β-Ketothiolase deficiency
Glutaric acidemia type I

DISORDERS OF FATTY ACID METABOLISM
Medium-chain acyl-CoA dehydrogenase deficiency
Very-long-chain acyl-CoA dehydrogenase deficiency
Long-chain 3-hydroxy-acyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency
Systemic primary carnitine deficiency

DISORDERS OF AMINO ACID METABOLISM
Classic phenylketonuria
Maple syrup urine disease
Homocystinuria
Citrullinemia type 1
Argininosuccinic acidemia
Tyrosinemia type I

HEMOGLOBINOPATHIES
Sickle cell anemia (hemoglobin SS disease)
Hemoglobin S/β-thalassemia
Hemoglobin S/C disease

ENDOCRINE DISORDERS
Primary congenital hypothyroidism
Congenital adrenal hyperplasia

OTHER DISORDERS
Classic galactosemia
Biotinidase deficiency
Glycogen storage disease type II (Pompe disease)
Mucopolysaccharidosis type 1
X-linked adrenoleukodystrophy
Cystic fibrosis
Hearing loss
Severe combined immunodeficiency (SCID)
Critical congenital heart disease
Spinal muscular atrophy (SMA) due to homozygous deletion of exon 7 in *SMN1*

*Adopted from https://www.hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html, last revised in February 2020.

Table 104.2 Secondary Conditions on the Recommended Uniform Screening Panel by the Advisory Committee on Heritable Disorders in Newborns and Children of the U.S. Health Resources & Services Administration

ORGANIC ACID METABOLISM DISORDERS
Methylmalonic acidemia with homocystinuria
Malonic acidemia
2-Methyl-3-hydroxybutyric aciduria
Isobutyryl-CoA dehydrogenase deficiency
2-Methylbutyryl-CoA dehydrogenase deficiency
3-Methylglutaconic aciduria

FATTY ACID OXIDATION DISORDERS
Short-chain acyl-CoA dehydrogenase deficiency
Glutaric acidemia type 2
Medium-/short-chain 3-hydroxy-acyl-CoA dehydrogenase deficiency
Medium-chain ketoacyl-CoA thiolase deficiency
Carnitine palmitoyltransferase IA deficiency
Carnitine palmitoyltransferase II deficiency
Carnitine-acylcarnitine translocase deficiency
2,4-Dienoyl-CoA reductase deficiency

AMINO ACID METABOLISM DISORDERS
Hyperphenylalaninemia, benign (not classic phenylketonuria)
Tyrosinemia type II
Tyrosinemia type III
Defects of biopterin cofactor biosynthesis
Defects of biopterin cofactor regeneration
Argininemia
Hypermethioninemia
Citrullinemia type II (citrin deficiency)

HEMOGLOBINOPATHIES
Hemoglobin variants (including hemoglobin E)

OTHERS
Galactose epimerase deficiency
Galactokinase deficiency
T-cell–related lymphocyte deficiencies

Table 104.3 Select Inborn Errors of Metabolism Associated with Neurologic and Laboratory Manifestations in Neonates

DETERIORATION IN CONSCIOUSNESS
Metabolic Acidosis
Organic acidemias
Disorders of pyruvate metabolism
Fatty acid oxidation defects
Fructose-1,6-bisphosphatase deficiency
Glycogen storage diseases
Mitochondrial respiratory chain defects
Disorders of ketone metabolism

HYPOGLYCEMIA*
Fatty acid oxidation defects
Disorders of gluconeogenesis
Disorders of fructose and galactose metabolism
Glycogen storage diseases
Disorders of ketogenesis
Organic acidemias
Hyperinsulinemic hypoglycemias
Mitochondrial respiratory chain defects
Neonatal intrahepatic cholestasis caused by citrin deficiency
Disorders of pyruvate metabolism
Carbonic anhydrase VA deficiency

Continued

Table 104.3 Select Inborn Errors of Metabolism Associated with Neurologic and Laboratory Manifestations in Neonates—cont'd

HYPERAMMONEMIA**
Urea cycle disorders
Organic acidemias
Fatty acid oxidation disorders
Disorders of pyruvate metabolism
GLUD1-related hyperinsulinemic hypoglycemia
Carbonic anhydrase VA deficiency

SEIZURES AND HYPOTONIA
Antiquitin deficiency (pyridoxine-dependent epilepsy)
Pyridoxamine 5′-phosphate oxidase (PNPO) deficiency (pyridoxal phosphate-responsive epilepsy)
Folate metabolism disorders
Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency)
Urea cycle disorders
Organic acidemias
Fatty acid oxidation disorders
Disorders of creatine biosynthesis and transport
Disorders of neurotransmitter metabolism
Molybdenum cofactor deficiency and sulfite oxidase deficiency
Serine deficiency disorders
Glycine encephalopathy
Asparagine synthetase deficiency
Mitochondrial respiratory chain defects
Zellweger spectrum disorders
Congenital disorders of glycosylation
Purine and pyrimidine metabolism defects

NEONATAL APNEA
Glycine encephalopathy
Asparagine synthetase deficiency
Urea cycle disorders
Organic acidemias
Disorders of pyruvate metabolism
Fatty acid oxidation defects
Mitochondrial respiratory chain defects

*Refer to Table 104.4 for more details on the metabolic disorders associated with neonatal hypoglycemia.
**Refer to Table 104.5 for more details on the differential diagnosis of neonatal and infantile hyperammonemia.
Modified from El-Hattab AW. Inborn errors of metabolism. *Clin Perinatol.* 2015;42:413–439, Box 1.

Table 104.4 Select Inborn Errors of Metabolism Associated with Neonatal Hypoglycemia

CATEGORY OF DISORDERS	DISORDERS
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency Medium-chain acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency
Disorders of gluconeogenesis	Fructose-1,6-diphosphatase deficiency Phosphoenolpyruvate carboxykinase deficiency
Disorders of fructose and galactose metabolism	Hereditary fructose intolerance Classic galactosemia
Glycogen storage diseases (GSD)	GSD type Ia (glucose-6-phosphatase deficiency) GSD type Ib (impaired glucose-6-phosphate exchanger) GSD type III (glycogen debrancher enzyme deficiency) GSD type VI (liver glycogen phosphorylase deficiency) GSD type IX (phosphorylase kinase deficiencies)
Disorders of ketone metabolism	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency Mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase deficiency Succinyl-CoA:3-oxoacid-CoA transferase (SCOT) deficiency β-Ketothiolase deficiency
Disorders of amino acid metabolism	Maple syrup urine disease
Organic acidemias	Propionic acidemia Methylmalonic acidemia Isovaleric acidemia Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency)
Hyperinsulinemic hypoglycemia	*HADH*-related disorder (3-alpha-hydroxyacyl-CoA dehydrogenase deficiency) *GLUD1*-related disorder (hyperammonemia-hyperinsulinism syndrome [HIHA])
Other	Mitochondrial respiratory chain defects Neonatal intrahepatic cholestasis caused by citrin deficiency Pyruvate carboxylase deficiency Carbonic anhydrase VA deficiency

Modified from Zinn AB. Inborn errors of metabolism. In: Martin RJ, Fanaroff AA, Walsh MC, eds. *Fanaroff & Martin's Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant,* 10th ed. Philadelphia: Elsevier; 2015: Table 99.17, p. 1605.

Lethargy, poor feeding, seizures, and coma may also be seen in infants with hypoglycemia (Table 104.4) (see Chapters 113 and 147), hypocalcemia (Chapters 69 and 611), and hyperammonemia (Table 104.5) (Chapter 105). Measurements of blood concentrations of glucose and calcium and prompt response to intravenous injection of glucose or calcium help guide the diagnostic decisions.

Every organ can be affected by metabolic disorders. However, *physical examination* usually reveals nonspecific findings; most signs are related to the central nervous system such as lethargy, coma, seizures, hyperventilation, or opisthotonus. Hepatomegaly is a common finding in a variety of inborn errors of metabolism (Table 104.6). Cardiomyopathy (Table 104.7), dysmorphic features (Table 104.8),

Table 104.5 Differential Diagnosis of Hyperammonemia

INBORN ERRORS OF METABOLISM
Urea Cycle Enzyme Defects
N-acetylglutamate synthase (NAGS) deficiency
Carbamoyl phosphate synthetase one (CPS1) deficiency
Ornithine transcarbamylase (OTC) deficiency
Argininosuccinate synthetase (ASS) deficiency (citrullinemia type 1)
Argininosuccinate lyase (ASL) deficiency (argininosuccinic aciduria)
Arginase 1 deficiency
Transport and Synthesis Defects of Urea Cycle Intermediates
Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH syndrome)
Citrullinemia type 2 caused by citrin deficiency
Lysinuric protein intolerance
Ornithine aminotransferase deficiency
Carbonic anhydrase VA deficiency
Organic Acidemias
Propionic acidemia
MMUT-related methylmalonic acidemia and cobalamin metabolism disorders
Isovaleric acidemia
Fatty Acid Oxidation Disorders
Long-chain fatty acid oxidation defects
Systemic primary carnitine deficiency
Other
Pyruvate carboxylase deficiency
GLUD1-related hyperinsulinemic hypoglycemia
Neonatal iron overload disorders (e.g., hereditary hemochromatoses)

ACQUIRED DISORDERS
Transient Hyperammonemia of the Newborn
Diseases of the Liver and Biliary Tract
Liver failure
Biliary atresia
Severe Systemic Neonatal Illness
Neonates sepsis
Heart failure
Medications
Valproic acid
Cyclophosphamide
5-Pentanoic acid
Asparaginase
Other
Reye syndrome

ANATOMIC VARIANTS
Vascular bypass of the liver (e.g., a portosystemic anastomosis)

TECHNICAL
Inappropriate sample collection (e.g., capillary blood or prolonged placement of a tourniquet)
Sample not immediately analyzed

Modified from El-Hattab AW. Inborn errors of metabolism. *Clin Perinatol*. 2015;42:413–439, Box 8.

and fetal hydrops (Table 104.9) are additional potential manifestations of a metabolic disorder (Table 104.10). Occasionally, a peculiar odor may offer an invaluable clue leading to the right diagnosis (Table 104.11).

In an increasing number of patients, a metabolic condition may be recognized months or years after birth. This is more typical in patients carrying milder autosomal recessive pathogenic variants, in mitochondrial disorders, in females affected by X-linked recessive conditions, and specific metabolic conditions that usually present later in life. There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or nonspecific catabolic stress such as an infection, overfeeding, prolonged fasting, or physical exertion. Thus an inborn error of metabolism should be considered in any child with one or more of the following unexplained clinical manifestations: failure to thrive; coarse facial features and reduced range of motion in the joints; developmental delay; intellectual disability; developmental regression; motor deficits or adventitious movements (e.g., dystonia, choreoathetosis, ataxia); seizures; catatonia; myopathy; intermittent episodes of unexplained vomiting, acidosis, mental deterioration, psychosis, or coma; hepatomegaly; renal stones; renal dysfunction, especially Fanconi syndrome or renal tubular acidosis; cardiomyopathy; persistent leukopenia; megaloblastic anemia; and unusual odor (particularly during an acute illness) (Table 104.12).

Diagnosis usually requires a variety of specific laboratory studies. Plasma amino acid analysis, total plasma homocysteine, plasma acylcarnitine profile, total and free carnitine levels, and urine organic acid assay, although not exhaustive in their diagnostic scope, are useful as initial screening tests to evaluate for a suspected inborn error of metabolism. Measurements of plasma ammonia, glucose, lactate, bicarbonate, and pH are readily available in hospitals and very helpful *initially* in differentiating major causes of genetic metabolic disorders (Table 104.13 and Fig. 104.2). Elevation of blood ammonia is usually caused by defects of urea cycle enzymes, organic acidemias, and disorders of fatty acid oxidation. Infants with elevated blood ammonia levels from urea cycle defects tend to have normal serum pH and bicarbonate values; without measurement of blood ammonia, they may remain undiagnosed and succumb to their disease. In organic acidemias, elevated plasma ammonia is accompanied by severe acidosis caused by accumulation of organic acids, ketone bodies, and lactate in body fluids.

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (e.g., hyperglycinemia) or galactosemia should be considered. Galactosemic infants may also manifest cataracts, hepatomegaly, ascites, and jaundice.

Currently, more targeted assays, such as those used with newborn screening, have the highest sensitivity in the diagnosis or monitoring of specific disorders in question. However, some success has been shown in the context of undiagnosed individuals where metabolomic (assays for entire small molecule metabolites) data can be correlated with genomic information to provide supporting evidence for a pathogenic variant in a suspected causal gene.

TREATMENT

Most patients with genetic disorders of metabolism respond to one or more of the following treatments:

1. Special diets play an important role in the treatment of affected children. Dietary changes should be tailored to the pathophysiology of the condition and vary greatly among disorders.
2. Hemodialysis for expeditious removal of accumulated noxious compounds. This is a very effective modality for treatment of the acute phase of the condition.
3. Catabolic states in patients at risk for metabolic crisis can be treated with fluids containing dextrose and electrolytes.
4. Administration of the deficient metabolite.
5. Administration of the cofactor or coenzyme to maximize the residual enzyme activity.
6. Activation of alternative pathways to reduce the noxious compounds accumulated because of the genetic abnormality.
7. Administration of the deficient enzyme.
8. Bone marrow transplantation.
9. Liver and kidney transplantation.

Table 104.6 Select Metabolic Disorders Associated with Hepatic Dysfunction

CATEGORY OF DISORDERS	DISORDERS
Disorders of amino acid metabolism	Tyrosinemia type I Citrullinemia type II caused by citrin deficiency Disorders of methionine metabolism Urea cycle disorders
Biliary tract disorders and disorder of bile acid synthesis	See Chapter 383
Disorders of fructose and galactose metabolism	Hereditary fructose intolerance Classic galactosemia Epimerase deficiency galactosemia
Congenital disorders of glycosylation	Multiple types
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency Very-long-chain acyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency
Glycogen storage disorders (GSD)	GSD type 1a (deficiency of glucose-6-phosphatase catalytic activity) GSD type 1b (a defect in glucose-6-phosphate exchanger encoded by *SLC37A4*) GSD type III (glycogen debrancher enzyme deficiency) GSD type IV (glycogen branching enzyme deficiency) GSD type VI (liver glycogen phosphorylase deficiency)
Peroxisomal disorders	Zellweger spectrum disorders Disorders of peroxisomal β-oxidation
Mitochondrial respiratory chain (RC) defects	Mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) defects: Specific single-nucleotide pathogenic variants in mtDNA Large-scale mtDNA re-arrangements (Pearson syndrome) Disorders of mitochondrial translation (e.g., $tRNA^{Glu}$) Disorder of protein synthesis of RC complexes Disorders affected the assembly or stabilization of RC complexes (e.g., *BCS1L*) Disorders of cofactor biosynthesis (e.g., coenzyme Q10) Disorders of mitochondrial transport and dynamics mtDNA depletion syndromes (e.g., *DGUOK, MPV17, POLG, SUCLG1*)
Lysosomal storage disorders	Niemann-Pick disease type C
Other	α_1-Antitrypsin deficiency

Modified from Zinn AB. Inborn errors of metabolism. In: Martin RJ, Fanaroff AA, Walsh MC, eds. *Fanaroff & Martin's Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant,* 10th ed. Philadelphia: Elsevier; 2015: Table 99.5, p. 1579.

Table 104.7 Select Metabolic Disorders Associated with Cardiomyopathy

CATEGORY OF DISORDERS	DISORDERS
Organic acidemias	Propionic acidemia Cobalamin C deficiency 3-methylglutaconic acidurias (e.g., Barth syndrome and DCMA syndrome)
Lysosomal storage disorders	Sphingolipidoses (e.g., Fabry disease) Oligosaccharidoses and mucolipidoses (e.g., I-cell disease) Mucopolysaccharidoses
Glycogen storage disorders (GSD)	GSD type II (Pompe disease) GSD type III (glycogen debrancher enzyme deficiency) *PRKAG2*-related disorders (includes lethal congenital glycogen storage disease of heart)
Congenital disorders of glycosylation	Multiple types
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency *ACAD9*-related disorder (mitochondrial acyl-CoA dehydrogenase deficiency) Multiple acyl-CoA dehydrogenase deficiency (includes glutaric aciduria type 2) Very-long-chain acyl-CoA dehydrogenase deficiency Systemic primary carnitine deficiency
Mitochondrial respiratory chain (RC) defects	Mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) defects: Specific single-nucleotide pathogenic variants in mtDNA Large-scale mtDNA deletions Disorders of mitochondrial translation (e.g., $tRNA^{Leu}$) Disorders of protein synthesis of RC complexes (e.g., *MT-ATP6, MT-ATP8, NDUFS2, NDUFV2, SDHA, SCO2, COX10, COX15*) Disorders affecting the assembly or stabilization of RC complexes (e.g., *TMEM70*) Disorders of cofactor biosynthesis (e.g., coenzyme Q10) Disorders of mitochondrial transport and dynamics (e.g., *SLC25A3*) mtDNA depletion syndromes (e.g., *SUCLG1*)
Other	Danon disease

DCMA, dilated cardiomyopathy with ataxia.

Hypermethioninemia	Boiled cabbage
Cystinuria Tyrosinemia type I	Sulfur
Hawkinsinuria	"Swimming pool"
Oasthouse urine disease	Hopslike

In select inborn errors of metabolism, organ transplantation modalities may offer the best treatment modality to stabilize a metabolic patient and improve quality of life. To date, replacement of the affected gene with a normal copy using gene therapy has been successful in only a few diseases.

Treatment of genetic disorders of metabolism is complex and requires medical and technical expertise. Effective treatment is best achieved by a team of specialists—metabolic genetics specialist, nutritionist, neurologist, and psychologist—in a major medical center. The therapeutic regimen often needs to be tailored to the individual patient because of large phenotypic variations in the severity of the disease, even within a single family. Providing genetic counseling, education, and ongoing social services support for the family is the key to successful long-term therapy. Even in patients with poor prognoses, every effort should be made to establish correct diagnoses premortem.

Hyperammonemia	Hypoglycemia
Metabolic acidosis	Liver dysfunction
Lactic acidosis	Pancytopenia
Ketosis	

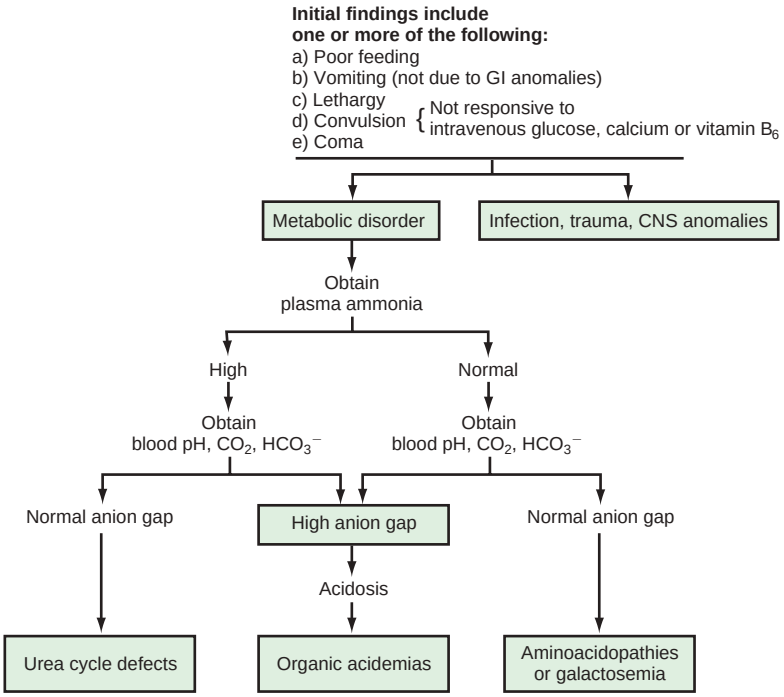

Fig. 104.2 Algorithm showing the initial clinical approach to a full-term newborn infant with a suspected genetic metabolic disorder. This schema is a guide to elucidate some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases affected by disorders or intermediate metabolism. CNS, Central nervous system; GI, gastrointestinal; HCO_3^-, bicarbonate.

Chapter 105

Defects in Metabolism of Amino Acids

105.1 Phenylalanine

Oleg A. Shchelochkov and Charles P. Venditti

Phenylalanine is an essential amino acid. Dietary phenylalanine that is not used for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 105.1). Deficiency of the enzyme **phenylalanine hydroxylase (PAH)** or one of its cofactors **tetrahydrobiopterin (BH_4)** causes accumulation of phenylalanine and its metabolites in body fluids and in the brain.

Elevations of phenylalanine in the plasma reflect the degree of enzyme deficiency, presenting as a spectrum of biochemical and clinical findings. In patients with **severe PAH deficiency** (also referred to as *classical phenylketonuria*), plasma phenylalanine levels on an unrestricted diet usually exceed 20 mg/dL (>1,200 µmol/L). Patients with milder PAH pathogenic variants have plasma phenylalanine levels between 10 mg/dL (600 µmol/L) and 20 mg/dL (1,200 µmol/L). Levels between 2 and 10 mg/dL (120 and 600 µmol/L) on an unrestricted diet are observed in patients with **mild hyperphenylalaninemia**. In affected infants with plasma concentrations >20 mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 105.1) that are excreted in the urine, giving rise to the term *phenylketonuria* (PKU). These metabolites have no known role in the mechanisms of central nervous system (CNS) damage in PKU patients, but their presence in body fluids can signify the severity of the condition. The **brain** is most vulnerable to the damage incurred by PKU, but the exact mechanism of injury remains elusive. Both toxic elevations of phenylalanine and insufficient tyrosine may play roles. Phenylalanine hydroxylase converts phenylalanine to **tyrosine**, which is necessary for the production of neurotransmitters such as epinephrine, norepinephrine, and dopamine (Fig. 105.2). If the degree of enzymatic block is severe, tyrosine becomes an essential amino acid and may be deficient if its intake is not adequate. On the other hand, observations that lower concentrations of phenylalanine in plasma and brain tissue are associated with improved neurobehavioral outcomes support the view that toxic levels of phenylalanine are key to PKU pathogenesis. High blood levels of phenylalanine can saturate the transport system across the blood-brain barrier (BBB) and inhibit the cerebral uptake of other large neutral amino acids such as the branched-chain amino acids tyrosine and tryptophan, impairing brain protein synthesis.

SEVERE PHENYLALANINE HYDROXYLASE DEFICIENCY (CLASSIC PHENYLKETONURIA)

Elevations of plasma phenylalanine >20 mg/dL (>1,200 µmol/L), if untreated, invariably result in the development of signs and symptoms of classic PKU, except in uncommon and unpredictable cases.

Clinical Manifestations

The affected infant appears normal at birth. Profound intellectual disability gradually develops if the infant remains untreated. Cognitive delay may not be evident for the first few months. In untreated patients, 50–70% will have an IQ below 35, and 88–90% will have an IQ below 65. Less than 5% of untreated patients attain IQ scores in the average range. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive and show autistic behaviors, including stereotypic hand movements and rhythmic rocking.

Untreated and undertreated infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears with age. Affected children have an odor of phenylacetic acid, which has been described as musty or "mousey." Neurologic signs include seizures (approximately 25%), spasticity, hyperreflexia, tremors, and athetosis; >50% have electroencephalographic (EEG) abnormalities. Microcephaly, prominent maxillae with widely spaced teeth, enamel hypoplasia, and growth retardation are other common findings in untreated children. Low bone mineral density and osteopenia have been reported in affected individuals of all ages. Although inadequate intake of natural proteins seems to be the major culprit, the exact pathogenesis of this sequela remains unclear.

Long-term care of patients with PKU is best achieved by a team of experienced professionals (metabolic specialist, nutritionist, and psychologist), typically in a regional treatment center. The clinical manifestations of classical PKU are rarely seen in countries where neonatal screening programs for the detection of PKU are in effect.

Non-PKU Hyperphenylalaninemia

Implementation of universal screening for PKU led to identification of a group of infants in whom initial plasma concentrations of phenylalanine are above normal (i.e., >2 mg/dL, or 120 µmol/L) but <20 mg/dL (1,200 µmol/L). These infants typically do not excrete phenylketones. Patients with non-PKU hyperphenylalaninemia may still require dietary therapy, depending on their untreated plasma phenylalanine level. Attempts have been made to classify these patients into different subgroups depending on the degree of hyperphenylalaninemia, but the effects of this classification on PKU management and outcomes remain to be clarified. The possibility of deficiency of tetrahydrobiopterin (BH_4) should be investigated in all infants, especially those with milder forms of hyperphenylalaninemia.

Diagnosis

Because of the gradual and nonspecific nature of early clinical symptoms such as vomiting, developmental delay, or eczematoid rash, hyperphenylalaninemia is usually diagnosed through newborn screening in all developed countries. In infants with positive screening results, the diagnosis should be confirmed by quantitative measurement of plasma phenylalanine concentration and molecularly by identifying pathogenic variants in *PAH*. Identification and measurement of phenylketones in the urine have no place in any screening program. In countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for the diagnosis of infants with developmental and neurologic abnormalities. All patients with a biochemical diagnosis of hyperphenylalaninemia should undergo pterin measurements in blood or urine to evaluate for defects in BH_4 synthesis or recycling.

Neonatal Screening for Hyperphenylalaninemia

Effective and relatively inexpensive methods for mass screening of newborn infants are used in the United States and many other countries. A few drops of blood, which are placed on a filter paper and mailed to a central laboratory, are used for assay. The screening method of choice uses **tandem mass spectrometry**, which can identify all forms of hyperphenylalaninemia with a low false-positive rate and excellent accuracy and precision. The addition of the phenylalanine:tyrosine molar ratio can improve test specificity and reduce the number of false-positive results. Diagnosis must be confirmed by measurement of plasma phenylalanine concentration and, ultimately by identifying pathogenic variants in *PAH*. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4 hours after birth, even in the absence of protein feeding. However, to reduce the number of false-negative results, especially in the milder forms of the condition, it is recommended that the blood for screening be obtained in the first 24-48 hours of life after feeding protein.

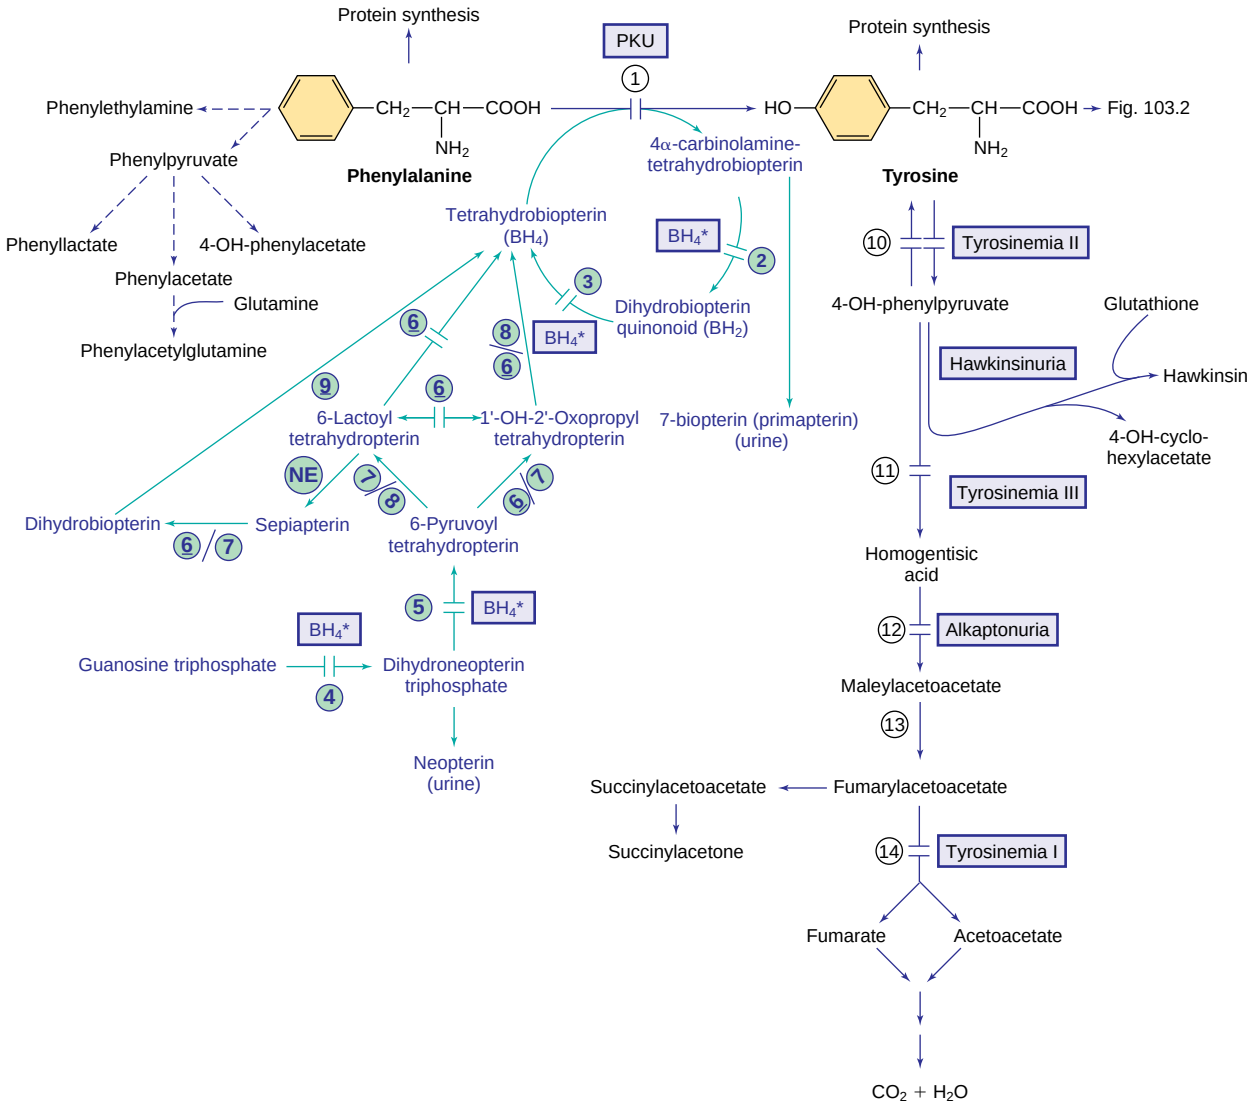

Fig. 105.1 Pathways of phenylalanine and tyrosine metabolism. Enzyme defects causing genetic conditions are depicted as *horizontal bars* crossing the reaction arrow(s). Pathways for synthesis of cofactor BH_4 are shown in *purple*. BH_4* refers to defects of BH_4 metabolism that affect the phenylalanine, tyrosine, and tryptophan hydroxylases (see Figs. 105.2 and 105.5). PKU, Phenylketonuria; NE, nonenzymatic. **Enzymes:** *(1)* Phenylalanine hydroxylase, *(2)* pterin-carbinolamine dehydratase, *(3)* dihydrobiopterin reductase, *(4)* guanosine triphosphate (GTP) cyclohydrolase, *(5)* 6-pyruvoyltetrahydropterin synthase, *(6)* sepiapterin reductase, *(7)* carbonyl reductase, *(8)* aldolase reductase, *(9)* dihydrofolate reductase, *(10)* tyrosine aminotransferase, *(11)* 4-hydroxyphenylpyruvate dioxygenase, *(12)* homogentisic acid dioxygenase, *(13)* maleylacetoacetate isomerase, *(14)* fumarylacetoacetate hydrolase.

Treatment

The mainstay of treatment of PKU is a *low-phenylalanine diet*. The general consensus is to start diet treatment immediately in patients with blood phenylalanine levels >10 mg/dL (600 µmol/L). It is recommended that infants with persistent (more than a few days) plasma levels of phenylalanine ≥6 mg/dL (360 µmol/L) should also be treated with a phenylalanine-restricted diet similar to that in classic PKU. The goal of therapy is to reduce phenylalanine levels in the plasma and brain. Formulas free of or low in phenylalanine are commercially available. The diet should be started as soon as the diagnosis is established. Because phenylalanine is not synthesized endogenously, the diet should provide phenylalanine to prevent phenylalanine deficiency. Dietary phenylalanine tolerance is determined based on age and severity of the PAH deficiency. **Phenylalanine deficiency** is manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death. Furthermore, tyrosine can become an essential amino acid in this disorder, and its adequate intake must be ensured. Special food items low in phenylalanine are commercially available for dietary treatment of affected children and adults.

There is no firm consensus concerning optimal levels of blood phenylalanine in affected patients either across different countries or among treatment centers in the United States. The current recommendation is to maintain blood phenylalanine levels between 2 and 6 mg/dL (120 and 360 µmol/L) throughout life. Discontinuation of therapy, even in adulthood, may cause deterioration of neurocognitive performance.

Lifelong adherence to a low-phenylalanine diet is extremely difficult. Patients who maintain good control as children but discontinue the phenylalanine-restricted diet as teenagers or adults may experience significant difficulties with executive function, concentration, emotional liability, and depression. Executive dysfunction may also occur in early-treated children despite diet treatment.

Given the difficulty of maintaining a strict low-phenylalanine diet, there are continuing attempts to find other modalities for treatment of these patients. Administration of **large neutral amino acids** (LNAAs) is one approach to dietary therapy. LNAAs (tyrosine, tryptophan, leucine, isoleucine, valine, methionine, histidine, and phenylalanine) use the same transporter protein (LNAA type 1 or LAT-1) for transit

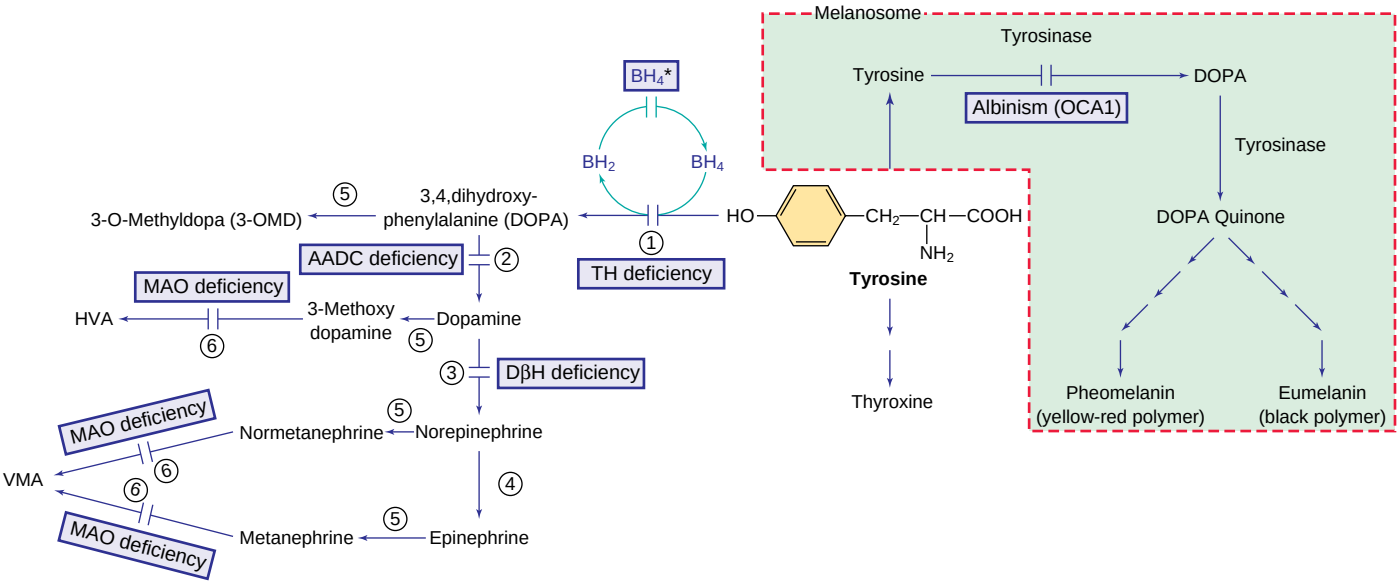

Fig. 105.2 Other pathways involving tyrosine metabolism. BH_4* indicates hyperphenylalaninemia caused by tetrahydrobiopterin (BH_4) deficiency (see Fig. 105.1). HVA, Homovanillic acid; VMA, vanillylmandelic acid. **Enzymes:** *(1)* Tyrosine hydroxylase (TH), *(2)* aromatic L-amino acid decarboxylase (AADC), *(3)* dopamine β-hydroxylase (DβH), *(4)* phenylethanolamine-*N*-methyltransferase (PNMT), *(5)* catechol *O*-methyltransferase (COMT), *(6)* monoamine oxidase (MAO).

through the intestinal cell membrane and BBB. Binding of LNAAs to the transporter is a competitive process. Therefore when LNAAs compete with phenylalanine at the transport level, their large concentrations in the intestinal lumen and blood can reduce the uptake of phenylalanine into the bloodstream and the brain, respectively. Large, controlled clinical trials are necessary to establish the efficacy of this treatment.

Oral administration of BH_4, the cofactor for PAH, may result in the reduction of plasma phenylalanine in some patients with PAH deficiency. Plasma phenylalanine in these patients may decrease enough to allow for considerable modification of their dietary restriction. In very rare cases the diet may be discontinued because the phenylalanine remains under 6 mg/dL (360 µmol/L). The response to BH_4 cannot be predicted consistently based on the genotype alone, especially in compound heterozygous patients. **Sapropterin dihydrochloride**, a synthetic form of BH_4, which acts as a cofactor in patients with residual PAH activity, is approved by the U.S. Food and Drug Administration (FDA) and the European Medicine Agency (EMA) to reduce phenylalanine levels in PKU. A sustained decrease of plasma phenylalanine by at least 30% is consistent with sapropterin responsiveness. Injectable PEGylated recombinant phenylalanine ammonia–lyase has been approved by the FDA and EMA for adult PKU patients with uncontrolled blood phenylalanine levels greater than 600 µmol/L despite prior management.

Pregnancy in Women with PAH Deficiency (Maternal Phenylketonuria)

Pregnant women with PAH deficiency who are not on a phenylalanine-restricted diet have a very high risk of having offspring with intellectual disability, microcephaly, growth retardation, congenital malformations, and congenital heart disease. These complications are directly correlated with elevated maternal blood phenylalanine levels during pregnancy. Prospective mothers who have been treated for PAH deficiency should be maintained on a phenylalanine-restricted diet before and during pregnancy. The best observed outcomes occur when strict control of maternal blood phenylalanine concentration is instituted before pregnancy. Plasma phenylalanine levels >6 mg/dL (360 µmol/L) after conception are associated with increased incidence of intrauterine growth restriction and congenital malformations, as well as lower performance on neurocognitive testing. However, there is strong evidence that phenylalanine control instituted after conception can also result in improved outcomes. The recommended phenylalanine concentration is 2-6 mg/dL (120-360 µmol/L) throughout the pregnancy, although some expert groups advocate plasma phenylalanine levels <4 mg/dL (<240 µmol/L). All women with PAH deficiency who are of childbearing age should be counseled properly regarding the risk of congenital anomalies in their offspring.

HYPERPHENYLALANINEMIA CAUSED BY DEFICIENCY OF THE COFACTOR TETRAHYDROBIOPTERIN

In 1–3% of infants with hyperphenylalaninemia, the defect resides in one of the enzymes necessary for production or recycling of the cofactor BH_4 (see Fig. 105.1). If these infants are misdiagnosed as having PKU, they may deteriorate neurologically despite adequate control of plasma phenylalanine. BH_4 is synthesized from guanosine triphosphate (GTP) through several enzymatic reactions (see Fig. 105.1). In addition to acting as a cofactor for PAH, BH_4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are involved in the biosynthesis of dopamine (see Fig. 105.2) and serotonin (see Fig. 105.5), respectively. Therefore patients with hyperphenylalaninemia resulting from BH_4 deficiency also manifest neurologic findings related to deficiencies of these neurotransmitters. Four enzyme deficiencies leading to defective BH_4 formation cause hyperphenylalaninemia with concomitant deficiencies of dopamine and serotonin: autosomal recessive GTP cyclohydrolase I deficiency (encoded by *GCH1*), 6-pyruvoyl-tetrahydropterin synthase deficiency (encoded by *PTS*), dihydropteridine reductase deficiency (encoded by *QDPR*), and pterin-4-α-carbinolamine dehydratase deficiency (encoded by *PCBD1*). 6-Pyruvoyl-tetrahydropterin synthase is the most frequent cause of hyperphenylalaninemia-associated BH_4 deficiency. Autosomal dominant forms of GTP cyclohydrolase I deficiency and sepiapterin reductase deficiency result in deficiencies of neurotransmitters without hyperphenylalaninemia (see Chapter 105.11).

Clinical Manifestations

Infants with cofactor BH_4 deficiency are identified during screening programs for PKU because of hyperphenylalaninemia. Plasma phenylalanine levels may be as high as those in classic PKU or may be in the milder range. However, clinical manifestations of the neurotransmitter disorders differ greatly from those of PKU. Neurologic symptoms of the neurotransmitter disorders often manifest in the first few months of life and include extrapyramidal signs (choreoathetotic or dystonic limb movements, axial and truncal hypotonia, hypokinesia), feeding

difficulties, and autonomic abnormalities. Intellectual disability, seizures, hypersalivation, and swallowing difficulties can also be seen. The symptoms are usually progressive and often have a marked diurnal fluctuation. Prognosis and outcome strongly depend on the age of diagnosis, treatment, and the underlying enzyme defect.

Diagnosis

Despite the low incidence of BH_4 synthesis and recycling defects, all newborns with hyperphenylalaninemia detected through newborn screening *must* be screened for BH_4 synthesis defects. BH_4 deficiency and the responsible enzyme defect may be diagnosed by several studies.

Measurement of Neopterin and Biopterin

Neopterin (an oxidative product of dihydroneopterin triphosphate) and biopterin (an oxidative product of dihydrobiopterin and BH_4) are measured in body fluids, especially urine (see Fig. 105.1). In patients with the autosomal recessive form of GTP cyclohydrolase I deficiency, urinary excretion of both neopterin and biopterin is reduced and is often very low. In patients with 6-pyruvoyl-tetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in biopterin excretion. Patients with pterin-4-α-carbinolamine dehydratase deficiency can be identified by detecting urinary primapterin (an isomer of biopterin). In dihydropteridine reductase deficiency, no consistent pattern in the excretion of neopterin and biopterin has been observed, thus necessitating enzymatic studies of DHPR in erythrocytes and/or molecular confirmation through *QDPR* gene analysis.

Cerebrospinal Fluid Studies

Examination of cerebrospinal fluid (CSF) may reveal decreased levels of dopamine and serotonin metabolites (see Chapter 105.11).

BH_4 Loading Test

An oral dose of BH_4 (20 mg/kg) normalizes plasma phenylalanine and the phenylalanine:tyrosine ratio in patients with BH_4-responsive deficiency within 4-12 hours. The baseline blood phenylalanine should be elevated (>400 μmol/L) to enable interpretation of the results. This may be achieved by discontinuing diet therapy for 2 days before the test. In BH_4-responsive PAH deficiency, blood phenylalanine levels may decrease during the BH_4 loading test but increase later, even with BH_4 supplementation. Patients who demonstrate phenylalanine levels within the normal range over at least 1 week without a phenylalanine-restricted diet can continue BH_4 supplementation as the sole treatment for the hyperphenylalaninemia. However, it is imperative that plasma phenylalanine levels be monitored prospectively to ensure that phenylalanine levels remain within the normal range.

Molecular Testing

Sequencing and deletion/duplication analysis are clinically available and have an important role in confirming the biochemical diagnosis of PAH deficiency and of the BH_4 synthesis and recycling disorders.

Enzyme Assay

The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes or in erythrocytes. 6-Pyruvoyl-tetrahydropterin synthase activity can be measured in liver tissue, fibroblasts, and erythrocytes. Pterin-4-α-carbinolamine dehydratase activity can be measured in liver tissue and fibroblasts. GTP cyclohydrolase I activity can be measured in the liver and in cytokine (interferon-γ)–stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells). Molecular testing offers a more convenient method to secure the diagnosis in this group of disorders.

Treatment

The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS. Control of hyperphenylalaninemia is important in patients with cofactor deficiency because high levels of phenylalanine cause intellectual disability and interfere with the transport of neurotransmitter precursors (tyrosine and tryptophan) into the brain. Plasma phenylalanine should be maintained as close to normal as possible (<6 mg/dL or <360 μmol/L). This can be achieved by oral supplementation of BH_4 (5-20 mg/kg/day). Sapropterin dihydrochloride, the synthetic form of BH_4, is commercially available but expensive. In patients receiving dietary interventions, phenylalanine and tyrosine deficiencies should be avoided.

Lifelong supplementation with neurotransmitter precursors such as L-dopa and 5-hydroxytryptophan, along with carbidopa to inhibit degradation of L-dopa before it enters the CNS, is necessary in most of these patients even when treatment with BH_4 normalizes plasma levels of phenylalanine. BH_4 does not readily enter the brain to restore neurotransmitter production. To minimize untoward side effects (especially L-dopa–induced dyskinesia), the treatment should be started with low doses of L-dopa/carbidopa and 5-hydroxytryptophan. The treatment should be gradually adjusted based on response to therapy and clinical improvement for each individual patient. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency. Unfortunately, attempting to normalize neurotransmitter levels using neurotransmitter precursors usually does not fully resolve the neurologic symptoms because of the inability to attain normal levels of BH_4 in the brain. Patients often demonstrate intellectual disability, fluctuating abnormalities of tone, eye movement abnormalities, poor balance and coordination, decreased ability to ambulate, and seizures despite supplementation with neurotransmitter precursors.

Hyperprolactinemia occurs in patients with BH_4 deficiency and may be the result of hypothalamic dopamine deficiency. Measurement of serum prolactin levels may be a convenient method for monitoring adequacy of neurotransmitter replacement in affected patients.

Some drugs, such as trimethoprim/sulfamethoxazole, methotrexate, and other antileukemic agents, are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH_4 deficiency.

Genetics and Prevalence

All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. Autosomal dominant forms of GTP cyclohydrolase I deficiency and sepiapterin reductase deficiency result in neurotransmitter disorders without hyperphenylalaninemia (see Chapter 105.11). The prevalence of PKU in the United States is estimated at 1 in 14,000 to 1 in 20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1 in 50,000 live births. Most patients are compound heterozygotes for two different pathogenic variants.

TETRAHYDROBIOPTERIN DEFECTS WITHOUT HYPERPHENYLALANINEMIA

105.2 Tyrosine

Oleg A. Shchelochkov and Charles P. Venditti

Tyrosine is derived from ingested proteins or is synthesized endogenously from phenylalanine. It is used for protein synthesis and as a precursor of dopamine, norepinephrine, epinephrine, melanin, thyroxine, and quinoproteins. Excess tyrosine is metabolized to carbon dioxide and water through the tyrosine degradation pathway (see Fig. 105.1). Hereditary causes of hypertyrosinemia include deficiencies of the enzymes fumarylacetoacetate hydrolase **(FAH)**, tyrosine aminotransferase **(TAT)**, and 4-hydroxyphenylpyruvate dioxygenase **(4-HPPD)**. **Acquired hypertyrosinemia** may occur in severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is a cofactor for 4-HPPD), and hyperthyroidism. Hypertyrosinemia is common in blood samples obtained soon after eating and in premature infants.

TYROSINEMIA TYPE I (FUMARYLACETOACETATE HYDROLASE DEFICIENCY, HEPATORENAL TYROSINEMIA)

Tyrosinemia type I is a severe multisystemic disease caused by FAH deficiency. Liver, kidney, and nerve damage is likely caused by metabolites of tyrosine degradation, especially fumarylacetoacetate and succinylacetone.

Clinical Manifestations and Natural History

Affected infants may appear healthy at birth but develop symptoms in the first year of life. Most patients present between 2 and 6 months of age but rarely may become symptomatic in the first month or appear unaffected beyond the first year of life. Earlier presentation confers poorer prognosis. In untreated children, a 1-year mortality can approach 60% if infants develop symptoms before 2 months of age and decrease to 4% in infants who become symptomatic after 6 months.

An acute **hepatic crisis** typically heralds the disease onset and is usually precipitated by an intercurrent illness leading to a catabolic state. Fever, irritability, vomiting, hemorrhage, hepatomegaly, jaundice, elevated levels of serum transaminases, hypoglycemia, and neuropathy are common. An odor resembling boiled cabbage resulting from increased methionine metabolites may be present. Without treatment, hepatic crises may progress to liver failure and death. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis and eventually hepatocellular carcinoma occur with increasing age.

Episodes of acute **peripheral neuropathy** resembling acute porphyria occur in approximately 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated with extensor hypertonia of the neck and trunk, vomiting, paralytic ileus, and occasionally self-induced injuries of the tongue or buccal mucosa. Marked weakness occurs in about 30% of episodes, which may lead to respiratory failure requiring mechanical ventilation. Crises typically last 1-7 days, but recuperation from paralytic crises can take weeks to months.

Renal involvement manifests as a Fanconi renal syndrome with hyperphosphaturia, hypophosphatemia, normal–anion gap metabolic acidosis, and vitamin D–resistant rickets. Nephromegaly and nephrocalcinosis may be present on ultrasound examination. Glomerular abnormalities can be observed in adolescents and older patients.

Hypertrophic cardiomyopathy and hyperinsulinism are seen in some infants.

Laboratory Findings

Elevated levels of succinylacetone in serum and urine are diagnostic for tyrosinemia type I (see Fig. 105.1). Succinylacetone levels may fall below the diagnostic threshold in patients treated with nitisinone. In untreated patients, serum α-fetoprotein is increased, often greatly, and liver-synthesized coagulation factors are decreased in most patients. Increased levels of α-fetoprotein are present in the cord blood of affected infants, indicating liver damage beginning prenatally. Serum transaminase levels are often increased, with marked increases during acute hepatic episodes. Serum concentration of bilirubin is usually normal but can be increased in severe liver failure. Plasma tyrosine levels are usually elevated at diagnosis, but this is a nonspecific finding and can vary depending on dietary intake. Plasma levels of other amino acids, particularly methionine, may also be elevated in patients with liver damage. Hyperphosphaturia, hypophosphatemia, and generalized aminoaciduria may occur. Urinary 5-aminolevulinic acid (also known as *delta-aminolevulinic acid*) is elevated due to the inhibition of 5-aminolevulinate dehydratase by succinylacetone (see Fig. 112.1).

Diagnosis is usually established by demonstration of elevated succinylacetone in urine or blood. Neonatal screening for hypertyrosinemia using tyrosine alone detects only a fraction of patients with tyrosinemia type I. Succinylacetone assayed by many neonatal screening programs has higher sensitivity and specificity than tyrosine and is the preferred metabolite for screening. Tyrosinemia type I should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary fructose intolerance, neonatal iron storage disease, giant cell hepatitis, citrullinemia type II, citrin deficiency, and hemophagocytic lymphohistiocytosis (see Chapter 105.12).

Treatment and Outcome

A diet low in phenylalanine and tyrosine can slow, but not halt, the progression of the condition. The treatment of choice is **nitisinone** (NTBC), which inhibits 4-HPPD, reduces the flux of tyrosine metabolites to FAH, and decreases the production of the offending compounds fumarylacetoacetate and succinylacetone (see Fig. 105.1). The dose of nitisinone is titrated to the lowest, most effective dose (usually targeting the blood range of 20-40 μmol/L), aiming to suppress succinylacetone production while maintaining a plasma tyrosine level <400 μmol/L (7.2 mg/dL). This treatment with nitisinone can prevent acute hepatic and neurologic crises. Although nitisinone greatly slows disease progression, pretreatment liver damage cannot be completely reversed. Therefore patients must be followed for the development of cirrhosis or hepatocellular carcinoma. On imaging, the presence of even a single liver nodule usually indicates underlying cirrhosis. Most liver nodules in FAH-deficient patients are benign, but current imaging techniques cannot accurately distinguish all malignant nodules. For patients with severe liver failure not responding to nitisinone, liver transplantation is an effective therapy, which can also alleviate the risk of hepatocellular carcinoma. The impact of nitisinone treatment on liver transplantation is under study, but the greatest positive effect is seen in patients treated early, such as children detected by neonatal screening, before developing clinical symptoms. In early-treated patients, nitisinone has greatly reduced the need for liver transplantation. Because nitisinone treatment can increase plasma tyrosine, a low-tyrosine, low-phenylalanine diet is recommended. Rarely, nitisinone-treated patients develop corneal crystals, presumably composed of tyrosine, but these tend to be reversible with strict dietary compliance. This finding, combined with observations of developmental delay in some patients with tyrosinemia type II who chronically have elevated tyrosine levels, suggest that a diet low in phenylalanine and tyrosine should be continued in patients treated with nitisinone. The dietary treatment of patients with tyrosine and phenylalanine restriction necessitates surveillance of growth and development by ensuring adequate intake of amino acids and other nutrients.

Genetics and Prevalence

Tyrosinemia type I is inherited as an autosomal recessive trait and is caused by biallelic pathogenic variants in *FAH*. DNA analysis is useful for carrier testing in groups at risk for specific pathogenic variants, such as French Canadians from the Saguenay-Lac Saint-Jean region of Quebec. The prevalence of tyrosinemia type I is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint-Jean region and approximately 1 in 100,000 live births worldwide. Prenatal screening can be performed by measurement of succinylacetone in amniotic fluid.

TYROSINEMIA TYPE II (TYROSINE AMINOTRANSFERASE DEFICIENCY, RICHNER-HANHART SYNDROME, OCULOCUTANEOUS TYROSINEMIA)

Tyrosinemia type II is a rare autosomal recessive disorder caused by deficiency of cytosolic tyrosine aminotransferase that results in palmar and plantar hyperkeratosis, herpetiform corneal ulcers, and intellectual disability (see Fig. 105.1). *Ocular manifestations,* which may occur as early as 6 months of age, include excessive tearing, redness, pain, and photophobia. Corneal lesions are presumed to be caused by tyrosine crystals deposition. In contrast to herpetic ulcers, corneal lesions in tyrosinemia type II stain poorly with fluorescein and often are bilateral. *Skin lesions,* which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms, and fingertips. Intellectual disability, which occurs in approximately 50% of patients, is usually mild to moderate. The contribution of consanguinity in this rare disorder is incompletely understood.

The principal **laboratory finding** in untreated patients is marked hypertyrosinemia, >500 μmol/L, and it may reach 1,100-2,750 μmol/L. Surprisingly, in some patients urinary 4-hydroxyphenylpyruvic acid and its metabolites can be elevated despite them being downstream

from the metabolic block (see Fig. 105.1). It is hypothesized that other transaminases in the presence of high tyrosine concentrations can produce 4-hydroxyphenylpyruvic acid in mitochondria, where it cannot be further degraded. In contrast to tyrosinemia type I, liver and kidney function tend to be normal, as are serum concentrations of other amino acids and succinylacetone. Tyrosinemia type II is caused by tyrosine aminotransferase *(TAT)* gene pathogenic variants, causing a deficiency of cytosolic TAT activity in the liver.

Diagnosis of type II tyrosinemia is established by an assay of plasma tyrosine concentration in patients with suggestive findings and can be confirmed molecularly. An assay of hepatic TAT requires a liver biopsy and is rarely indicated.

Treatment with a diet low in tyrosine and phenylalanine, aiming to achieve plasma tyrosine levels <500 μmol/L, helps improve skin and eye manifestations. Early dietary intervention can lead to improved intellectual outcomes.

TYROSINEMIA TYPE III (PRIMARY DEFICIENCY OF 4-HYDROXYPHENYLPYRUVATE DIOXYGENASE)

Tyrosinemia type III is an autosomal recessive condition caused by biallelic pathogenic variants in *HPD* encoding the enzyme 4-HPPD. Only a few patients with tyrosinemia type III have been reported. Most were detected by amino acid chromatography performed for various neurologic findings. Therefore ascertainment bias likely confounds current understanding of this disorder. Some asymptomatic infants with 4-HPPD deficiency have been identified by neonatal screening for hypertyrosinemia. Age at presentation varied between 1 and 17 months. In symptomatic patients, developmental delay, seizures, intermittent ataxia, and self-injurious behavior have been reported. Liver and renal abnormalities tend to be absent.

The role of 4-HPPD deficiency in the disease needs further study. The **diagnosis** is suspected in children with sustained moderate increases in plasma levels of tyrosine (typically 350-700 μmol/L on a normal diet) and the presence of 4-hydroxyphenylpyruvic acid and its metabolites, urinary 4-hydroxyphenyllactate and 4-hydroxyphenylacetate. The diagnosis should be confirmed by demonstrating biallelic pathogenic variants in *HPD* or, rarely, by demonstrating a low activity of the 4-HPPD enzyme. The latter requires a liver biopsy and is not usually indicated.

Given a possible association with neurologic abnormalities and corneal deposition of tyrosine crystals, dietary control of plasma tyrosine levels is recommended. One could also consider a trial with vitamin C, the cofactor for 4-HPPD, which can help lower plasma tyrosine in some patients.

HAWKINSINURIA

Hawkinsinuria is a condition allelic to tyrosinemia type III (4-HPPD deficiency). Some specific missense variants (e.g., p.Ala33Thr or p.Asn241Ser) in *HPD* that encode 4-HPPD can result in uncoupling of typical oxidization of 4-hydroxyphenylpyruvate to homogentisic acid and lead to premature release of quinolacetic acid. The abnormal enzyme, incapable of normally oxidizing 4-hydroxyphenylpyruvate to homogentisic acid, forms an intermediate that reacts with glutathione to form the unusual organic acid **hawkinsin** ([2-L-cystein-*S*-yl-1,4-dihydroxycyclohex-5-en-1-yl]acetic acid, see Fig. 105.1). As a result, secondary glutathione deficiency may ensue. Hawkinsinuria is inherited as an autosomal dominant trait. In one patient, compound heterozygosity for alleles associated with hawkinsinuria and tyrosinemia type III produced biochemical features of hawkinsinuria.

The clinical course of this rare disorder is incompletely understood. Individuals with hawkinsinuria may present with symptoms only during infancy. The symptoms usually appear in the first few months of life, typically after weaning from breastfeeding and with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, anemia, mild hepatomegaly, renal tubular acidosis, and an unusual odor are reported manifestations of this disorder. Neurocognitive development is usually normal.

Symptomatic infants and asymptomatic affected children and adults excrete hawkinsin, 4-hydroxyphenylpyruvate, and its metabolites (4-hydroxyphenyllactate and 4-hydroxyphenylacetate) as well as 4-hydroxycyclohexylacetate and 5-oxoproline (due to secondary glutathione deficiency) in their urine. Plasma tyrosine is moderately elevated in symptomatic infants and may normalize in asymptomatic older patients.

Treatment consists of a low-protein diet during infancy. Breastfeeding is encouraged. Successful long-term use of *N*-acetyl-L-cysteine to treat secondary glutathione deficiency has been reported. A trial with vitamin C is recommended. Although the affected enzyme is susceptible to inhibition by nitisinone, clinical studies showing its efficacy in symptomatic infants are lacking, and the indications for its use are not known.

TRANSIENT TYROSINEMIA OF THE NEWBORN

In a small number of newborn infants, plasma tyrosine may be as high as 3,300 μmol/L during the first 2 weeks of life. Most affected infants are premature and are on a high-protein diet. Transient tyrosinemia is thought to result from delayed maturation of 4-HPPD (see Fig. 105.1). Lethargy, poor feeding, and decreased motor activity are noted in some patients. Most are asymptomatic and are identified by a high blood phenylalanine or tyrosine level on routine newborn screening. Laboratory findings include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The finding of hypertyrosinemia differentiates this condition from PKU. 4-Hydroxyphenylpyruvic acid and its metabolites are present in the urine. Hypertyrosinemia tends to resolve spontaneously in the first 2 months of life and can be improved by reducing dietary protein to below 2 g/kg/day and by administering vitamin C. Mild intellectual deficits have been reported in some infants who had this condition, but the causal relationship to hypertyrosinemia has not been conclusively established.

ALKAPTONURIA

Alkaptonuria is a rare (approximately 1 in 250,000 live births) autosomal recessive disorder caused by a deficiency of homogentisate 1,2-dioxigenase encoded by *HGD*. Large amounts of homogentisic acid are formed (see Fig. 105.1) and excreted in urine or deposited in tissues. Alkaptonuria has a worldwide distribution, with a higher disease prevalence in the Dominican Republic and Slovakia.

The main **clinical manifestations** of alkaptonuria consist of ochronosis and arthritis in adulthood. The only sign in children is blackening of the urine on standing, caused by oxidation and polymerization of homogentisic acid. A history of gray- or black-stained diapers should suggest the diagnosis. This sign may never be noted, thus delaying the diagnosis until adulthood. *Ochronosis,* seen clinically as dark spots on the sclera or ear cartilage, results from the accumulation of the black polymer of homogentisic acid. *Arthritis* is another result of this deposition and can be disabling with advancing age. It can involve the spine and large joints (shoulders, hips, and knees) and is usually more severe in males. As with rheumatoid arthritis, the alkaptonuric arthritis has acute exacerbations, but its radiologic findings are more typical of osteoarthritis, with characteristic narrowing of the joint spaces and calcification of the intervertebral disks. A high incidence of heart disease (mitral and aortic valvulitis, calcification of heart valves, myocardial infarction) has been reported.

The **diagnosis** is confirmed by finding massive excretion of homogentisic acid on urine organic acid testing. Tyrosine levels are normal. The enzyme is expressed in high levels only in the liver and kidneys.

Treatment of the arthritis is symptomatic. In clinical trials, nitisinone, an inhibitor of 4-HPPD, has been shown to reduce urinary homogentisic acid. Additional studies are needed to establish its clinical efficacy and safety profile.

TYROSINE HYDROXYLASE DEFICIENCY

See Chapter 105.11.

ALBINISM

See also Chapters 662 and 694.

Albinism is caused by impaired synthesis and distribution of **melanin**, the main pigment of the skin and eye (Table 105.1). Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes

Table 105.1 Classification of Major Causes of Albinism

TYPE	GENE	DISTINGUISHING MOLECULAR AND CLINICAL FEATURES
OCULOCUTANEOUS ALBINISM (OCA)		
OCA1A (severe deficiency)	*TYR*	OCA1A (no melanin synthesis) vs OCA1B (minimal amounts of melanin present). OCA1A results in poorer visual outcomes.
OCA2 (tyrosinase positive)	*OCA2*	Newborns typically have light pigment, and hair color can darken with age.
OCA3 (Rufous, red OCA)	*TYRP1*	TYRP1 is required for maturation of eumelanin, but not reddish pheomelanin.
OCA4	*SLC45A2*	Newborns typically have light pigment, and hair color can darken with age. Clinically, it tends to overlap with OCA2.
OCA6	*SLC24A5*	*SLC24A5* encodes the protein NCKX5 involved in the maturation of melanosomes.
OCA7	*LRMDA*	Tends to be associated with poorer visual outcomes.
OCA8	*DCT*	*DCT* encodes dopachrome tautomerase involved in the melanin synthesis upstream of TYRP1. Likely results in milder forms of OCA.
Hermansky-Pudlak syndrome	Multiple genes	A multisystemic, genetically heterogenous disorder characterized by OCA, bleeding tendency, interstitial pneumonia, and granulomatous colitis, among other complications.
Chédiak-Higashi syndrome	*LYST*	Results in partial OCA, bleeding tendency, immunodeficiency, and hemophagocytic lymphohistiocytosis.
OCULAR ALBINISM (OA)		
OA1 (Nettleship-Falls ocular albinism)	*GPR143*	X-linked inheritance. Affected males present with significant ocular manifestations with minor skin involvement.
LOCALIZED ALBINISM		
Piebaldism	*KIT* and *SNAI2*	Pathogenic variants in *KIT* have been associated with a number of phenotypes, including piebaldism, mastocytosis, familial, and sporadic cancers.
Waardenburg syndrome (WS1-WS4)	See text.	See text.

originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), hair follicles, and inner ear. The melanin in the eye is confined to the iris stromal and retinal pigment epithelia, whereas in skin and hair follicles, it is secreted into the epidermis and hair shaft. Albinism can be caused by deficiencies of melanin synthesis, by some hereditary defects of melanosomes, or by disorders of melanocyte migration. Neither the biosynthetic pathway of melanin nor many facets of melanocyte cell biology are completely elucidated (see Fig. 105.2). The end products are two pigments: *pheomelanin,* which is a yellow-red pigment, and *eumelanin,* a brown-black pigment.

Clinically, primary albinism can be *generalized* or *localized.* Primary generalized albinism can be *ocular* or *oculocutaneous.* Some syndromes feature albinism in association with platelet, immunologic, or neurologic dysfunction. In generalized oculocutaneous albinism, hypopigmentation can be either complete or partial. Individuals with complete albinism do not develop either generalized (tanning) or localized (pigmented nevi) skin pigmentation.

The **diagnosis** of albinism is usually evident, but for some children whose families are particularly light-skinned, normal variation may be a diagnostic consideration. Unlike patients with albinism, unaffected fair-skinned children progressively develop pigmentation with age, do not exhibit the eye manifestations of albinism, and have pigmentary development similar to other family members. The clinical diagnosis of oculocutaneous albinism, as opposed to other types of cutaneous hypopigmentation, requires the presence of characteristic eye findings.

The **ocular manifestations** of albinism include hypopigmentation of the iris and retina, often with foveal hypoplasia, along with reduced visual acuity, refractive errors, nystagmus, alternating strabismus, and iris transillumination (diffuse reddish hue of the iris produced during ophthalmoscopic or slit-lamp examination of the eye).

Albinism is also associated with an abnormality in routing optic fibers at the chiasm. Unlike in pigmented individuals, in patients with albinism, the majority of nerve fibers from the temporal side of the retina cross to the contralateral hemisphere of the brain. This results in impaired depth perception, alternating strabismus, and a characteristic pattern of visual evoked potentials. These findings are highly specific for albinism. Regular ophthalmologic follow-up is recommended for patients with oculocutaneous albinism. Correction of refractive errors can maximize visual function. Usually, the alternating strabismus does not result in amblyopia and does not require surgery.

Patients with albinism should be counseled to avoid ultraviolet (UV) radiation by wearing protective long-sleeved clothing and by using sunscreens with a sun protection factor (SPF) rating >30. Melanin is also present in the cochlea; therefore albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Genetics of Albinism

Oculocutaneous albinism is inherited as an autosomal recessive trait. Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different pathogenic variants of the same gene. Implicated genes are involved in different stages of melanogenesis and melanosome maturation (see Table 105.1). The classification outlined next is based on the distribution of albinism in the body and the affected genes. Genetic analysis is clinically available for most forms of albinism (see Table 105.1). Molecular diagnosis is of little use therapeutically in isolated albinism but can be helpful for precise genetic counseling of families.

Oculocutaneous (Generalized) Albinism

Lack of pigment is generalized, affecting skin, hair, and eyes. At least eight genetically distinct forms of oculocutaneous albinism **(OCA)** have been identified of which seven have pathogenic variants in

associated genes (OCA1, OCA2, OCA3, OCA4, OCA6, OCA7, and OCA8). Many forms of OCA may not be clinically distinguishable from one another. All affected individuals have ocular manifestations of albinism. All known forms of OCA are inherited as autosomal recessive traits.

OCA1

The defect in patients with OCA1 resides in the tyrosinase gene, *TYR*. Many pathogenic variants have been identified. Most affected individuals are compound heterozygotes. A clinical clue to the diagnosis of OCA1 is complete lack of pigment at birth. The condition can be subdivided into OCA1A and OCA1B, based on enzyme activity and difference in clinical manifestations as a function of age. In patients with OCA1A, the most severe form of OCA, both *TYR* alleles have pathogenic variants that completely inactivate tyrosinase. Clinically, lack of pigment in the skin (milky white), hair (white hair), and eyes (red-gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

Patients with OCA1B have *TYR* gene pathogenic variants that preserve some residual activity. Clinically, they completely lack pigment at birth but with age become light blond with light-blue or hazel eyes. They develop pigmented nevi and freckles, and they may tan.

OCA2

OCA2 is the *most common form of generalized OCA,* particularly in patients of African ancestry. Clinically, the phenotype is highly variable; most patients demonstrate some pigmentation of the skin and eyes at birth and continue to accumulate pigment throughout life. The hair is yellow at birth and may darken with age. They have pigmented nevi and freckles, and some may tan. They may be clinically indistinguishable from OCA1B patients. Individuals with OCA2, however, have normal tyrosinase activity in hair bulbs. The defect is in the *OCA2* gene, which is an orthologue of the *p* (pink-eyed dilution) gene in the mouse. This gene produces the P protein, a melanosome membrane–bound protein. Patients with **Prader-Willi** and **Angelman** syndromes caused by microdeletion of chromosome 15q12 that includes the *OCA2* gene have mild pigmentary deficiency (see Chapter 98.8).

OCA3

This form has been identified predominantly in patients of African and Asian ancestry. Patients with OCA3 can make pheomelanin but not eumelanin. Patients have reddish hair and reddish-brown skin as adults. The skin color is peculiar to this form. In young persons the coloration may resemble that of OCA2. The altered gene *TYRP1* encodes the tyrosinase-related protein 1, the function of which is not well-understood.

OCA4

Similar manifestations to OCA2 (both in the skin and the eyes) have been observed in OCA4 patients (mostly from Japan) with pathogenic variants in the *SLC45A2* gene.

Ocular Albinism

Patients with ocular albinism **(OA)** present in the first months of life with nystagmus, hypopigmentation of the iris and fundus, foveal hypoplasia, and decreased visual acuity. Electron microscopy demonstrates characteristic macromelanosomes in skin biopsies or hair root specimens. Most patients affected by OA have ocular albinism type 1 **(OA1)**, an X-linked disorder caused by pathogenic variants in the *GPR143* gene. A rare form of OA with late-onset sensorineural deafness and apparent autosomal dominant inheritance has also been reported.

Ocular Albinism Type 1 (Nettleship-Falls Ocular Albinism)

OA1 is an X-linked disorder characterized by congenital nystagmus, reduced pigmentation of ocular structures, and visual impairment in affected males. Heterozygous females may present with segments of abnormal retinal pigmentations. Infrequently, depending on the pattern of X chromosome inactivation, heterozygous females may also present with severe manifestations, including nystagmus, iris and foveal hypopigmentation, foveal hypoplasia, and reduced visual acuity. In families with darker skin complexion, mild skin hypopigmentation can be seen. The diagnosis of OA1 is suspected in males with features of albinism in the eye, normal to mildly reduced skin pigmentation, and a family history suggestive of an X-linked transmission. It is a nonprogressive disorder, and the eye findings often improve with age. In patients who are the first of their families to be affected, genetic analysis of *GPR143* helps confirm the diagnosis.

Syndromic Forms of Generalized Albinism

Hermansky-Pudlak Syndrome

This group of autosomal recessive disorders is caused by biallelic pathogenic variants in one of ten genes *(HPS1, AP3B1, HPS3, HPS4, HPS5, HPS6, DTNBP1, BLOC1S3, BLOC1S6, AP3D1)*. Hermansky-Pudlak syndrome **(HPS)** can be suspected in patients with albinism associated with a bleeding diathesis, inflammatory bowel disease (IBD), and/or pulmonary fibrosis. Disease subtype can be established with molecular studies (see Chapter 533). Genes associated with HPS are required for normal structure and function of lysosome-derived organelles, including melanosomes and platelet-dense bodies. Patients have a tyrosinase-positive OCA of variable severity associated with platelet dysfunction (caused by the absence of platelet-dense bodies). A ceroid-like material accumulates in tissues. HPS is pan-ethnic. Patient ancestry can help develop a cost-effective testing strategy. HPS is prevalent in two regions of Puerto Rico (**type 1** in the northwest and **type 3** in the central regions because of different founder effects). The cutaneous and ocular symptoms of albinism are present. Patients can develop epistaxis, postsurgical bleeding, or abundant menses. Bleeding time is prolonged, but platelet count is normal. Major complications include progressive pulmonary fibrosis in young adults and Crohn's-like IBD in adolescents and young adults. Kidney failure and cardiomyopathy have been reported. Neutropenia has been described in HPS **type 2**. Treatment is symptomatic.

Chédiak-Higashi Syndrome

Patients with this rare autosomal recessive condition have OCA of variable severity and susceptibility to infection (see Chapter 156). Bacterial infections of the skin and the upper respiratory tract are common. Giant peroxidase-positive lysosomal granules can be seen in granulocytes in a blood smear. Patients have a reduced number of melanosomes, which are abnormally large (macromelanosomes) and can have silvery-gray hair. The bleeding tendency is typically mild. If treatment is not successful, children can reach a stage of the disease known as the **accelerated phase**, which is a major, life-threatening complication of Chédiak-Higashi syndrome. It is caused by macrophage activation resulting in hemophagocytic lymphohistiocytosis with manifestations that include fever, lymphadenopathy, hepatosplenomegaly, cytopenia, and an elevated plasma ferritin level. Patients surviving childhood may develop cerebellar atrophy, peripheral neuropathy, and cognitive delay. Pathogenic variants in *LYST* are the only known cause for this syndrome. Hematopoietic stem cell transplantation offers an effective approach to control immunodeficiency and hematologic abnormalities and to prevent development of the accelerated phase.

Other Disorders Featuring Generalized Albinism

Hypopigmentation can be a feature in other syndromes, some with abnormalities of lysosomal biogenesis or melanosome biology. **Griscelli syndrome** patients have silver-gray hair, pigmentary dilution of skin, and melanosomal clumping in hair shafts and the center of melanocytes, with intellectual disability or macrophage activation with hemophagocytosis in different subtypes. All forms are autosomal recessive caused by pathogenic variants in *MLPH, MYO5A,* or *RAB27A*. **Vici syndrome** patients have combined immunodeficiency, intellectual disability, agenesis of the corpus callosum, cataracts, and cleft lip/palate. It is autosomal recessive, caused by pathogenic variants in *EPG5*. Patients with **MAPBP-interacting protein deficiency** have a short stature, recurrent infections, and neutropenia, and inheritance occurs in an autosomal recessive manner due to pathogenic variants in the gene *LAMTOR2*.

Localized Albinism

Localized albinism refers to localized patches of hypopigmentation of skin and hair, which may be evident at birth or develop with time. These conditions are caused by abnormal migration of melanocytes during embryonic development.

Piebaldism

Piebaldism is an autosomal dominant inherited condition in which the individual is usually born with a white forelock. The underlying skin is depigmented and devoid of melanocytes. In addition, there are usually white macules on the face, trunk, and extremities. Pathogenic variants in the *KIT* and *SNAI2* genes have been identified in affected patients.

Waardenburg Syndrome

In Waardenburg syndrome, a white forelock is often associated with lateral displacement of the inner canthi of the eyes, a broad nasal bridge, heterochromia of irides, and sensorineural deafness. This condition is inherited as an autosomal dominant trait with four main subtypes known. Patients with Waardenburg syndrome type 1 (**WS1**, the *most common form*) have all the previous clinical findings, including lateral displacement of the inner canthi. The condition is typically caused by pathogenic variants (>90%) in the *PAX3* gene. Patients with Waardenburg syndrome type 2 **(WS2)** have the clinical findings of WS1 except for the lateral displacement of the inner canthi. Genetically, this is a heterogeneous condition caused by pathogenic variants in several genes, including *MITF, SOX10,* and *SNAI2*. Patients with Waardenburg syndrome type 3 **(WS3)** have all the findings seen in individuals with WS1 plus hypoplasia and contractures of the upper limbs. It is caused by heterozygous or homozygous pathogenic variants of the *PAX3* gene. Finally, Waardenburg syndrome type 4 **(WS4)**, associated with **Hirschsprung disease**, is genetically heterogeneous, with pathogenic variants in different genes (*EDN3, EDNRB,* or *SOX10*) identified.

Other causes of **localized hypopigmentation** include vitiligo and hypomelanosis of Ito (see Chapter 694).

105.3 Methionine

Oleg A. Shchelochkov and Charles P. Venditti

The usual pathway for catabolism of methionine, an essential amino acid, produces S-*adenosylmethionine,* which serves as a methyl group donor for methylation reactions for a variety of compounds, and *cysteine,* which is formed through a series of reactions collectively called *trans-sulfuration* (Fig. 105.3).

HOMOCYSTINURIA (HOMOCYSTINEMIA)

Normally, most *homocysteine,* an intermediate compound of methionine degradation, is remethylated to methionine. This methionine-sparing reaction is catalyzed by the enzyme methionine synthase, which requires a metabolite of folic acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B_{12} (methylcobalamin) as a cofactor (see Fig. 105.3). In healthy individuals, most plasma homocysteine is either protein-bound or exists as disulfides. Three major forms of homocystinemia and homocystinuria have been identified.

Homocystinuria Caused by Cystathionine β-Synthase Deficiency (Classic Homocystinuria)

Classic homocystinuria is the most common inborn error of methionine metabolism. It is an autosomal recessive condition caused by biallelic pathogenic variants in *CBS* encoding cystathionine β-synthase. Clinical presentation in the first years of life is nonspecific. Universal newborn screening to detect elevated methionine in dried blood spot samples can identify most affected infants. Second-tier testing after a positive newborn screen result should include plasma methionine and total plasma homocysteine and followed up by confirmatory testing using *CBS* molecular gene analysis. Most affected patients are compound heterozygotes for two different alleles. Heterozygous carriers are asymptomatic.

Infants with classic homocystinuria appear healthy at birth. **Clinical manifestations** during infancy are nonspecific and may include failure to thrive and developmental delay. Without newborn screening, the diagnosis can be delayed and is usually made after 3 years of age, when subluxation of the ocular lens *(ectopia lentis)* occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive intellectual disability is common. Neurocognitive scores in the average range have been reported; IQ scores range from 10 to 135. Higher IQ scores are seen in vitamin B_6–responsive patients. Psychiatric and behavioral disorders have been observed in more than 50% of affected patients. Seizures are seen in approximately 20% of untreated patients. Affected individuals with homocystinuria manifest skeletal abnormalities resembling those of Marfan syndrome (see Chapter 743): tall with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or pectus carinatum, genu valgum, pes cavus, high-arched palate, and crowding of the teeth have been reported. These children usually have a fair complexion, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main x-ray finding. Thromboembolic episodes involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is likely caused by elevated homocysteine levels leading to abnormal angiogenesis and inhibition of fibrinolytic activity. The risk of thromboembolism increases after surgical procedures or dehydration. Spontaneous pneumothorax and acute pancreatitis are rare complications.

Elevations of both total plasma homocysteine and methionine in body fluids are the diagnostic laboratory findings. Cysteine is low or absent in plasma. Total plasma homocysteine is the preferred analyte for screening and management of classic homocystinuria. Free plasma homocysteine may normalize or remain normal when total plasma homocysteine is lowered. If urinary homocystine is used for diagnostic purposes, a freshly voided urine sample is preferred because this compound is unstable and may disappear after prolonged storage. The diagnosis may be established by molecular analysis of *CBS.* Prenatal diagnosis is feasible by DNA analysis or by performing an enzyme assay of cultured amniotic cells.

Treatment with high doses of vitamin B_6 (100-200 mg/day) can produce significant improvement in patients who are responsive to this therapy. Approximately 40% of affected patients respond to high doses of vitamin B_6 and usually have milder clinical manifestations than those who are unresponsive to vitamin B_6 therapy. The degree of response to vitamin B_6 treatment may vary across families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B_6 until folic acid (1-5 mg/day) has been added to the treatment regimen. For patients who are unresponsive to vitamin B_6, lifelong restriction of methionine intake in conjunction with cysteine supplementation is also recommended. The need for dietary restriction and its extent remains controversial in patients with the vitamin B_6–responsive form. In some patients with this form, addition of betaine may obviate the need for any dietary restriction. *Betaine* (trimethylglycine, 6 g/day for adults or 100-200 mg/kg/day for children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 105.3), which may result in elevation of plasma methionine levels. This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B_6 therapy. Cerebral edema has occurred in a patient with vitamin B_6–nonresponsive homocystinuria and dietary noncompliance during betaine therapy.

More than 100 pregnancies in women with classic homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full-term and healthy at birth. Postpartum thromboembolic events occurred in a few mothers.

The screening of newborn infants for classic homocystinuria has been performed worldwide, with an estimated prevalence of 1 in

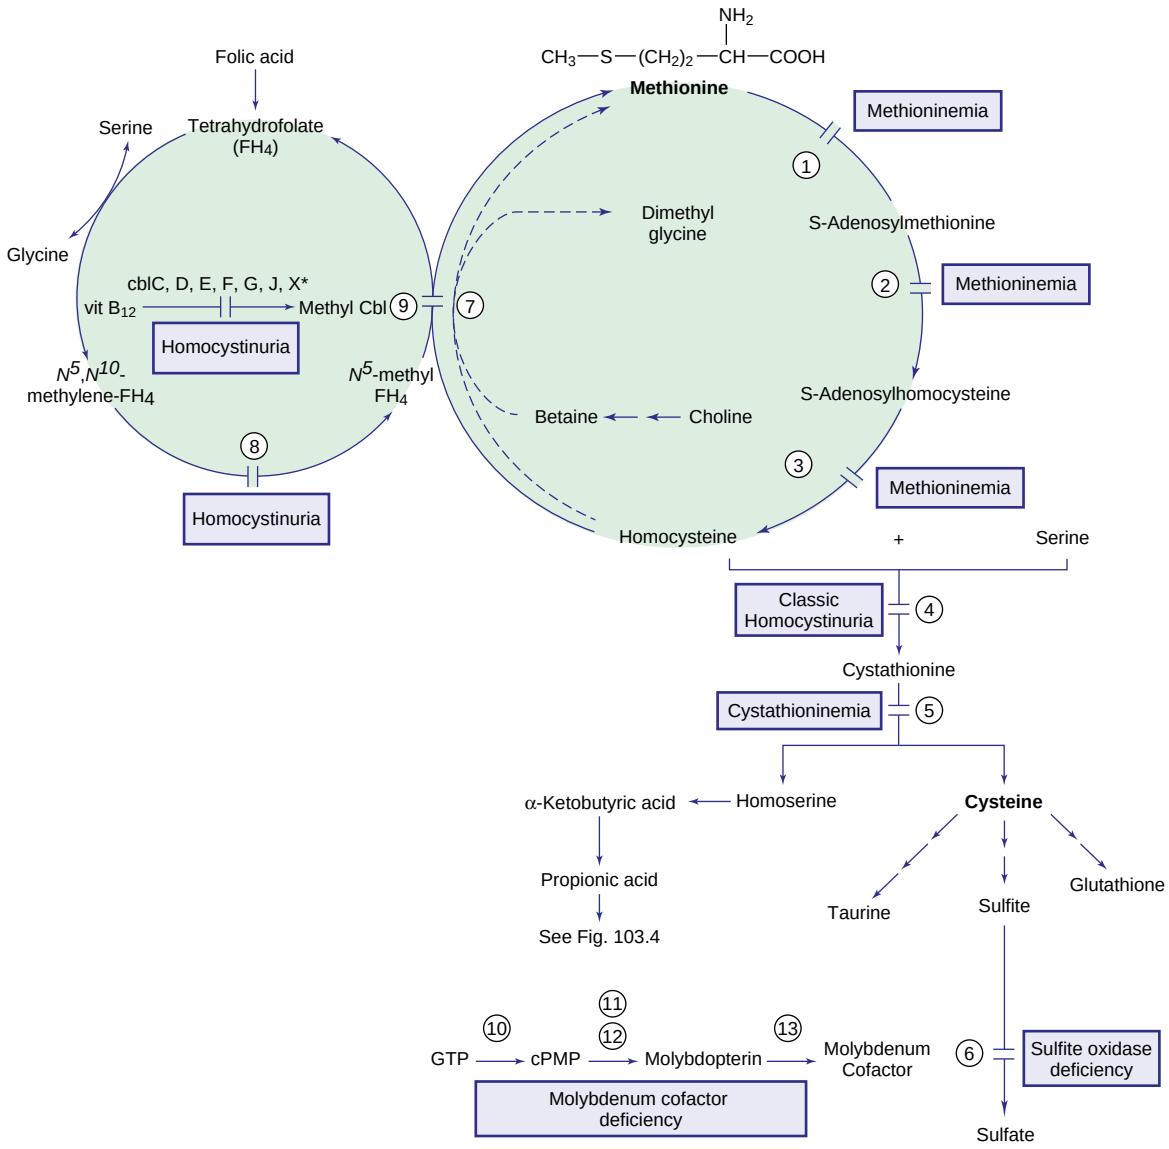

Fig. 105.3 Pathways in the metabolism of sulfur-containing amino acids. **Enzymes:** *(1)* Methionine adenosyltransferase (MAT I/III), *(2)* glycine *N*-methyltransferase, *(3)* *S*-adenosylhomocysteine hydrolase, *(4)* cystathionine synthase, *(5)* cystathionase, *(6)* sulfite oxidase, *(7)* betaine homocysteine methyltransferase, *(8)* methylene tetrahydrofolate reductase, *(9)* methionine synthase (cblG), *(10)* molybdenum cofactor biosynthesis protein 1, *(11)* molybdopterin synthase, *(12)* adenylyltransferase and sulfurtransferase (*MOCS3*), *(13)* gephyrin. GTP, Guanosine triphosphate; cPMP, cyclic pyranopterin monophosphate. *Defects in cblC, D, F, J, and X result in methylmalonic acidemia and homocystinuria.

200,000 to 1 in 350,000 live births, although it can be more common in some parts of the world (e.g., 1 in 1,800 in Qatar). Early treatment of patients identified by screening has produced favorable results. The mean IQ of patients with the vitamin B_6–unresponsive form treated in early infancy was in the normal range. Dislocation of the lens appeared to be preventable in some patients.

Homocystinuria Caused by Defects in Methylcobalamin Formation

Methylcobalamin is the cofactor for methionine synthase, which catalyzes remethylation of homocysteine to methionine. At least seven distinct defects in the intracellular metabolism of cobalamin may interfere with the formation of methylcobalamin (for a more detailed discussion on cobalamin metabolism, see Chapter 105.6 and Figs. 105.3 and 105.4). The seven defects are designated as *cbl*C, *cbl*D (including *cbl*D variant 1), *cbl*E (methionine synthase reductase), *cbl*G (methionine synthase), *cbl*F, *cbl*J, and *cbl*X. Patients with *cbl*C, *cbl*D, *cbl*F, *cbl*J, and *cbl*X defects have **methylmalonic acidemia** *in addition* to homocystinuria, because the formation of both adenosylcobalamin and methylcobalamin is impaired.

Patients with *cbl*E, *cbl*G, and *cbl*D variant one defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (Fig. 105.4). The clinical manifestations are similar in patients with these three defects. Nonspecific symptoms such as vomiting, poor feeding, failure to thrive, lethargy, hypotonia, seizures, and developmental delay may occur in the first few months of life. Late-onset forms of these disorders may present with neurocognitive defects, psychosis, and peripheral neuropathy. **Laboratory findings** include megaloblastic anemia, hyperhomocysteinemia, homocystinuria, and hypomethioninemia. The absence of hypermethioninemia differentiates these conditions from cystathionine β-synthase deficiency. Renal artery thrombosis, hemolytic uremic syndrome, pulmonary hypertension, and optic nerve atrophy have been reported in some patients with these defects.

Diagnosis is established by DNA testing or using complementation studies performed in cultured fibroblasts. Prenatal diagnosis can be accomplished by studies in amniotic cell cultures. *cbl*E, *cbl*G, and *cbl*D variant one deficiencies are inherited as autosomal recessive traits. The gene for *cbl*E is *MTRR*, encoding methionine synthase reductase.

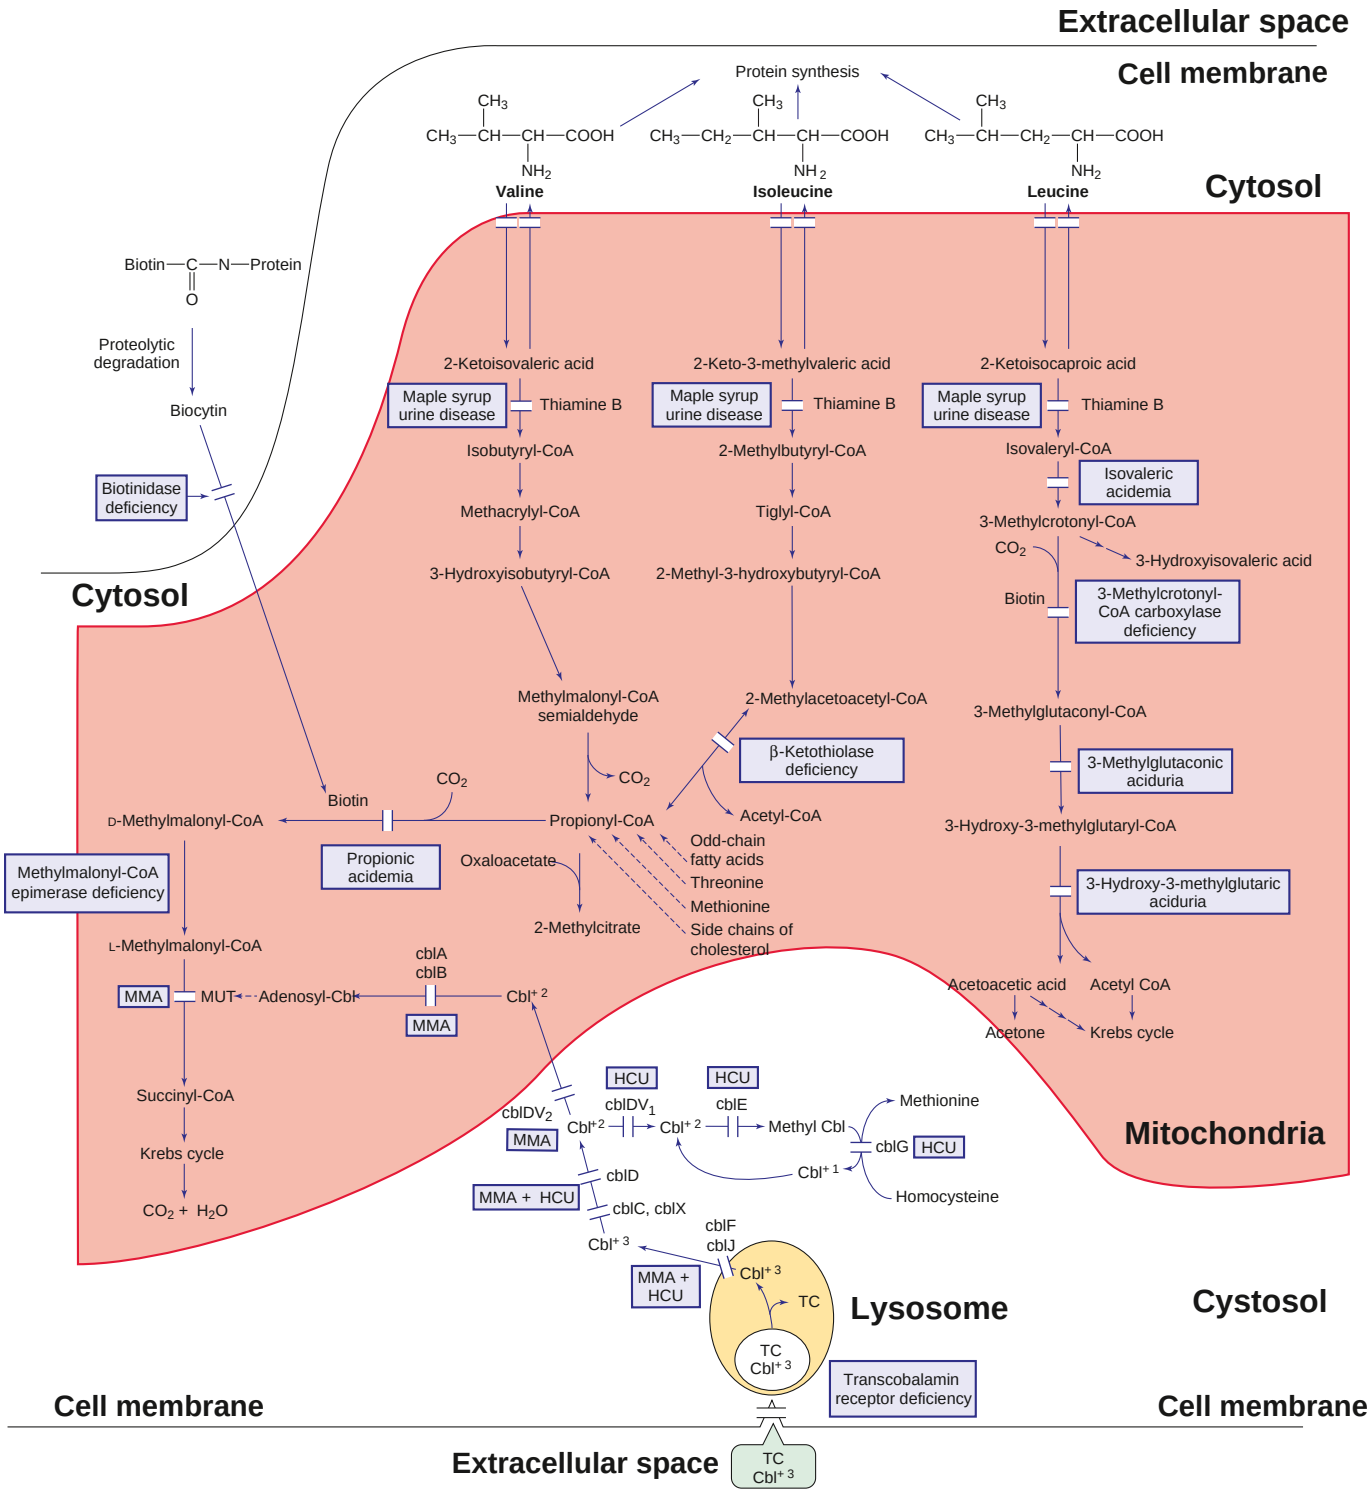

Fig. 105.4 Pathways in the metabolism of the branched-chain amino acids, biotin, and vitamin B_{12} (cobalamin). Adenosyl Cbl, Adenosylcobalamin; Cbl, cobalamin; *cbl*, defect in metabolism of cobalamin; *cbl*DV1, *cbl*D variant 1; *cbl*DV2, *cbl*D variant 2; HCU, homocystinuria; methyl Cbl, methylcobalamin; MMA, methylmalonic acidemia; MUT, mutase; OHCbl, hydroxycobalamin; TC, transcobalamin; TCR, transcobalamin receptor. See text for the name of the enzymes.

The gene for *cbl*G is *MTR*, encoding methionine synthase. The *cbl*D variant one deficiency is caused by pathogenic variants affecting the C-terminal of the *MMADHC* gene.

Treatment with vitamin B_{12} in the form of high-dose parenteral hydroxycobalamin (0.3 mg/kg/day) helps improve the clinical and biochemical findings. Results vary among both diseases and sibships.

Homocystinuria Caused by Deficiency of Methylenetetrahydrofolate Reductase (MTHFR Deficiency)

This enzyme reduces 5,10-methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 105.3). The severity of the enzyme defect and the clinical manifestations vary considerably

in different families. **Clinical findings** vary from apnea, seizure, microcephaly, coma, and death to developmental delay, ataxia, motor abnormalities, peripheral neuropathy, and psychiatric manifestations. Thromboembolism has also been observed. Exposure to the anesthetic nitrous oxide (which inhibits methionine synthase) in patients with MTHFR deficiency may result in neurologic deterioration and death.

Laboratory findings include moderate hyperhomocysteinemia and homocystinuria. The methionine concentration is low or low-normal. This finding helps differentiate MTHFR deficiency from classic homocystinuria caused by cystathionine β-synthase deficiency. The diagnosis can be confirmed by molecular analysis of *MTHFR* or by the enzyme assay in cultured fibroblasts or leukocytes.

MTHFR deficiency should be differentiated from **mild hyperhomocysteinemia** due to two common variants in the *MTHFR* gene. Two "thermolabile" polymorphisms have been extensively studied: c.665C>T (p.Ala222Val, previously referred to as c.677C>T) and c.1286A>C (p.Glu429Ala, formerly referred to as c.1298A>C). These variants may minimally affect levels of plasma total homocysteine in some patients and are often confounded by dietary folate deficiency. Population-based studies revealed a surprisingly high prevalence of homozygosity for these polymorphisms in the general population: up to 10–15% of North American Whites and >25% in some Hispanics. The best data support a role for the c.665C>T polymorphic variant (formerly c. 677C>T) as a risk factor for neural tube defects. Although clinical tests for this polymorphic variant are widely available, meta-analyses have not supported the association between the *MTHFR* polymorphic variants and risk for venous thromboembolism or between mild hyperhomocysteinemia and an increased risk for coronary heart disease. It is hypothesized that fortification of flour with folate may have decreased the strength of associations observed in the past.

Homocystinuria caused by the loss of function in MTHFR (MTHFR deficiency) is an autosomal recessive disorder. The **diagnosis** can be confirmed by *MTHFR* gene analysis. Prenatal diagnosis can be achieved by molecular analysis of *MTHFR* of known familial pathogenic variants or by measuring MTHFR enzyme activity in cultured chorionic villus cells or amniocytes.

Treatment of MTHFR deficiency with a combination of folic acid, vitamin B_6, vitamin B_{12}, methionine supplementation, and betaine has been tried. Of these, early treatment with betaine appears to have the most beneficial effect.

HYPERMETHIONINEMIA

Primary (Genetic) Hypermethioninemia

Elevation of plasma level of methionine occurs in several genetic conditions. These should be differentiated from acquired (nongenetic) forms of hypermethioninemia, which can occur under various conditions of physiologic stress, especially when involving liver dysfunction.

Classic Homocystinuria

See earlier discussion.

Hepatic Methionine Adenosyltransferase (MAT I/MAT III) Deficiency (Mudd Disease). This hepatic enzyme, which has two isoforms, MAT I (tetrameric) and MAT III (dimeric), is encoded by a single gene, *MAT1A,* and is involved in the first step of methionine catabolism (see Fig. 105.3). Another structurally similar enzyme, MAT II, is encoded by a different gene, *MAT2A,* and is expressed predominantly in nonhepatic tissues (e.g., kidney, brain, lymphocytes). Deficiency of MAT I/MAT III causes hypermethioninemia. In severe deficiency, total plasma homocysteine can also be elevated. The majority of these patients have been diagnosed in the neonatal period through screening for classic homocystinuria. Most affected individuals have residual enzyme activity and remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of an unusual odor to their breath, likely caused by accumulation of dimethylsulfide. A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (intellectual disability, dystonia, dyspraxia).

Laboratory studies reveal markedly elevated levels of plasma methionine with a normal or low level of *S*-adenosylmethionine, normal concentrations of *S*-adenosylhomocysteine, and normal or slightly elevated total plasma homocysteine. These findings help differentiate MAT I/MAT III deficiency from other causes of hypermethioninemia.

No uniformly accepted therapeutic regimen has yet emerged. Long-term follow-up to monitor for neurologic and liver abnormalities should be considered. Diets low in methionine result in lowering of plasma methionine, but the advisability of such diets has been questioned because lowering plasma methionine, an essential amino acid, causes further lowering of *S*-adenosylmethionine, thus interfering with reactions of remethylation. Supplementation with *S*-adenosylmethionine in conjunction with a low-methionine diet seems prudent, but no large clinical experience is yet available. Normal pregnancies producing normal offspring have been reported in mothers with MAT I/MAT III *(MAT1A)* deficiency. The condition is inherited as an autosomal recessive trait, although the pathogenic variant p.Arg264His in *MAT1A* appears to disrupt protein dimerization and may result in mild hypermethioninemia even in heterozygous patients.

Glycine *N*-Methyltransferase Deficiency. Glycine *N*-methyltransferase *(GNMT)* mediates catabolism of *S*-adenosylmethionine to *S*-adenosylhomocysteine (see Fig. 105.3). A few patients with deficiency of this enzyme have been reported to date. Clinically, patients were asymptomatic except for mild hepatomegaly and elevated serum levels of aminotransferases. Other laboratory findings included hypermethioninemia and very high levels of serum *S*-adenosylmethionine. No specific treatment has yet been identified. The condition is inherited as an autosomal recessive trait.

S-Adenosylhomocysteine Hydrolase (SAHH) Deficiency. SAHH deficiency (see Fig. 105.3) has been described infrequently. Intellectual disability, severe hypotonia, and progressive liver dysfunction were common clinical findings. Laboratory studies included elevated levels of serum creatine kinase, hypoalbuminemia (associated with fetal hydrops in one family), hypoprothrombinemia, and greatly elevated levels of serum *S*-adenosylhomocysteine with moderate elevations of plasma methionine and *S*-adenosylmethionine. Marked elevation in *S*-adenosylhomocysteine has been thought to cause inhibition of methyltransferases, including those involved in the synthesis of creatine (see Fig. 105.10) and choline, resulting in their deficiencies. Brain MRIs often reveal delayed myelination of the white matter. The diagnosis can be achieved by *AHCY* gene analysis or, if needed, by biochemical assay of red blood cells, cultured skin fibroblasts, or liver biopsy. Treatment with a low-methionine diet has been used, but its long-term effectiveness has not been established.

Tyrosinemia Type I. See Chapter 105.2.

Citrin Deficiency. See Chapter 105.12.

Acquired (Nongenetic) Hypermethioninemia

Hypermethioninemia occurs in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme MAT. Adjusting protein intake under the control of plasma methionine usually resolves the abnormality. Hypermethioninemia is also commonly found in patients with various forms of liver disease.

PRIMARY CYSTATHIONINEMIA (CYSTATHIONINURIA)

Cystathionase (cystathionine γ-lyase encoded by *CTH*) deficiency results in massive cystathioninuria and mild to moderate cystathioninemia. Cystathionase deficiency of this enzyme is inherited as an autosomal recessive trait, with an estimated prevalence of 1 in 14,000 live births. A wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in some individuals *without* apparent clinical findings suggest that cystathionase deficiency may be of no clinical significance. Many reported cases are responsive to oral administration of large doses of vitamin B_6 (~100 mg/day). When cystathioninuria is discovered in a patient, vitamin B_6 treatment can be tried, but its beneficial effect has not been established.

Primary cystathioninuria needs to be differentiated from secondary cystathioninuria, which can occur in patients with vitamin B_6 and/or

B_{12} deficiency, liver disease (particularly damage caused by galactosemia), thyrotoxicosis, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

105.4 Cysteine and Cystine

Oleg A. Shchelochkov and Charles P. Venditti

Cysteine is a sulfur-containing amino acid synthesized from methionine (see Fig. 105.3). Oxidation of cysteine forms *cystine,* a poorly soluble dimer. The most common genetic disorders of cysteine and cystine metabolism are cystinuria (see Chapter 584) and cystinosis (see Chapter 569.3).

SULFITE OXIDASE DEFICIENCY AND MOLYBDENUM COFACTOR DEFICIENCY

In the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see Fig. 105.3). Sulfite oxidase is encoded by *SUOX* and requires a molybdenum-pterin complex called *molybdenum cofactor.* This cofactor is also necessary for the function of two other enzymes in humans: xanthine dehydrogenase (oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase (involved in oxidizing a number of natural compounds and drugs). Three enzymes, encoded by three different genes (*MOCS1, MOCS2,* and *GPHN*), are involved in the synthesis of the cofactor. Deficiency of any of the three enzymes causes cofactor deficiency with similar phenotypes. Most patients, who were originally diagnosed as having **sulfite oxidase deficiency**, have been shown to have **molybdenum cofactor deficiency**. Sulfite oxidase deficiency and molybdenum cofactor deficiency are autosomal recessive disorders.

The enzyme and cofactor deficiencies present with overlapping and often nonspecific **clinical manifestations**. Refusal to feed, vomiting, an exaggerated startle reaction, severe intractable seizures (tonic, clonic, myoclonic), cortical atrophy with subcortical multicystic lesions, and severe developmental delay may develop within a few weeks after birth. The biochemical diagnosis should be considered in infants presenting with neonatal seizures and neonates with symptoms reminiscent of hypoxic-ischemic encephalopathy. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period. The intractable seizures seen in this condition are in part a consequence of secondary vitamin B_6 dependency. The accumulation of sulfites in body fluids in this condition causes the inhibition of the *antiquitin* enzyme, which is necessary for the conversion of α-amino adipic semialdehyde to α-aminoadipic acid; the resultant accumulation of α-aminoadipic semialdehyde and its cyclic form, P6C, causes the inactivation of pyridoxal-5-phosphate (the active form of vitamin B_6), leading to **vitamin B_6–dependent** epilepsy (see also Chapter 105.14).

Affected children excrete large amounts of sulfite, thiosulfate, *S*-sulfocysteine, xanthine, and hypoxanthine in the urine. Serum uric acid and urinary excretion of sulfate and uric acid are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation of sulfite to sulfate at room temperature may produce false-negative results. Increased concentrations of α-aminoadipic semialdehyde and P6C can be found in the CSF, plasma, and urine.

Diagnosis is confirmed by analysis of affected genes (often using a multigene panel). Infrequently, measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies is required. Prenatal diagnosis is possible by DNA studies or by performing an assay of sulfite oxidase activity in cultured amniotic cells, in samples of chorionic villi. The prevalence of these deficiencies in the general population is not known but likely is very low.

Patients with *MOCS1*-related molybdenum cofactor deficiency may benefit from daily intravenous **cyclic pyranopterin monophosphate** (a cPMP analogue), a compound under investigation in a multicenter clinical trial. Large doses of vitamin B_6 may alleviate the frequency and severity of seizures but do not seem to alter the devastating neurologic outcome. A cysteine-restricted diet under control of plasma amino acids to avoid essential amino acid deficiencies can be attempted in some patients, but the long-term efficacy of this approach is unknown.

105.5 Tryptophan

Oleg A. Shchelochkov and Charles P. Venditti

Tryptophan is an essential amino acid and a precursor for nicotinic acid (niacin) and serotonin (Fig. 105.5). The genetic disorders of metabolism of serotonin, one of the major neurotransmitters, are discussed in Chapter 105.11.

HARTNUP DISEASE

Hartnup disease is an autosomal recessive condition caused by biallelic pathogenic variants in *SLC6A19*. This gene encodes a monoamino-monocarboxylic amino acid transporter (B^0AT1), which facilitates transport of neutral amino acids, including tryptophan, across the intestinal mucosa and renal tubules. Patients show significant variability in presentation, likely related to nutritional factors, environment, and genetic heterogeneity of modifier genes (e.g., two proteins, TMEM27 and ACE2, that interact with B^0AT1). The prevalence of Hartnup disorder is estimated to be 1 in 20,000 to 1 in 55,000 live births. Most children with Hartnup disease remain asymptomatic. Decreased intestinal absorption of tryptophan in conjunction with its increased renal loss can lead to reduced availability of tryptophan for niacin synthesis. **Tryptophan deficiency** can be accentuated by malabsorption such as celiac disease. One of the more noticeable clinical manifestations in the rare symptomatic patient is **cutaneous photosensitivity**. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, a pellagra-like rash may develop. The rash may be pruritic, and a chronic eczema may develop. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and can respond to niacin supplementation. Cognitive development is usually normal. Episodic psychiatric manifestations such as irritability, emotional instability, depression, and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Most children diagnosed with Hartnup disorder by neonatal screening have remained asymptomatic. This indicates that other factors are also involved in the pathogenesis of the clinical condition.

The main laboratory finding is **aminoaciduria**, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This finding helps differentiate Hartnup disorder from other causes of generalized aminoaciduria, such as renal Fanconi syndrome. Plasma concentrations of neutral amino acids are normal or mildly decreased. This seemingly unexpected finding reflects compensatory mechanisms that maintain normal transport and utilization of amino acids. The indole derivatives (especially indican) may be found in large amounts in some patients, resulting from bacterial breakdown of unabsorbed tryptophan in the intestines.

Diagnosis of Hartnup disorder is established by the intermittent nature of symptoms and characteristic findings on the urine amino acid analysis. When necessary, the diagnosis can be confirmed molecularly by *SLC6A19* gene analysis.

Treatment with nicotinic acid or nicotinamide (50-300 mg/day) and a high-protein diet results in a favorable response in symptomatic patients with Hartnup disorder. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to establish. Normal outcome for both the mother and fetus has been reported in several affected women.

105.6 Isoleucine, Leucine, Valine, and Related Organic Acidemias

Oleg A. Shchelochkov, Irini Manoli, and Charles P. Venditti

The early steps in the degradation of the branched-chain amino acids (BCAAs)—isoleucine, leucine, and valine—are similar (see Fig. 105.4). Under catabolic conditions, BCAAs in the muscle tissue undergo a reversible reaction of transamination catalyzed by BCAA transaminase. α-Ketoacids formed by this reaction then undergo an oxidative decarboxylation step mediated by a branched-chain α-ketoacid dehydrogenase **(BCKDH)** complex. The deficiency of BCKDH results in **maple syrup urine disease**, whereas the deficiency of enzymes mediating more distal reactions results in accumulation of enzyme-specific levels of organic acids excreted in the urine, thus giving those inborn errors of metabolism the eponyms **organic acidemias** and **organic acidurias**. These disorders typically cause metabolic acidosis, which usually occurs in the first few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. Figure 105.6 presents an approach to infants suspected of having an organic acidemia. The diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine), amino acid analysis (blood), and identifying pathogenic variants in the respective gene.

Organic acidemias *are not limited* to defects in the catabolic pathways of BCAAs. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 105.14), disorders of the γ-glutamyl cycle (see Chapter 105.11), those associated with lactic acid (see Chapter 107), and dicarboxylic acidemias associated with defective fatty acid degradation (see Chapter 106).

MAPLE SYRUP URINE DISEASE

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (BCKDH) using thiamine (vitamin B_1) pyrophosphate as a coenzyme. This mitochondrial enzyme consists of four subunits: $E_{1\alpha}$, $E_{1\beta}$, E_2, and E_3. The E_3 subunit is shared with two other dehydrogenases: pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Deficiency of any of these subunits causes maple syrup urine disease **(MSUD)** (see Fig. 105.4), a disorder named after the sweet odor of maple syrup discerned from body fluids, especially cerumen, sweat, and urine. Clinical conditions caused by defects in $E_{1\alpha}$, $E_{1\beta}$, E_2 and E_3 are designated as MSUD type 1A, type 1B, type 2, and type 3, respectively. This classification, however, is not very helpful clinically because the severity of clinical manifestations does not correlate with, or correspond specifically to, any single enzyme subunit. An affected infant with a type 1A defect can have clinical manifestations ranging from relatively mild to very severe. A more useful classification, based on clinical findings and response to thiamine administration, delineates five phenotypes of MSUD.

Classic Maple Syrup Urine Disease

Classic MSUD has the most severe clinical manifestations. The BCKDH complex activity in this group varies between 0% and 2% of controls. Patients with uncontrolled or poorly controlled disease develop signs of acute encephalopathy. The mechanisms underlying this life-threatening complication are complex, but leucine and its derivative, α-ketoisocaproic acid, appear to be the key factors underlying acute encephalopathy. Elevated leucine competitively inhibits the uptake of other amino acids by the LNAA transporter. Once taken up by the brain tissue, leucine is metabolized by BCAA aminotransferase to α-ketoisocaproic acid, which disrupts metabolism of neurotransmitters and amino acids (glutamate, γ-aminobutyric acid [GABA], glutamine, alanine, and aspartate). α-Ketoisocaproic acid can reversibly inhibit oxidative phosphorylation and result in cerebral lactic acidosis. Collectively, these processes are detrimental to the normal function of neurons and glia, clinically manifesting as *encephalopathy* and *brain edema,* referred to as **leucinosis**. Affected infants who appear healthy at birth develop poor feeding and vomiting in the first days of life. Lethargy and coma may ensue within a few days. Physical examination reveals hypertonicity and muscular rigidity with severe opisthotonos. Periods of hypertonicity may alternate with bouts of flaccidity manifested as repetitive movements of the extremities ("boxing" and "bicycling"). Neurologic findings are often mistakenly thought to be caused by generalized sepsis and meningitis. Cerebral edema may be present; seizures occur in most infants, and hypoglycemia is common. In contrast to most hypoglycemic states, correction of the blood glucose concentration *does not* improve the clinical condition. Aside from the blood glucose and varying degrees of ketoacidosis, routine laboratory findings are usually unremarkable. If left untreated, death can occur in the first few weeks or months of life.

Diagnosis was classically suspected because of the peculiar odor of maple syrup in urine, sweat, and cerumen. It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine and a depressed level of alanine. Alloisoleucine is a stereoisomer of isoleucine not normally found in blood and is the most sensitive and specific diagnostic marker for all forms of MSUD. Leucine levels are usually higher than those of isoleucine and valine. Urine contains high levels of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1N HCl) to the urine; a yellow precipitate of 2,4-dinitrophenylhydrazone is formed in a positive test. Neuroimaging during the acute state may show cerebral edema, which is most

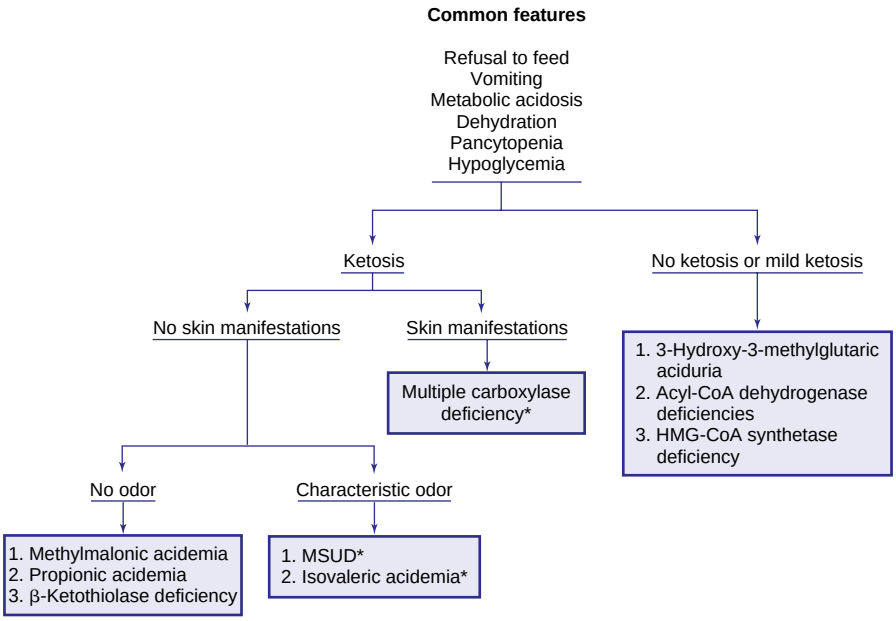

Fig. 105.6 Clinical algorithmic approach to infants with organic acidemia. *Asterisks* indicate disorders in which patients have a characteristic odor (see text and Table 105.2). MSUD, Maple syrup urine disease.

prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and internal capsule. After recovery from the acute state and with advancing age, hypomyelination and cerebral atrophy may be seen in neuroimaging of the brain.

Treatment of the acute state is aimed at hydration and rapid removal of the BCAAs and their metabolites from the tissues and body fluids. Uptake of leucine by the brain and accumulation of the downstream metabolite, α-ketoisocaproic acid, appear to be the key metabolic events underlying the MSUD encephalopathy. Therefore MSUD management strategies focus on decreasing plasma leucine to control acute and chronic manifestations of the disease.

Because renal clearance of leucine is low, hydration alone may not produce a rapid improvement. *Hemodialysis* is the most effective mode of therapy in critically ill infants and should be instituted promptly; significant decreases in plasma levels of leucine, isoleucine, and valine are usually seen within 24 hours. Sufficient calories and nutrients should be provided intravenously or orally as soon as possible to reverse the patient's catabolic state. Cerebral edema, if present, may require treatment with mannitol, diuretics (e.g., furosemide), or hypertonic saline. Counterintuitively, supplementation with isoleucine and valine is also needed to achieve adequate control of the plasma leucine level in MSUD patients and to sustain the net protein synthesis in tissues. Judiciously administered isoleucine and valine will compete with leucine for the LNAA transporter at the BBB, decrease leucine entry into the CNS, and help in the prevention and treatment of leucine encephalopathy. Phenylbutyrate, a nitrogen scavenger used to treat hyperammonemia in urea cycle disorders, has been shown to activate the BCKDH complex and lower BCAA levels, with promising results in a subset of MSUD patients.

Treatment after recovery from the acute state requires a diet low in BCAAs. Synthetic formulas devoid of leucine, isoleucine, and valine are available commercially. Because these amino acids cannot be synthesized endogenously, age-appropriate amounts of BCAAs should be provided in the diet in the form of complete protein. To avoid essential amino acid deficiencies, the amount should be titrated carefully by performing frequent analyses of plasma amino acids, with close attention to plasma isoleucine, leucine, and valine levels. A clinical condition resembling **acrodermatitis enteropathica** (see Chapter 691) occurs in affected infants whose plasma isoleucine or valine had been *overrestricted*; the addition of isoleucine or valine, respectively, to the diet will hasten the recovery of the skin rash. Patients with MSUD need to remain on the diet for life. Liver transplantation is offered to patients with classic MSUD, allowing some patients to lift protein restrictions and improve metabolic control during intercurrent illnesses.

The long-term prognosis of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation such as infection or surgery, especially in mid-childhood. Cognitive and other neurologic deficits are common sequelae.

Intermediate (Mild) Maple Syrup Urine Disease

Children with intermediate MSUD develop milder disease after the neonatal period. Clinical manifestations are insidious and limited to the CNS. Patients have mild to moderate intellectual disability with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the BCAAs and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased, whereas those of lactate and pyruvate tend to be normal. These children are commonly diagnosed during an intercurrent illness, when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3–40% of the reference population. Because patients with thiamine-responsive MSUD usually have manifestations similar to the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

Intermittent Maple Syrup Urine Disease

In intermittent MSUD, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, laboratory findings are indistinguishable from those of the classic form, and death may occur. Treatment of the acute attack of intermittent MSUD is similar to that of the classic form. After recovery, although a normal diet can be tolerated, a low-BCAA diet is recommended. The BCKDH activity in patients with the intermittent form is higher than in the classic form and may reach 40% of the control activity.

Thiamine-Responsive Maple Syrup Urine Disease

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine show dramatic clinical and biochemical improvement. Although some respond to treatment with thiamine at 10 mg/day, others may require as much as 100 mg/day for at least 3 weeks before a favorable response is observed. These patients also require a BCAA-restricted diet. The enzymatic activity in these patients can be up to 40% of the reference population.

Maple Syrup Urine Disease Caused by Deficiency of E_3 Subunit (MSUD Type 3)

Although sometimes referred to as "maple syrup urine disease type 3," this very rare disorder leads to clinical and biochemical abnormalities that encompass a wide range of mitochondrial reactions. The E_3 subunit, dihydrolipoamide dehydrogenase, is a component of the BCKDH complex, pyruvate dehydrogenase complex, and α-ketoglutarate dehydrogenase complex. Causative biallelic pathogenic variants in *DLD* that encode the E_3 dihydrolipoamide dehydrogenase cause lactic acidosis, elevated pyruvate, and signs and symptoms similar to intermediate MSUD. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 months of age. Abnormal movements can progress to ataxia or Leigh syndrome. Death may occur in early childhood.

Laboratory findings include persistent lactic acidosis with high levels of plasma pyruvate and alanine. Plasma BCAA concentrations are moderately increased. Patients excrete large amounts of lactate, pyruvate, α-ketoglutarate, and the three branched-chain ketoacids in their urine.

No effective treatment is available. BCAA-restricted diets and treatment with high doses of thiamine, biotin, and lipoic acid have been ineffective.

Genetics and the Prevalence of Maple Syrup Urine Disease

Biallelic pathogenic variants in any of the following genes may result in the clinical and biochemical manifestations of MSUD: *BCKDHA* (encodes subunit $E_{1\alpha}$), *BCKDHB* (encodes subunit $E_{1\beta}$), *DBT* (encodes subunit E_2), and *DLD* (encodes subunit E_3). Genotype-phenotype correlations are difficult to establish and are usually imprecise. The exception is thiamine-responsive MSUD, shown to be caused by pathogenic variants in *DBT*. Most patients are compound heterozygotes inheriting two different pathogenic alleles. Pathogenic variants in *BCKDHA* (45%) and *BCKDHB* (35%) account for approximately 80% of cases. Pathogenic variants in *DBT* are responsible for 20% of MSUD cases.

The prevalence is estimated at 1 in 185,000 live births. Classic MSUD is more prevalent in the Old Order Mennonites in the United States, at an estimated 1 in 380 live births. Affected patients in this population are homozygous for a specific pathogenic variant (c.1312T>A) in the *BCKDHA*-encoding $E_{1\alpha}$ subunit.

Early detection of MSUD is possible by universal newborn screening. In many cases, however, especially those with classic MSUD, the infant may be very ill by the time screening results become available (see Chapter 104). Prenatal diagnosis has been accomplished by enzyme assay of the cultured amniocytes, cultured chorionic villus tissue, or direct assay of samples of the chorionic villi and by identification of the known pathogenic variants in the affected gene.

Successful pregnancies have occurred in women with different forms of MSUD. The teratogenic potential of leucine during pregnancy is unknown. Tight control of isoleucine, leucine, and valine before and during the pregnancy is important to minimize the risk of metabolic decompensation and to optimize fetal nutrition. Mothers affected by MSUD require close monitoring and meticulous management of nutrition, electrolytes, and fluids in the postpartum period.

BRANCHED-CHAIN α-KETOACID DEHYDROGENASE KINASE DEFICIENCY

A defect in the regulation of BCKDH by BCKDH kinase (BCKDK), the enzyme responsible for phosphorylation-mediated inactivation of the BCKDH complex, causes the *reverse* biochemical phenotype of MSUD. Pathogenic variants in *BCKDK* decrease the negative regulation by the kinase, resulting in uncontrolled degradation and depletion of isoleucine, leucine, and valine in plasma and the brain. Patients with BCKDK deficiency present with low plasma concentrations of isoleucine, leucine, and valine associated with autism, intellectual impairment, fine motor coordination problems, and seizures.

BRANCHED-CHAIN AMINO ACID TRANSPORTER DEFICIENCY

Isoleucine, leucine, and valine are transported across the BBB mainly by the heterodimeric LNAA transporter LAT1 encoded by *SLC7A5*. A defect in LAT1 caused by pathogenic variants in *SLC7A5* results in low brain concentrations of isoleucine, leucine, and valine. Patients with this defect may present similarly to BCKDK-deficient patients, with autism, microcephaly, gross motor delays, and in some cases, seizures.

ISOVALERIC ACIDEMIA

Isovaleric acidemia **(IVA)** is an autosomal recessive condition caused by biallelic pathogenic variants in *IVD* resulting in the deficient activity of isovaleryl–coenzyme A (CoA) dehydrogenase (see Fig. 105.4). The prevalence of IVA is estimated to range between 1 in 62,500 (in parts of Germany) and 1 in 250,000 live births (in the United States). Decreased or absent activity of isovaleryl-CoA dehydrogenase results in impaired leucine degradation. Accumulating derivatives of isovaleric acid, isovalerylcarnitine, isovalerylglycine, and 3-hydroxyisovaleric acid can be detected in body fluids and thus enable the biochemical diagnosis and screening. Clinically, the course of IVA can be highly variable, ranging from essentially asymptomatic to severe. Introduction of newborn screening and proactive management of IVA has changed the prognosis and clinical course. Older siblings of symptomatic newborn infants have been reported with identical genotype and biochemical abnormalities but without clinical manifestations, suggesting that presymptomatic detection of affected patients on the newborn screen can improve clinical outcomes.

Patients with severe IVA can present with vomiting, severe acidosis, hyperammonemia, hypoglycemia, hypocalcemia, and bone marrow suppression in infancy. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. Vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of "sweaty feet" or "rancid cheese" may be present. Infants who survive this acute episode are at risk of developing episodes of metabolic decompensation later in life. In the mild form without treatment, typical clinical manifestations of severe IVA (vomiting, lethargy, acidosis, or coma) may not appear until the child is a few months or years old. Acute episodes of metabolic decompensation may occur during a catabolic state, such as infection, dehydration, surgery, or high-protein intake. Acute episodes may be mistaken for diabetic ketoacidosis. Some patients may experience acute and recurrent episodes of pancreatitis.

Laboratory findings during the acute attacks include ketoacidosis, neutropenia, thrombocytopenia, and occasionally pancytopenia. Hypocalcemia, hypoglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle (see Chapter 105.12). In urea cycle defects, the infant usually shows no significant ketoacidosis (see Fig. 105.6).

Diagnosis is established by demonstrating marked elevations of isovaleric acid metabolites (isovalerylglycine, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine (C5-carnitine). C5-carnitine can be measured in dried blood spots, enabling universal newborn screening using tandem mass spectrometry. The diagnosis can be confirmed by molecular analysis of the *IVD* gene. In some patients with equivocal results, measurement of the enzyme activity in cultured skin fibroblasts may be necessary.

Treatment of the acute attack is aimed at rehydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis, and facilitation of the isovaleric acid excretion. L-Carnitine (100 mg/kg/day orally) also increases removal of isovaleric acid by forming isovalerylcarnitine, which is excreted in the urine. Because isovalerylglycine has a high urinary clearance, some centers recommend glycine supplementation (250 mg/kg/day) to enhance the formation of isovalerylglycine. Temporary restriction of protein intake (<24 hours) may be beneficial in some cases. In patients with significant hyperammonemia (blood ammonia >200 μmol/L), measures that reduce blood ammonia should be employed (see Chapter 105.12). Renal replacement therapy may be needed if the previously described measures fail to produce significant clinical and biochemical improvement. Long-term management of IVA patients requires restriction of protein according to age-appropriate intake (recommended dietary allowance of protein). Patients benefit from carnitine supplementation with or without glycine. Normal development can be achieved with early and proper treatment.

Prenatal diagnosis can be accomplished using *IVD* gene analysis if causative pathogenic variants are known or, less frequently, by using an enzyme assay of cultured amniocytes. Successful pregnancies with favorable outcomes have been reported. Universal newborn screening of IVA is used in the United States and other countries (see Chapter 104).

MULTIPLE CARBOXYLASE DEFICIENCIES (DEFECTS OF THE BIOTIN CYCLE)

Biotin is a water-soluble vitamin that serves as a cofactor for four carboxylase enzymes in humans: pyruvate carboxylase, acetyl-CoA carboxylase, propionyl-CoA carboxylase, and 3-methylcrotonyl-CoA carboxylase. The latter two are involved in the catabolic pathways of leucine, isoleucine, and valine (see Fig. 105.4).

Most dietary biotin is bound to proteins. Free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria, and perhaps by biotinidase. **Biotinidase**, found in serum and most tissues, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases; see Fig. 105.4). Free biotin must form a covalent bond with the apocarboxylases to produce the activated enzyme (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies either in holocarboxylase synthetase or in biotinidase result in the impaired catalytic activity of carboxylases and organic acidemias.

Holocarboxylase Synthetase Deficiency

Infants with this rare autosomal recessive disorder become symptomatic in the first few weeks of life. Symptoms may appear as early as a few hours after birth to as late as 8 years of age. Clinically, shortly after birth, affected infants develop breathing difficulties (tachypnea and apnea). Feeding problems, vomiting, and hypotonia are also usually present. If the condition remains untreated, *generalized erythematous rash with exfoliation and alopecia,* failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests with susceptibility to infection. Urine may have a peculiar odor, which has been described "tomcat urine." The rash, when present, helps to differentiate this condition from other organic acidemias (see Fig. 105.6).

Laboratory findings include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids and their conjugates (lactic acid, 3-methylcrotonic acid, 3-methylcrotonylglycine, tiglylglycine, 3-OH-propionic acid, methylcitric acid, and 3-hydroxyisovaleric acid) in body fluids. **Diagnosis** is confirmed by identification of pathogenic variants in *HLCS* or by the enzyme assay in lymphocytes or cultured fibroblasts. Most pathogenic variants cause the enzyme to have an increased K_m (Michaelis-Menten dissociation constant) for biotin; the enzyme activity in such patients can be restored by the administration of large doses of biotin. Newborn screening can identify holocarboxylase synthetase–deficient infants by detecting elevated C5-OH-carnitine on tandem mass spectrometry. In these infants, biotinidase enzymatic assay would be normal.

Treatment with biotin (10-20 mg/day orally) usually results in an improvement in clinical manifestations and biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, complete resolution may not be achieved even with large doses (up to 60 mg/day) of biotin.

Prenatal diagnosis can be accomplished by prenatal molecular analysis of known pathogenic variants in *HLCS* or by assaying enzyme activity in cultured amniotic cells. Pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy. Affected infants were normal at birth, but the efficacy of prenatal treatment remains unclear.

Biotinidase Deficiency

Impaired biotinidase activity results in biotin deficiency. Affected infants may develop clinical manifestations similar to those seen in infants with holocarboxylase synthetase deficiency. Unlike the latter, however, symptoms tend to appear later, when the child is several months or years old. The delay in onset of symptoms presumably results from the availability of free biotin derived from the mother or the diet. Clinical manifestations are mostly confined to the skin and the nervous system. Without treatment, atopic or seborrheic dermatitis, candidiasis, alopecia, ataxia, seizures (usually myoclonic), hypotonia, developmental delay, optic nerve atrophy, sensorineural hearing loss, and immunodeficiency resulting from impaired T-cell function may occur. A small number of children with *intractable seborrheic dermatitis* and *partial* (15–30% activity) biotinidase deficiency, in whom the dermatitis resolved with biotin therapy, have been reported; these children were otherwise asymptomatic. Asymptomatic children and adults with this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial biotinidase deficiency. With universal newborn screening leading to early identification and treatment of the affected patients, the clinical disease should become extinct.

Laboratory findings and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency. **Diagnosis** can be established by measurement of the enzyme activity in the serum and confirmed by identifying biallelic pathogenic variants in *BTD*. **Treatment** with free biotin (5-20 mg/day) results in a dramatic clinical and biochemical improvement. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency. The prevalence of this autosomal recessive disorder is estimated to be 1 in 60,000 live births. **Prenatal diagnosis** is possible by identification of known pathogenic variants in *BTD* or, less frequently, by the measurement of the enzyme activity in the amniotic cells, although in practice, a prenatal approach is rarely used.

Multiple Carboxylase Deficiency Caused by Acquired Biotin Deficiency

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients with prolonged use of antiepileptic drugs (phenobarbital, phenytoin, primidone, carbamazepine), and in children with short bowel syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin, decreasing its absorption. Infants with acquired biotin deficiency may develop dermatitis, alopecia, and candidal skin infections. This condition readily responds to treatment with oral biotin.

3-METHYLCROTONYL-COA CARBOXYLASE DEFICIENCY

This enzyme is one of the four carboxylases requiring biotin as a cofactor (see Fig. 105.4). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which causes diminished activity of all four carboxylases (see earlier). 3-Methylcrotonyl-CoA carboxylase (3-MCC) is a heteromeric enzyme consisting of α (biotin containing) and β subunits, encoded by the genes *MCCC1* and *MCCC2,* respectively. 3-MCC deficiency can be detected in the newborn period by identifying elevated 3-hydroxyisovalerylcarnitine (C5-OH) in dried blood spots. Universal newborn screening using tandem mass spectrometry has identified an unexpectedly high number of infants with 3-MCC deficiency, with its prevalence ranging between 1 in 2,400 and 1 in 68,000.

Clinical manifestations are highly variable, ranging from completely asymptomatic adults (including mothers of affected newborn infants), to children presenting with developmental delay without episodes of metabolic decompensation, to patients with seizures, hyperammonemia, and metabolic acidosis. Rarely, infants who are affected by severe 3-MCC deficiency may appear healthy at birth but later develop acute episodes of vomiting, hypotonia, lethargy, and convulsions after a minor infection, in some cases progressing to life-threatening complications (e.g., Reye syndrome, coma). In patients prone to developing these symptoms, the onset is usually between 3 weeks and 3 years of age. Among infants identified through newborn screening, 85–90% of children remain apparently asymptomatic. The reason for differences in outcomes is unknown. None of the symptoms reported so far could be clearly attributed to the degree of enzyme deficiency.

Laboratory findings during acute episodes include mild to moderate metabolic acidosis, ketosis, hypoglycemia, hyperammonemia, and elevated serum transaminase levels. Large amounts of 3-hydroxyisovalerate and 3-methylcrotonylglycine are found in the urine. Urinary excretion of 3-methylcrotonate is usually not detected in this condition because the accumulated 3-methylcrotonyl-CoA is converted to 3-hydroxyisovalerate. The plasma acylcarnitine profile shows elevated 3-hydroxyisovalerylcarnitine (C5-OH). Severe secondary carnitine deficiency is common. 3-MCC deficiency should be differentiated biochemically from multiple carboxylase deficiency (see earlier), in which, in addition to 3-hydroxyisovalerate, lactate and metabolites of propionic acid are also present. **Diagnosis** may be confirmed by molecular analysis of *MCCC1* and *MCCC2* or by measurement of the enzyme activity in cultured fibroblasts. Documentation of normal activities of other carboxylases is necessary to rule out multiple carboxylase deficiency.

Treatment of acute episodes is similar to that of isovaleric acidemia (see earlier). Hydration and measures to correct both hypoglycemia and severe metabolic acidosis by infusing glucose and sodium bicarbonate should be instituted promptly. Secondary carnitine deficiency, seen in up to 50% of patients, can be corrected with L-carnitine supplementation. For symptomatic patients, some centers recommend keeping protein intake at the recommended dietary allowance in conjunction with the oral administration of L-carnitine and the proactive management of catabolic states. Normal physiologic growth and development are expected in most patients.

3-MCC deficiency is an autosomal recessive condition. Biallelic pathogenic variants in either *MCCC1* or *MCCC2* result in the enzyme deficiency with overlapping clinical features.

3-METHYLGLUTACONIC ACIDURIAS

The 3-methylglutaconic acidurias comprise a heterogeneous group of metabolic disorders characterized by excessive excretion of 3-methylglutaconic acid in the urine (Table 105.2). Other metabolites found in 3-methylglutaconic aciduria patients may include 3-methylglutaric acid and 3-hydroxyisovaleric acid. The current classification distinguishes between primary and secondary forms. **Primary** 3-methylglutaconic aciduria is caused by the deficiency of mitochondrial 3-methylglutaconyl-CoA hydratase (see Fig. 105.4), formerly *3-methylglutaconic aciduria type I*. **Secondary** 3-methylglutaconic aciduria can be further classified based on the underlying mechanism (e.g., defective phospholipid remodeling versus dysfunction of mitochondrial membrane) or now the more preferred classification based on the underlying molecular cause. Known causes of secondary 3-methylglutaconic aciduria include the X-linked *TAZ*-related syndrome **(Barth syndrome)**, *OPA3*-related 3-methylglutaconic aciduria **(Costeff syndrome)**, *SERAC1*-related syndrome **(MEGDEL syndrome)**, *TMEM70*-related syndrome, and *DNAJC19*-related syndrome **(DCMA syndrome)**.

Significant and persistent 3-methylglutaconic aciduria with negative molecular evaluation for known genetic causes represents a heterogeneous group called 3-methylglutaconic aciduria **not otherwise specified** awaiting further molecular characterization. Primary and secondary 3-methylglutaconic aciduria should be distinguished from mild and transient urinary elevations of 3-methylglutaconic acid seen in patients affected by other metabolic disorders or liver dysfunction, such as mitochondrial disorders of diverse etiology.

3-Methylglutaconyl-CoA Hydratase Deficiency

Two main clinical presentations have been described for 3-methylglutaconyl-CoA hydratase deficiency, an autosomal recessive disorder (see Fig. 105.4). In the **childhood** form, nonspecific neurodevelopmental findings such as speech delay or regression, choreoathetoid movements, optic nerve atrophy, and mild psychomotor delay may be present. Metabolic acidosis may occur during a catabolic state. In the **adulthood** form, affected individuals may remain asymptomatic until the second or third decade of life, when a clinical picture of *slowly progressing leukoencephalopathy* with optic nerve atrophy, dysarthria, ataxia, spasticity, and dementia occurs. Brain MRI typically shows white matter abnormalities, which may precede the appearance of clinical symptoms by years. Asymptomatic pediatric and adult patients have also been reported. Patients excrete large amounts of 3-methylglutaconic acid and moderate amounts of 3-hydroxyisovaleric and 3-methylglutaric acids in urine. **Treatment** with L-carnitine may help some patients. The effectiveness of a low-leucine diet has not been established. The condition is caused by biallelic pathogenic variants in *AUH* and is inherited in an autosomal recessive manner.

Barth Syndrome (*Tafazzin*-Related Disorder)

This X-linked condition is caused by a deficiency of *tafazzin,* a mitochondrial protein, encoded by the *TAFAZZIN* gene. This enzyme is necessary for remodeling of immature cardiolipin into its mature form. *Cardiolipin,* a mitochondrial phospholipid, is critical for the integrity of the inner mitochondrial membrane. **Clinical manifestations** of Barth syndrome usually begin in the first year of life in a male infant and include cardiomyopathy, hypotonia, growth restriction, hypoglycemia, and mild to severe neutropenia. The onset of clinical manifestations may be as late as adulthood, but most affected individuals become symptomatic by adolescence. If patients survive infancy, relative improvement may occur with advancing age. Cognitive development is usually normal, although delayed motor function and learning disabilities occur.

Laboratory findings include mild to moderate increases in urinary excretion of 3-methylglutaconic, 3-methylglutaric, and 2-ethylhydracrylic acids. Unlike primary 3-methylglutaconic aciduria (type I), urinary excretion of 3-hydroxyisovaleric acid is not elevated. The activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. *Neutropenia is a common finding.* Lactic acidosis, hypoglycemia, low serum cholesterol, low prealbumin, and abnormal mitochondrial ultrastructure are also common. Total cardiolipin and subclasses of cardiolipin are very low in skin fibroblast cultures from these patients. The monolysocardiolipin/cardiolipin ratio in cultured fibroblast is useful for establishing the diagnosis in patients with negative or equivocal molecular results. Because of its nonspecific presentation, the condition is likely underdiagnosed and underreported.

The condition is inherited in an *X-linked* recessive manner. The gene *(TAFAZZIN)* has been mapped to chromosome Xq28. The modest 3-methylglutaconic aciduria seen in Barth syndrome is thought to be related to the defect in the mitochondrial membrane, causing the leakage of this organic acid. Gene-specific treatment is not available. Patients with an unsatisfactory response to medical management of cardiomyopathy may benefit from cardiac transplantation. Daily aspirin to reduce the risk of strokes has been described. Regular use of granulocyte colony stimulating factor (G-CSF) can help limit recurrent infections in patients with neutropenia.

OPA3-Related 3-Methylglutaconic Aciduria (Costeff Syndrome)

Clinical manifestations in patients with Costeff syndrome include early-onset optic nerve atrophy and later development of choreoathetoid movements, spasticity, ataxia, dysarthria, and cognitive impairment. Patients excrete moderate amounts of 3-methylglutaconic and 3-methylglutaric acids. Activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. The condition is inherited in an autosomal recessive manner. Pathogenic variants in *OPA3* are thought to cause electron transport chain dysfunction. Treatment is supportive.

Disorders Formerly Described as 3-Methylglutaconic Aciduria Type IV

3-Methylglutaconic aciduria type IV represents a group of disorders with a diverse genetic etiology. Two disorders in this group have been linked to specific molecular etiology, whereas other conditions are still awaiting the discovery of underlying molecular defects.

MEGDEL syndrome (3-*me*thylglutaconic aciduria with *d*eafness, *e*ncephalopathy, and *L*eigh-like) is an autosomal recessive disorder caused by pathogenic variants in *SERAC1*. Affected patients experience optic nerve atrophy, progressive deafness, dystonia, feeding difficulty with dysphagia, spasticity, and basal ganglia injury similar to patients

Table 105.2 Primary and Select Secondary 3-Methylglutaconic Acidurias

GROUP	DISORDER	GENE (CHROMOSOME)	PREVIOUS CLASSIFICATION	DISEASE MECHANISM	CLINICAL DESCRIPTION
Primary 3-methylglutaconic aciduria	3-Methylglutaconyl-CoA hydratase deficiency	*AUH* (9q22.31)	Type I	Enzyme deficiency in the leucine degradation pathway	Depending on age, variable presentation is seen ranging from younger asymptomatic patients to older patients with progressive leukoencephalopathy
Secondary 3-methylglutaconic acidurias	Barth syndrome	*TAZ* (Xq28)	Type II	Defective phospholipid remodeling	X-linked inheritance, cardiomyopathy, endocardial fibroelastosis, proximal myopathy, failure to thrive, neutropenia, dysmorphic findings
	Costeff syndrome	*OPA3* (19q13.32)	Type III	Mitochondrial membrane dysfunction	Progressive optic nerve atrophy, chorea, spastic paraparesis, cognitive impairment
	MEGDEL syndrome	*SERAC1* (6q25.3)	Type IV	Defective phospholipid remodeling	Progressive deafness, dystonia, spasticity, basal ganglia changes
	TMEM70-related disorder	*TMEM70* (8q21.11)	Type IV	Mitochondrial membrane dysfunction	Developmental delay, failure to thrive, metabolic decompensations, microcephaly, cardiomyopathy, dysmorphic findings
	3-Methylglutaconic aciduria, not otherwise specified	Unknown	Type IV	Unknown	Variable presentation
	DCMA syndrome	*DNAJC19* (3q26.33)	Type V	Mitochondrial membrane dysfunction	Cardiomyopathy, ataxia, optic nerve atrophy, failure to thrive

DCMA, Dilated cardiomyopathy ataxia syndrome; MEGDEL, 3-methylglutaconic aciduria deafness, encephalopathy, Leigh-like syndrome.

with Leigh syndrome. Laboratory evaluation reveals elevated urinary 3-methylglutaconic, high plasma lactate and alanine. Treatment is symptomatic.

***TMEM70*-related disorder** is also inherited in an autosomal recessive manner. Biallelic pathogenic variants in *TMEM70* result in a mitochondrial complex V deficiency, although the exact molecular mechanism of disease is unknown. Clinical manifestations include developmental delay, developmental regression, Reye syndrome–like episodes, intellectual disability, failure to thrive, microcephaly, cardiomyopathy, and dysmorphic findings. Patients are prone to metabolic decompensation, characterized by hyperammonemia (up to 900 µmol/L) and lactic acidosis, which are more common in the first year of life. **Acute hyperammonemic** episodes are treated with intravenous glucose, lipid emulsion, ammonia-scavenging drugs, and occasionally hemodialysis. Long-term therapy that has been described includes L-carnitine, coenzyme Q_{10}, and bicarbonate substitution (e.g., citric acid/sodium citrate). Patients require interval echocardiographic and electrocardiographic (ECG) monitoring to enable early diagnosis and management of cardiomyopathy.

DCMA Syndrome (*DNAJC19*-Related Syndrome, 3-Methylglutaconic Aciduria Type V)

DCMA syndrome (*d*ilated *c*ardio*m*yopathy with *a*taxia) is an autosomal recessive disorder identified in patients of Canadian Dariusleut Hutterite ancestry in the Great Plains of North America. As the disorder's abbreviated name suggests, affected individuals present with dilated cardiomyopathy, long QTc interval, and CNS involvement. Neurologic symptoms include intellectual disability, cerebellar involvement, and optic atrophy. Growth is affected in all patients. Intrauterine growth restriction is seen in up to 50% of patients. Cryptorchidism and hypospadias are frequent findings in affected boys. Urine organic acid assay reveals increased 3-methylglutaconic acid and 3-methylglutaric acid. Biallelic pathogenic variants in *DNAJC19* are the underlying cause of DCMA syndrome. Treatment is symptomatic. Interval echocardiography and ECG can prospectively identify patients requiring treatment for cardiomyopathy and long QTc interval.

β-KETOTHIOLASE (3-OXOTHIOLASE) DEFICIENCY (MITOCHONDRIAL ACETOACETYL-COA THIOLASE [T_2] DEFICIENCY)

The bidirectional reaction catalyzed by mitochondrial β-ketothiolase is involved in the final steps of both isoleucine catabolism and ketolysis. In the isoleucine catabolic pathway, the enzyme cleaves 2-methylacetoacetyl-CoA into propionyl-CoA and acetyl-CoA (see Fig. 105.4). In the fatty acid oxidation pathway, the enzyme generates two moles of acetyl-CoA from one mole of acetoacetyl-CoA (Fig. 105.7). The same enzyme can synthesize 2-methylacetoacetate-CoA and acetoacetyl-CoA in the reverse direction. The hallmark of this disorder is **ketoacidosis**, often triggered by infections, prolonged fasting, and large protein load. The mechanism of ketosis in this condition is incompletely understood, because in this enzyme deficiency one would expect impaired ketone formation (see Fig. 105.7). It is postulated that excess acetoacetyl-CoA produced from other sources can be used as a substrate for 3-hydroxy-3-methylglutaryl-CoA synthesis in the liver.

Clinical manifestations are quite variable, ranging from mild cases showing normal development to severe episodes of acidosis starting in the first year of life causing severe cognitive impairment. Unless identified on the newborn screening, affected children present with intermittent episodes of unexplained ketoacidosis. These episodes usually occur after an intercurrent infection and respond promptly to

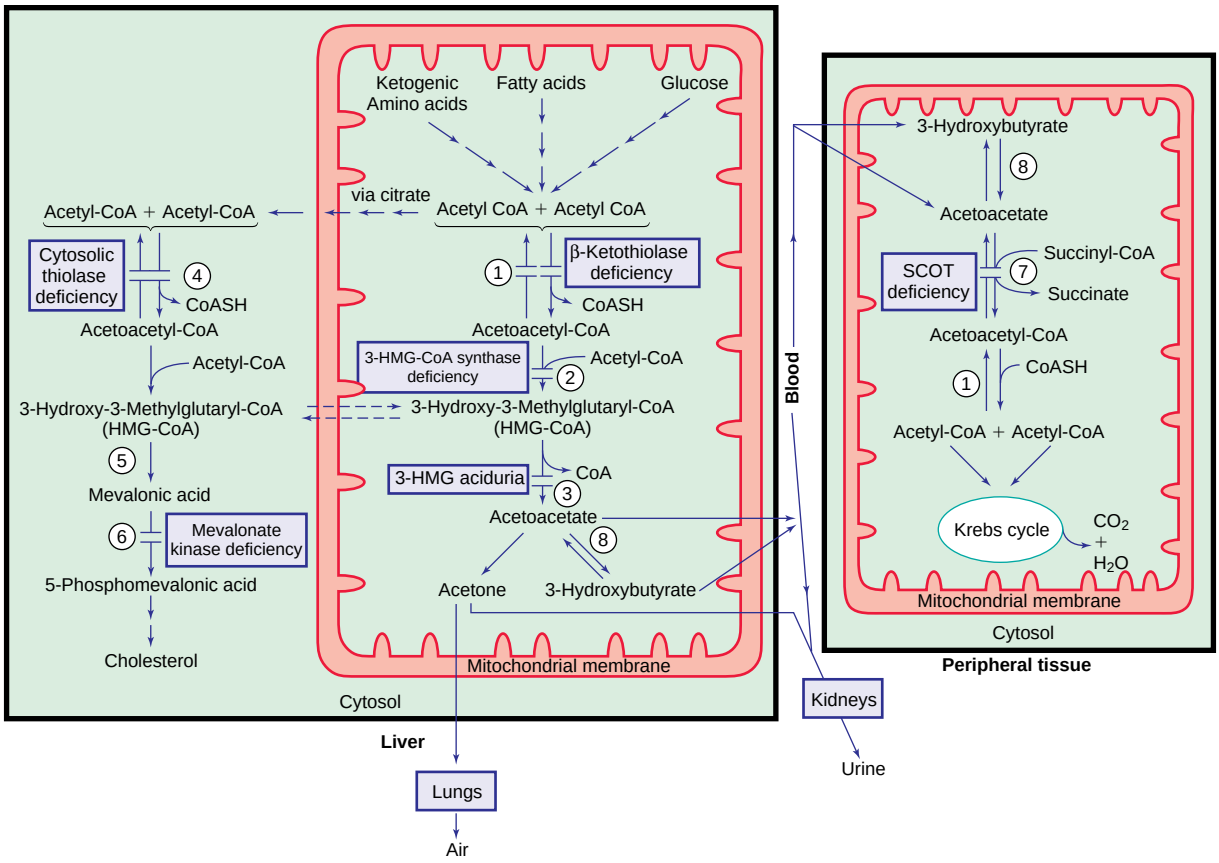

Fig. 105.7 Formation (liver) and metabolism (peripheral tissues) of ketone bodies and cholesterol synthesis. **Enzymes:** *(1)* Mitochondrial acetoacetyl CoA thiolase, *(2)* HMG-CoA synthase, *(3)* HMG-CoA lyase, *(4)* cytosolic acetoacetyl-CoA thiolase, *(5)* HMG-CoA reductase, *(6)* mevalonic kinase, *(7)* succinyl CoA:3-ketoacid CoA transferase (SCOT), *(8)* 3-hydroxybutyrate dehydrogenase.

intravenous fluids and bicarbonate therapy. Mild to moderate hyperammonemia may also be present during attacks. Both hypoglycemia and hyperglycemia have been reported in isolated cases. The child may be completely asymptomatic between episodes and may tolerate a normal protein diet. Cognitive development is normal in most children. The episodes may be misdiagnosed as salicylate poisoning because of the similarity of the clinical findings and the interference of elevated blood levels of acetoacetate with the colorimetric assay for salicylate.

Laboratory findings during the acute attack include ketoacidosis and hyperammonemia. Findings of ketones in the urine and hyperglycemia may be interpreted as diabetic ketoacidosis, and a high index of suspicion is needed to suspect this metabolic disorder. Urine organic acid assay can provide clues leading to a correct diagnosis. Urine contains large amounts of 2-methylacetoacetate and its decarboxylated products butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Lower concentrations of urinary metabolites can be seen when patients are stable. Mild hyperglycinemia may also be present. The plasma acylcarnitine profile shows elevations of C5:1 and C5-OH carnitines, although these metabolites can normalize between catabolic episodes. Absent or minimal elevations of C5:1 and C5-OH carnitines can result in false-negative results on the newborn screening of affected infants who were clinically well at the time of blood collection. The clinical and biochemical findings should be differentiated from those seen with propionic and methylmalonic acidemias (see later).

Treatment of acute episodes includes hydration. Recalcitrant metabolic acidosis can be severe enough to require infusion of bicarbonate. A 10% glucose solution with the appropriate electrolytes is used to suppress protein catabolism, lipolysis, and ketogenesis. Restriction of protein intake to age-appropriate physiologic requirements is recommended for long-term therapy. Oral L-carnitine (50-100 mg/kg/day) is also recommended to prevent possible secondary carnitine deficiency. The long-term prognosis for achieving a normal quality of life seems very favorable. Successful pregnancy with a normal outcome has been reported.

β-Ketothiolase deficiency is inherited in an autosomal recessive manner and may be more prevalent than appreciated. **Diagnosis** may be confirmed by molecular analysis of the *ACAT1* gene or using an enzyme assay of leukocytes or cultured fibroblasts.

CYTOSOLIC ACETOACETYL-COA THIOLASE DEFICIENCY

This enzyme catalyzes the cytosolic production of acetoacetyl-CoA from two moles of acetyl-CoA (see Fig. 105.7). Cytosolic acetoacetyl-CoA is the precursor of hepatic cholesterol synthesis. Cytosolic acetoacetyl-CoA thiolase (encoded by *ACAT2*) should be differentiated from the mitochondrial thiolase (see earlier and Fig. 105.4). Clinical manifestations in patients with this very rare enzyme deficiency have been incompletely characterized. Patients may present with severe progressive developmental delay, hypotonia, and choreoathetoid movements in the first few months of life. Laboratory findings are nonspecific; elevated levels of lactate, pyruvate, acetoacetate, and 3-hydroxybutyrate may be found in blood and urine. One patient had normal levels of acetoacetate and 3-hydroxybutyrate. Diagnosis can be aided by demonstrating a deficiency in cytosolic thiolase activity in liver biopsy or in cultured fibroblasts or by DNA analysis of *ACAT2*. No effective treatment has been described, although a low-fat diet helped to diminish ketosis in one patient.

MITOCHONDRIAL 3-HYDROXY-3-METHYLGLUTARYL-COA SYNTHASE DEFICIENCY

3-Hydroxy-3-methylglutaryl (HMG)-CoA synthase (mitochondrial or type 2) catalyzes synthesis of 3-HMG-CoA from acetoacetyl-CoA and acetyl-CoA in the mitochondria. This is a critical step in ketone body synthesis in the liver (see Fig. 105.7). Only a few patients with

deficiency of this enzyme have been reported. The principal clinical syndrome is *hypoketotic hypoglycemia* triggered by physiologic stress, such as infections or fasting. Age at presentation has ranged from infancy to 6 years. Children tend to be asymptomatic before these episodes and with appropriate management can remain stable after the recovery (except for mild hepatomegaly with fatty infiltration). Future episodes can be prevented by avoiding prolonged fasting during ensuing intercurrent illnesses. Hepatomegaly is the most consistent physical finding in these patients. **Laboratory findings** include hypoglycemia, acidosis with mild or no ketosis, elevated levels in liver function tests, and massive dicarboxylic aciduria. The clinical and laboratory findings may be confused with fatty acid metabolism defects (see Chapter 104). In contrast to the latter, in patients with HMG-CoA synthase deficiency, the blood concentrations of acylcarnitine conjugates are negative for acylcarnitine findings characteristic of fatty acid oxidation disorders. Treatment of the secondary carnitine deficiency with L-carnitine supplementation can result in elevated plasma acetylcarnitine (C2-carnitine), likely reflecting intracellular accumulation of acetyl-CoA.

Treatment consists of provision of adequate calories and avoidance of prolonged periods of fasting. No dietary protein restriction was needed.

The condition is inherited in an autosomal recessive manner and is caused by biallelic pathogenic variants in *HMGCS2*. The condition should be considered in any child with fasting hypoketotic hypoglycemia and may be more common than appreciated.

3-HYDROXY-3-METHYLGLUTARYL-COA LYASE DEFICIENCY (3-HYDROXY-3-METHYLGLUTARIC ACIDURIA)

3-HMG-CoA lyase (encoded by *HMGCL*) catalyzes the cleavage of 3-HMG-CoA to acetoacetate, a rate-limiting enzyme for ketogenesis (see Fig. 105.4 and Fig. 105.7). The deficiency of this enzyme is a rare disorder seen with increased frequency in Saudi Arabia, the Iberian Peninsula, and in Brazil in patients of Portuguese ancestry. Clinically, approximately 30% develop symptoms in the first few days of life, and >60% of patients become symptomatic between 3 and 11 months of age. Infrequently, patients may remain asymptomatic until adolescence. With the addition of 3-HMG-CoA lyase deficiency to the newborn screening using C5-OH-carnitine, many infants are identified presymptomatically in the newborn period. Similar to 3-HMG-CoA synthase deficiency, patients affected by 3-HMG-CoA lyase deficiency may present with acute hypoketotic hypoglycemia. Episodes of vomiting, severe hypoglycemia, hypotonia, acidosis with mild or no ketosis, and dehydration may rapidly lead to lethargy, ataxia, and coma. These episodes often occur during a catabolic state such as prolonged fasting or an intercurrent infection. Hepatomegaly is common. These manifestations may be mistaken for Reye syndrome or fatty acid oxidation defects such as medium-chain acyl-CoA dehydrogenase deficiency. Long-term complications can include dilated cardiomyopathy, hepatic steatosis, and pancreatitis. Development can be normal, but intellectual disability and seizures with abnormalities in the white matter seen on brain MRI have been observed in patients after prolonged episodes of hypoglycemia.

Laboratory findings include hypoglycemia, moderate to severe hyperammonemia, and acidosis. There is mild or no ketosis (see Fig. 105.7). Urinary excretion of 3-hydroxy-3-methylglutaric acid and other proximal intermediate metabolites of leucine catabolism (3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid) is markedly increased, causing the urine to smell like "cat's urine." Glutaric and dicarboxylic acids may also be increased in urine during acute attacks. Secondary carnitine deficiency is common. The condition is inherited in an autosomal recessive manner. 3-HMG-CoA lyase is encoded by the gene *HMGCL*. **Diagnosis** may be confirmed by molecular analysis of *HMGCL* or by enzyme assay in cultured fibroblasts, leukocytes, or liver specimens. Prenatal diagnosis is possible by molecular DNA analysis if the familial pathogenic variants are known or by enzymatic assay of the cultured amniocytes or a chorionic villi biopsy.

Treatment of acute episodes includes hydration, infusion of glucose to control hypoglycemia, provision of adequate calories, and administration of bicarbonate to correct acidosis. Hyperammonemia should be treated promptly (see Chapter 105.12). Dialysis may be required in patients with severe recalcitrant hyperammonemia. Restriction of protein and fat intake can be considered for long-term management. Oral administration of L-carnitine (50-100 mg/kg/day) prevents secondary carnitine deficiency. Prolonged fasting should be avoided.

SUCCINYL-COA:3-OXOACID-COA TRANSFERASE DEFICIENCY

Succinyl-CoA:3-oxoacid-CoA transferase **(SCOT)** deficiency and β-ketothiolase deficiency collectively are referred to as **ketone utilization disorders**. SCOT participates in the conversion of ketone bodies (acetoacetate and 3-hydroxybutyrate) generated in liver mitochondria into *acetoacetyl-CoA in the nonhepatic tissues* (see Fig. 105.7). A deficiency of this enzyme results in the accumulation of ketone bodies, ketoacidosis, increased use of glucose, and hypoglycemia. During fasting, patients tend to have a proportional elevation of plasma free fatty acids. The condition may be more common than recognized because many cases tend to be mild and remain undiagnosed. SCOT deficiency can be distinguished from β-ketothiolase deficiency by the absence of 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine, characteristic of the latter disorder. Plasma acylcarnitine profile tends to show no specific abnormalities.

A common clinical presentation is an acute episode of severe ketoacidosis in an infant who had been growing and developing normally. About half the patients become symptomatic in the first weeks of life, and practically all become symptomatic before 2 years of age. The acute episode is often precipitated by a catabolic state triggered by an infection or prolonged fasting. Without treatment, the ketoacidotic episode can result in death. A chronic subclinical ketosis may persist between the attacks. Development is usually normal, although severe and recurrent episodes of ketoacidosis and hypoglycemia can predispose patients to neurocognitive impairment.

Laboratory findings during the acute episode are nonspecific and include metabolic acidosis and ketonuria with high levels of acetoacetate and 3-hydroxybutyrate in blood and urine. No other organic acids are found in the blood or in the urine. Blood glucose levels are usually normal, but hypoglycemia has been reported in some affected newborn infants with severe ketoacidosis. Plasma amino acids and the plasma acylcarnitine profile are usually normal. Severe SCOT deficiency can be accompanied by ketosis even when patients are clinically stable. This condition should be considered in any infant with unexplained bouts of ketoacidosis. SCOT deficiency is an autosomal recessive disorder. **Diagnosis** can be established by molecular analysis of *OXCT1* or by demonstrating a deficiency of enzyme activity in cultured fibroblasts.

Treatment of acute episodes consists of rehydration with solutions containing dextrose, correction of acidosis, and the provision of a diet adequate in calories. Long-term treatment should include a high-carbohydrate diet and avoidance of prolonged fasting and administration of dextrose before anticipated or during established catabolic states.

MEVALONATE KINASE DEFICIENCY

Mevalonic acid, an intermediate metabolite of cholesterol synthesis, is converted to 5-phosphomevalonic acid by the action of the enzyme mevalonate kinase (MVK) (see Fig. 105.7). MVK deficiency presents with a range of symptoms. Mevalonic aciduria occupies the more severe end of the spectrum, whereas hyperimmunoglobulinemia D syndrome represents the milder form of the underlying enzyme defect. Both disorders are accompanied by recurrent fever, gastrointestinal symptoms, mucocutaneous manifestations, and lymphadenopathy. Patients with mevalonic aciduria also show growth retardation and nervous system involvement.

Mevalonic Aciduria

Clinical manifestations include failure to thrive, growth restriction, intellectual disability, hypotonia, ataxia, myopathy, hepatosplenomegaly,

cataracts, and facial dysmorphisms (dolichocephaly, frontal bossing, low-set ears, downward slanting of eyes, long eyelashes). Most patients experience recurrent crises characterized by fever, vomiting, diarrhea, hepatosplenomegaly, arthralgia, lymphadenopathy, edema, and morbilliform rash. These episodes typically last 2-7 days and recur up to 25 times a year. Death may occur during these crises.

Laboratory findings include marked elevation of mevalonic acid in urine; the concentration of urinary mevalonic acid ranges between 500 and 56,000 mmol/mol of creatinine (normal: <0.3 mmol/mol of creatinine). Plasma levels of mevalonic acid are also greatly increased (as high as 540 μmol/L; normal: <0.04 μmol/L). Mevalonic acid levels tend to correlate with the severity of the condition and increase during crises. Serum cholesterol concentration is normal or mildly decreased. Serum concentration of creatine kinase can be greatly increased. Inflammatory markers are elevated during the crises. Brain MRI may reveal progressive atrophy of the cerebellum.

Diagnosis may be confirmed by molecular analysis of *MVK* or by assaying the MVK activity in lymphocytes or cultured fibroblasts. The enzyme activity in this form of the condition is below the detection level. **Treatment** with high doses of prednisone helps in the acute crises, but because of side effects, it is not routinely used long term. TNF-α inhibitors and interleukin-1 receptor antagonists have shown to be effective in bringing significant clinical improvement, especially in patients with chronic inflammation and frequent attacks. The condition is inherited in an autosomal recessive manner. **Prenatal diagnosis** is possible by identifying known familial pathogenic variants in *MVK,* by measurement of mevalonic acid in the amniotic fluid, or by assaying the enzyme activity in cultured amniocytes or chorionic villi samples.

Hyperimmunoglobulinemia D Syndrome (Hyperimmunoglobulinemia D and Periodic Fever Syndrome)

Some pathogenic variants of the *MVK* gene cause milder enzyme deficiency and produce the clinical picture of **periodic fever with hyperimmunoglobulinemia D**. These patients have periodic bouts of fever associated with abdominal pain, vomiting, diarrhea, arthralgia, arthritis, hepatosplenomegaly, lymphadenopathy, and morbilliform rash (even petechiae and purpura), which usually start before 1 year of age. The attacks can be triggered by vaccination, minor trauma, or stress and can occur every 1-2 months, lasting 2-7 days. Patients are free of symptoms between acute attacks. The diagnostic laboratory finding is elevation of serum immunoglobulin D (IgD). IgA is also elevated in 80% of patients. During acute attacks, leukocytosis, increased C-reactive protein, and mild mevalonic aciduria may be present. High concentrations of serum IgD help differentiate this condition from familial Mediterranean fever. See Chapter 204 for treatment recommendations.

PROPIONIC ACIDEMIA (PROPIONYL-COA CARBOXYLASE DEFICIENCY)

Propionic acid is an intermediate metabolite of isoleucine, valine, threonine, methionine, odd-chain fatty acids, and side chains of cholesterol. Normally, propionic acid in the form of propionyl-CoA undergoes carboxylation to D-methylmalonyl-CoA, catalyzed by the mitochondrial enzyme propionyl-CoA carboxylase. This enzyme requires biotin as a cofactor; thus the disorders of biotin metabolism, among other findings, can also result in elevation of propionic acid metabolites (see Fig. 105.4). Propionyl-CoA carboxylase is a multimeric enzyme composed of two nonidentical subunits, α and β, encoded by two genes, *PCCA* and *PCCB,* respectively. Biallelic pathogenic variants in propionyl-CoA carboxylase result in an autosomal recessive disorder called *propionic acidemia.*

Clinical findings of propionic acidemia are not specific to this disorder only. In the severe form, patients develop symptoms in the first few days of life. Poor feeding, vomiting, hypotonia, lethargy, dehydration, a sepsis-like picture, and clinical signs of severe ketoacidosis progress rapidly to coma and death. Seizures occur in approximately 30% of affected infants. If an infant survives the first attack, similar episodes of metabolic decompensation may occur during an intercurrent infection, trauma, surgery, prolonged fasting, severe constipation, or after ingestion of a high-protein diet. Moderate to severe intellectual disability and neurologic manifestations reflective of extrapyramidal (dystonia, choreoathetosis, tremor) and pyramidal (paraplegia) dysfunction are common sequelae in survivors. Neuroimaging shows that these abnormalities, which often occur after an episode of metabolic decompensation, are the result of damage to the basal ganglia, especially to the globus pallidus. This phenomenon has been referred to as **metabolic stroke**. This is the main cause of neurologic sequelae seen in the surviving affected children. Additional long-term complications include failure to thrive, optic nerve atrophy, pancreatitis, cardiomyopathy, and osteopenia.

In the *milder* form, episodes of metabolic decompensation are less frequent, but these children are still at risk of developing intellectual disability, seizures, long QTc interval, and severe cardiomyopathy. Universal newborn screening can identify propionic acidemia by detecting elevated propionylcarnitine (C3-carnitine) with an abnormal C3/C2 ratio in dried blood spots. However, in patients with the mild form of propionic acidemia, propionylcarnitine may remain below the cutoff value set by the screening laboratory, resulting in a false-negative result. Therefore physicians should maintain a high index of suspicion for this disorder and follow up with a biochemical evaluation of infants and children presenting with unexplained ketosis or metabolic acidosis.

Laboratory findings during the acute attack include various degrees of metabolic acidosis, often with a large anion gap, ketosis, ketonuria, hypoglycemia, anemia, neutropenia, and thrombocytopenia. Moderate to severe hyperammonemia is common; plasma ammonia concentrations usually correlate with the severity of the disease. In contrast to other causes of hyperammonemia, plasma concentration of glutamine tends to be within normal limits or decreased. The presence of severe metabolic acidosis and normal to reduced plasma glutamine help differentiate propionic academia from hyperammonemia caused by urea cycle defects. Measurement of plasma ammonia is especially helpful in planning therapeutic strategies during episodes of exacerbation in a patient whose diagnosis has been established. Mechanisms of hyperammonemia in propionic acidemia are not well understood but are likely related to the perturbed biochemical and pH environment of the mitochondrial matrix, where the proximal part of the urea cycle resides.

Glycine concentration can be elevated in all body fluids (blood, urine, CSF) and possibly is the result of the inhibited glycine cleavage system in the hepatic mitochondria (Fig. 105.8). Glycine elevation has also been observed in patients with methylmalonic acidemia. These disorders were collectively referred to as *ketotic hyperglycinemia* in the past before the specific enzyme deficiencies were elucidated. Mild to moderate increase in blood lactate and lysine may also be present in these patients. Concentrations of propionylcarnitine, 3-hydroxypropionic acid, and methylcitric acid (presumably formed through condensation of propionyl-CoA with oxaloacetic acid) are greatly elevated in the plasma and urine of infants with propionic acidemia. Propionylglycine and other intermediate metabolites of BCAA catabolism, such as tiglylglycine, can also be found in urine. Moderate elevations in blood levels of glycine and previously mentioned organic acids can persist between the acute attacks. Brain imaging may reveal cerebral atrophy, delayed myelination, and abnormalities in the globus pallidus and other parts of the basal ganglia.

The **diagnosis** of propionic acidemia should be differentiated from multiple carboxylase deficiencies (see earlier and Fig. 105.6). In addition to propionic acid metabolites, infants with the latter condition excrete large amounts of lactic acid, 3-methylcrotonylglycine, and 3-hydroxyisovaleric acid. The presence of hyperammonemia may suggest a genetic defect in the urea cycle enzymes. Infants with defects in the urea cycle are usually *not* acidotic (see Fig. 105.1) and have elevated levels of plasma glutamine. The definitive diagnosis of propionic acidemia can be established through molecular analysis of *PCCA* and *PCCB* or by measuring the enzyme activity in leukocytes or cultured fibroblasts.

Treatment of acute episodes of metabolic decompensation includes hydration with solutions containing glucose, correction of acidosis, and amelioration of the catabolic state by provision of adequate calories through enteral or parenteral hyperalimentation. A brief restriction of

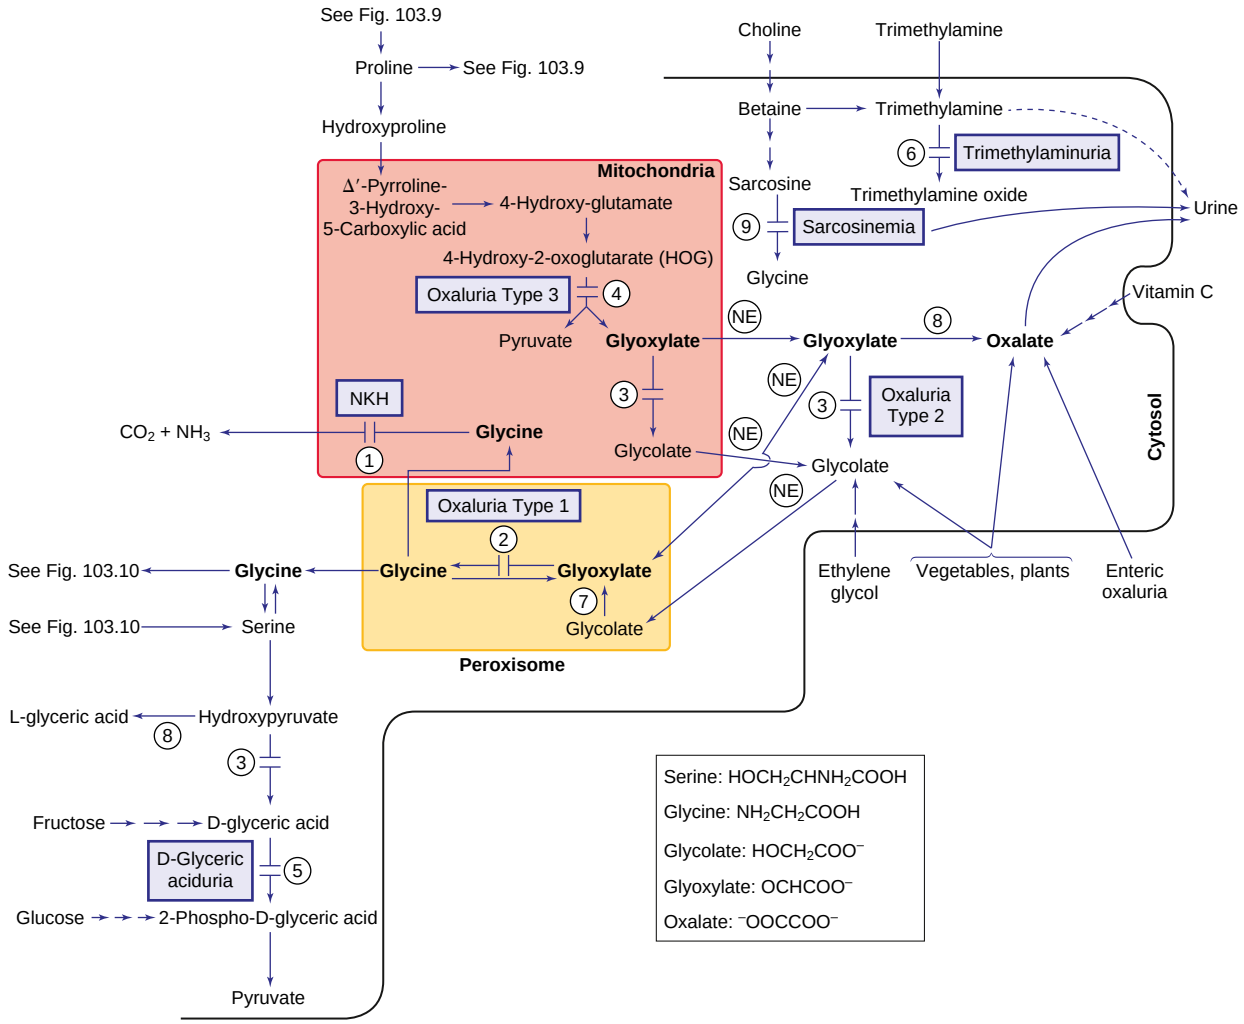

Fig. 105.8 Pathways in the metabolism of glycine and glyoxylic acid. **Enzymes:** *(1)* Glycine cleavage system, *(2)* alanine:glyoxylate aminotransferase, *(3)* glyoxylic reductase/hydroxypyruvate reductase (GR/HRP), *(4)* hydroxyoxoglutarate aldolase one (HOGA1), *(5)* glycerate kinase, *(6)* trimethylamine oxidase, *(7)* glycolate oxidase (D-amino acid oxidase), *(8)* lactate dehydrogenase, *(9)* sarcosine dehydrogenase. NE, Nonenzymatic; NKH, nonketotic hyperglycinemia.

protein intake, no more than 24 hours, is often necessary. Depending on the clinical status, gradual reintroduction of protein is recommended. If enteral feedings cannot be tolerated after 48 hours of protein restriction, parenteral nutrition should be instituted to achieve the age-specific recommended protein intake. Patients unable to tolerate the recommended dietary allowance of protein can receive specialized medical foods free of isoleucine, valine, threonine, and methionine. The composition and amount of protein typically vary among patients. The metabolic diet composition can be adjusted by monitoring growth and plasma amino acids drawn 3-4 hours after the typical feeding. Some patients may benefit from the suppression of propionogenic gut microflora. This can be achieved by oral antibiotics such as oral neomycin or metronidazole. Prolonged use of metronidazole should be avoided because it has been associated with reversible peripheral neuropathy and increased QTc interval. The risk of QTc prolongation can be problematic in propionic acidemia patients, who are at risk for cardiomyopathy and long QT interval. Baseline and interval ECGs are recommended before and after initiation of metronidazole therapy. Patients may benefit from management of constipation.

Patients with propionic acidemia often develop *secondary carnitine deficiency,* presumably as a result of the urinary loss of propionylcarnitine. Administration of L-carnitine (50-100 mg/kg/day orally or intravenously) helps restore free carnitine in blood. In patients with concomitant hyperammonemia, measures to reduce blood ammonia should be employed (see Chapter 105.12). Very ill patients with severe acidosis and hyperammonemia require hemodialysis to remove ammonia and other toxic compounds rapidly and efficiently. Carglumic acid and nitrogen scavengers (sodium benzoate, sodium phenylacetate, sodium phenylbutyrate) can aid in the treatment of acute hyperammonemia. Although no infant with propionic acidemia has been found to be responsive to biotin, this compound should be administered (10 mg/day orally) to all infants during the first attack and until the diagnosis is established and multiple carboxylase deficiency ruled out.

Long-term treatment consists of a low-protein diet meeting age-specific recommended dietary allowance and administration of L-carnitine (50-100 mg/kg/day orally). Some centers manage mild cases of propionic acidemia without medical foods, opting for only restricting the protein intake to the recommended dietary allowance. Patients unable to tolerate the recommended dietary intake of protein may require medical foods free of propionate precursors (isoleucine, valine, methionine, and threonine). Excessive use of medical foods while restricting natural-source protein may cause a deficiency of the essential amino acids, especially isoleucine and valine, which may cause a condition resembling **acrodermatitis enteropathica** (see Chapter 712). Over-restriction of methionine, especially in the first years of life, may contribute to the reduced brain growth and microcephaly. To avoid this problem, natural proteins should comprise most of the dietary protein. Some patients may require bicarbonate substitution (e.g., citric acid/sodium citrate) to correct chronic acidosis. The concentration of plasma ammonia usually normalizes between attacks, although

some patients may experience mild chronic hyperammonemia. Acute attacks triggered by infections, fasting, trauma, stress, constipation, or dietary indiscretions should be treated promptly and aggressively. Close monitoring of plasma ammonia, plasma amino acids obtained 3-4 hours after the last typical meal (especially isoleucine, leucine, valine, threonine, and methionine), and growth parameters is necessary to ensure the diet is appropriate. Orthotopic liver transplantation is used in clinically unstable patients experiencing recurrent hyperammonemia, frequent metabolic decompensations, and poor growth. Liver transplantation does not cure propionic acidemia, and lifelong dietary management and proactive management during periods of significant metabolic stress are recommended.

The long-term **prognosis** is poor. Death may occur during an acute attack. Normal psychomotor development is possible in a mild form identified through newborn screening. Children identified clinically may manifest some degree of permanent neurodevelopmental deficit, such as tremor, dystonia, chorea, and spasticity despite adequate therapy. These neurologic findings may be the sequelae of a metabolic stroke occurring during an acute decompensation. A long QTc interval and cardiomyopathy with potential progression to heart failure, fatal arrhythmias, and death may develop in older affected children despite adequate metabolic control. Acute pancreatitis is a common and severe complication in propionic acidemia. Osteoporosis can predispose to fractures, which can occur with minimal mechanical stress.

Prenatal diagnosis can be achieved by identification of known familial pathogenic variants in *PCCA* or *PCCB* or by measuring the enzyme activity in cultured amniotic cells or in samples of uncultured chorionic villi.

Propionic acidemia is inherited in an autosomal recessive manner. It has a worldwide prevalence of 1 in 105,000 to 1 in 250,000 live births. It is more prevalent in Greenlandic Inuits (1 in 1,000) and in some Saudi Arabian tribes (1 in 2,000 to 1 in 5,000 live births). Biallelic pathogenic variants in either gene result in similar clinical and biochemical manifestations. Although pregnancies with normal outcomes have been reported, the perinatal period poses special risks to females with propionic acidemia because of hyperemesis gravidarum, worsening cardiomyopathy, changing protein requirements, and risk of metabolic decompensation.

ISOLATED METHYLMALONIC ACIDEMIAS

Methylmalonic acidemias are a group of metabolic disorders of diverse etiology characterized by impaired conversion of methylmalonyl-CoA into succinyl-CoA. Propionyl-CoA derived from catabolism of isoleucine, valine, threonine, methionine, side chain of cholesterol, and odd-chain fatty acids is catalyzed by propionyl-CoA carboxylase to form D-methylmalonyl-CoA. Methylmalonyl-CoA epimerase then converts D-methylmalonyl-CoA to its enantiomer L-methylmalonyl-CoA. **Methylmalonyl-CoA epimerase deficiency** is a rare disorder associated with persistent elevations of propionate-related metabolites and methylmalonic acid. It may present with metabolic acidosis, ketosis, but patients appear more clinically stable than those with severe forms of methylmalonic acidemia.

In the next biochemical step, L-methylmalonyl-CoA is converted to succinyl-CoA by methylmalonyl-CoA mutase (see Fig. 105.4). The latter enzyme requires 5-deoxyadenosylcobalamin, a metabolite of vitamin B_{12}, as a coenzyme. Deficiency of either the mutase or its coenzyme results in the accumulation of methylmalonic acid and its precursors in body fluids. Two biochemical forms of methylmalonyl-CoA mutase deficiencies have been identified. These are designated *mut*^{0}, referring to no detectable enzyme activity, and *mut*$^-$, indicating residual, although insufficient, mutase activity. Patients with methylmalonic acidemia due to deficiency of the mutase apoenzyme (*mut*^{0}) are not responsive to hydroxocobalamin therapy.

In the remaining methylmalonic acidemia patients, the defect resides in the formation of adenosylcobalamin from dietary vitamin B_{12}. The absorption of dietary vitamin B_{12} in the terminal ileum requires *intrinsic factor,* a glycoprotein secreted by the gastric parietal cells. It is transported in the blood by haptocorrin and transcobalamin II. The transcobalamin II–cobalamin complex (TCII-Cbl) is recognized by a specific receptor on the cell membrane (a transcobalamin receptor encoded by *CD320*) and enters the cell by endocytosis. In the lysosome, TCII-Cbl is hydrolyzed, and, with the participation of LMBRD1 (*cbl*F) and ABCD4 (*cbl*J), free cobalamin is released into the cytosol (see Fig. 105.4). Biallelic pathogenic variants in either *LMBRD1* or *ABCD4* genes result in impaired release of cobalamin from lysosomes. In the cytoplasm, cobalamin binds to the MMACHC protein (see *cbl*C later), which removes a moiety attached to cobalt in the cobalamin molecule and reduces the cobalt from oxidation state +3 (cob[III]alamin) to +2 (cob[II]alamin). It then enters the mitochondria, where it is catalyzed by MMAB (*cbl*B) and MMAA (*cbl*A) to form adenosylcobalamin, a coenzyme for methylmalonyl-CoA mutase. The other arm of the pathway directs cytosolic cobalamin toward methionine synthase reductase (*cbl*E), which forms methylcobalamin, acting as a coenzyme for methionine synthase (*cbl*G, see Fig. 105.3). The MMADHC protein (see *cbl*D) appears to play a role in determining whether cobalamin enters the mitochondria or remains in the cytoplasm.

The uptake of TCII-Cbl by cells is impaired in individuals with pathogenic variants affecting the transcobalamin receptor *(CD320),* which is located on the cell surface. Individuals homozygous for pathogenic variants in the *CD320* gene encoding the transcobalamin receptor may have mild elevations of methylmalonic acid in the blood and urine. These patients can be identified by the newborn screen based on the elevated propionylcarnitine (C3-carnitine). In **transcobalamin receptor deficiency**, methylmalonic acid levels and plasma propionylcarnitine tend to normalize in the first year of life. It is not clear whether a long-term clinical phenotype is associated with this defect.

Nine different defects in the intracellular metabolism of cobalamin have been identified. These are designated *cbl*A through *cbl*G, *cbl*J, and *cbl*X, where *cbl* stands for a defect in any step of cobalamin metabolism. The *cbl*A, *cbl*B, and *cbl*D-MMA defects cause methylmalonic acidemia *alone*. In patients with *cbl*C, *cbl*D-combined methylmalonic acidemia and homocystinuria, *cbl*F, *cbl*J, and *cbl*X defects, synthesis of both adenosylcobalamin and methylcobalamin is impaired, resulting in *combined* methylmalonic acidemia and homocystinuria. The *cbl*D-homocystinuria, *cbl*E, and *cbl*G defects affect only the synthesis of methylcobalamin, resulting in homocystinuria without methylmalonic aciduria (see Chapter 105.3).

Biochemical manifestations of patients with isolated methylmalonic acidemia caused by *mut*^{0}, *mut*$^-$, *cbl*A, *cbl*B, and *cbl*D-MMA overlap. The wide variations in the severity of the clinical course range from very sick newborn infants to apparently asymptomatic adults. In **severe** forms, lethargy, feeding problems, vomiting, a sepsis-like picture, tachypnea (from metabolic ketoacidosis), and hypotonia may develop in the first few days of life and may progress to hyperammonemic encephalopathy, coma, and death if left untreated. Infants who survive the first attack may go on to develop similar acute metabolic episodes during a catabolic state such as infection or prolonged fasting or after ingestion of a high-protein diet. In certain situations, such acute events can cause a sudden injury of the basal ganglia, a metabolic stroke, resulting in a debilitating movement disorder. Between the acute attacks, the patient usually continues to exhibit hypotonia and feeding problems with failure to thrive, while other complications of the disease occur with age, including recurrent episodes of pancreatitis, bone marrow suppression, osteopenia, and optic nerve atrophy. Chronic renal failure and tubulointerstitial nephritis necessitating renal transplant have been reported in older patients. Renal complications are more severe in patients with the *mut*^{0} and severe *cbl*B forms of methylmalonic acidemia. In milder forms, patients may present later in life with hypotonia, failure to thrive, and developmental delay. Neurocognitive development of patients with mild methylmalonic acidemia may remain within the normal range.

The episodic nature of the condition and its biochemical abnormalities in some patients may be confused with those of *ethylene glycol (antifreeze) ingestion*. Furthermore, the peak of propionate in a blood sample from an infant with methylmalonic acidemia has been mistaken for ethylene glycol when the sample was assayed by gas chromatography without mass spectrometry.

Laboratory findings include ketosis, metabolic acidosis, hyperglycinemia, hyperammonemia, hypoglycemia, anemia, neutropenia, thrombocytopenia, and the presence of large quantities of methylmalonic acid in body fluids (see Fig. 105.6). Metabolites of propionic acid (3-hydroxypropionate and methylcitrate) are also found in the urine. The plasma acylcarnitine profile reveals elevated propionylcarnitine (C3-carnitine) and methylmalonylcarnitine (C4DC-carnitine). Hyperammonemia in methylmalonic acidemia may be confused with a urea cycle disorder. However, patients with defects in urea cycle enzymes are typically *not* acidotic and tend to have high plasma glutamine (see Fig. 105.12). The reason for hyperammonemia is not well understood, but it is likely related to the inhibition of the proximal urea cycle in the mitochondrial matrix.

The diagnosis can be confirmed by identifying pathogenic variants in the causal gene, by measuring propionate incorporation with complementation analysis in cultured fibroblasts, and by measuring the specific activity of the mutase enzyme in biopsies or cell extracts.

Treatment of acute attacks is similar to propionic acidemia. Long-term treatment consists of administration of a low-protein diet limited to the recommended dietary allowance and L-carnitine (50-100 mg/kg/day orally). Patients with severe forms of methylmalonic acidemia may require protein diet modifications similar to those prescribed for patients with propionic acidemia. Patients with isolated methylmalonic acidemia caused by defects in the intracellular metabolism of cobalamin (*cbl*A, *cblD*-MMA, and some patients with *cbl*B) respond to parenteral hydroxocobalamin. Chronic bicarbonate replacement therapy is usually required to correct chronic acidosis. Carglumic acid is used to improve ureagenic function by stimulating its first step catalyzed by the carbamoyl-phosphate synthetase 1 (CPS1) and to facilitate ammonia detoxification during acute hyperammonemia. Ammonia scavengers (sodium benzoate, sodium phenylacetate, sodium phenylbutyrate) should be used cautiously. Plasma ammonia tends to normalize between attacks, and chronic treatment of hyperammonemia is rarely needed. Stressful situations that may trigger acute attacks (infection, prolonged fasting, trauma, surgeries, high-protein meals) should be treated promptly.

Inadequate oral intake secondary to poor appetite, protein overrestriction, or essential amino acid deficiencies is a common complication in the long-term management of these patients. Consequently, enteral feeding through gastrostomy is often recommended early in the course of treatment. Close monitoring of blood pH, essential amino acid levels, blood and urinary concentrations of methylmalonate, and growth parameters is required to ensure that the nutritional prescription meets the patient's metabolic demands. In addition, frequent monitoring of kidney function, vision, hearing, and bone mineral density are necessary for early recognition and management of chronic complications. Glutathione deficiency responsive to treatment with ascorbate has been described.

Liver, kidney, and combined liver-kidney transplantations have been attempted in an increasing number of affected patients. Liver and liver-kidney transplantation can alleviate, but not eliminate, the metabolic abnormalities. Furthermore, liver and liver-kidney transplants do not provide complete protection against the occurrence of metabolic stroke. Kidney transplantation alone can restore the renal function but results in only minor improvement of the clinical stability of patients.

Prognosis depends on the severity of symptoms and the occurrence of complications. In general, patients with complete deficiency of mutase apoenzyme (mut^0) and severe forms of *cbl*B deficiency have the least favorable prognosis, and those with mut^- and *cbl*A defects have a better outcome.

Methylmalonic acidemia can be identified on the universal newborn screening by measuring propionylcarnitine (C3) using tandem mass spectrometry. The prevalence of all forms of methylmalonic aciduria is estimated at 1 in 50,000 to 1 in 100,000 live births. All defects causing isolated methylmalonic acidemia are inherited in an autosomal recessive manner. Pathogenic variants in the genes for *cbl*A *(MMAA)*, *cbl*B *(MMAB)*, and all forms of *cbl*D *(MMADHC)* have been identified in affected patients. The previously described *cbl*H group is identical to the *cbl*D-MMA defect.

COMBINED METHYLMALONIC ACIDURIA AND HOMOCYSTINURIA (*cblC, epi-cblC, cblD, cblF, cblJ,* AND *cblX* DEFECTS)

Combined methylmalonic acidemia and homocystinuria caused by *cbl*C deficiency is the most common type of intracellular cobalamin (vitamin B_{12}) biosynthesis defect. Deficiency of *cbl*C is as common as methylmalonyl-CoA mutase deficiency. The other disorders (*cbl*D, *cbl*F, *cbl*J, *cbl*X) are much rarer (see Figs. 105.3 and 105.4). Neurologic findings are prominent in patients with *cbl*C, *epi-cblC*, *cbl*D-combined, and *cbl*X defects. Most patients with the *cbl*C defect present in the first month of life because of failure to thrive, lethargy, poor feeding, developmental delay, nystagmus, and seizures. Hyperammonemia may be seen infrequently, whereas hyperglycinemia is not present, unlike in isolated *mut*-type methylmalonic acidemia. Intrauterine growth restriction and microcephaly suggest that *cbl*C can manifest prenatally in some affected infants. Late-onset patients with sudden development of dementia and myelopathy have been reported, even with presentation in adulthood. Megaloblastic anemia is a common finding in patients with *cbl*C defect. Mild to moderate increases in concentrations of methylmalonic acid and significant elevations in total plasma homocysteine are found in blood. Unlike classic homocystinuria, in untreated *cbl*C, patients' plasma methionine is low to normal. Retinal abnormalities (e.g., bull's eye maculopathy) resulting in severe progressive vision loss are common and can be seen as early as 3 months of age, even in prospectively identified and well-treated patients. **Thrombotic microangiopathy** can present as hemolytic uremic syndrome, pulmonary hypertension, and cor pulmonale. Hydrocephalus and noncompaction cardiomyopathy have been reported as complications in patients with *cbl*C defect.

Similar to *cblC* patients, males with *cbl*X have elevations of both total plasma homocysteine and methylmalonic acid, but they tend to have milder elevations of these metabolites. Unlike *cbl*C-deficient patients, who tend to respond to treatment, *cbl*X-deficient patients experience failure to thrive, severe developmental delay, and intractable epilepsy despite aggressive treatment.

Clinical findings in *cbl*F deficiency are quite variable. Patients may present with poor feeding, growth and developmental delay, and persistent stomatitis manifesting in the first months of life. Delay in diagnosis and treatment can be accompanied by hyperpigmentation of skin, developmental delay, intellectual disability, and short stature. Vitamin B_{12} malabsorption and low plasma vitamin B_{12} has been noted in patients with *cbl*F defect. Clinical manifestations of *cblJ* defect show significant overlap with those of the *cbl*F deficiency. Dysmorphic features and congenital heart disease have been reported in some patients with *cbl*F and *cbl*J defects.

Experience with **treatment** of patients with *cbl*C, *cbl*D, *cbl*F, *cbl*J, and *cbl*X defects is limited. Large doses of hydroxocobalamin (up to 0.3 mg/kg/day) in conjunction with betaine (up to 250 mg/kg/day) produce biochemical improvement with variable clinical effect. Patients with *cbl*F and *cblJ* deficiency typically show a favorable biochemical and clinical response to smaller hydroxocobalamin doses (1 mg once weekly to 1 mg daily parenterally). Folic or folinic acid supplementation is recommended. Dietary methionine deficiency should be avoided.

The *cbl*C disorder is caused by pathogenic variants in the *MMACHC* gene. A frameshift variant (c.271dupA) is seen in up to 40% of *MMACHC* alleles and is associated with a less favorable clinical outcome. Epi-*cbl*C, with a similar phenotype, is caused by compound heterozygous variants in *MMACHC* and *PRDX1,* a neighboring gene. Pathogenic variants in *PRDX1* cause hypermethylation and silencing of the promoter/exon 1 of *MMACHC,* resulting in repressed gene expression. The *cbl*D disorder is caused by pathogenic variants in the *MMADHC* gene. Pathogenic variants resulting in *cbl*D-homocystinuria affect the C-terminal domain of the gene product; those resulting in *cbl*D-MMA (e.g., causing only methylmalonic aciduria) affect the N-terminus. Patients with classic *cbl*D, with both homocystinuria and methylmalonic acidemia, have pathogenic variants resulting in decreased protein expression. The *cbl*F disorder is caused by pathogenic variants in the *LMBRD1* gene encoding a lysosomal membrane protein. The *cblJ* disorder is associated with pathogenic variants in the *ABCD4*

gene, encoding an adenosine triphosphate–binding cassette protein localized to the lysosomal membrane. The *cbl*X disorder is caused by pathogenic variants in the *HCFC1* gene on the X chromosome (Xq28), which encodes a transcription factor that appears to be essential for expression of the *MMACHC* gene. This is the only X-linked disorder in the B_{12} intracellular metabolism pathway. Rare defects resulting in a phenotype overlapping with *cbl*X deficiency have been associated with biallelic pathogenic variants in the genes *THAP11* or *ZNF143*.

ISOLATED HOMOCYSTINURIA

Patients with *cbl*D variant one, *cbl*E, and *cbl*G deficiency present with isolated homocystinuria without methylmalonic acidemia (see Chapter 105.3).

COMBINED MALONIC AND METHYLMALONIC ACIDURIA (*ACSF3*-RELATED DISORDER)

Combined *m*alonic and *m*ethyl*m*alonic *a*ciduria **(CMAMMA)** is a rare autosomal recessive disorder resulting from pathogenic variants in *ACSF3*. ACSF3 is a putative acyl-CoA synthetase required for the conversion of malonic and methylmalonic acids to their CoA derivatives in the mitochondrial matrix. The disorder can be suspected based on the presence of elevated malonic and methylmalonic acids in urine and plasma. It is distinguished from malonyl-CoA decarboxylase because methylmalonic acid is about fivefold greater than malonic acid in the urine. Plasma propionylcarnitine (C3-carnitine) in CMAMMA patients is normal, so universal newborn screening programs using C3-carnitine in blood spots to screen for methylmalonic acidemia would not detect this condition. The clinical phenotype is incompletely understood. Young patients identified prospectively in infancy through urine-based newborn screening were reported to be asymptomatic, but the long-term outcome in this cohort awaits further characterization. Older patients ascertained clinically have highly variable presentations, including metabolic crises, failure to thrive, seizures, memory problems, optic nerve or spinal cord atrophy, and progressive neurodegeneration. Treatment of CMAMMA is supportive and includes avoidance of an excessively high-protein diet. Vitamin B_{12} supplementation does not appear to lower malonic and methylmalonic metabolites in body fluids.

105.7 Glycine

Oleg A. Shchelochkov and Charles P. Venditti

Glycine is a nonessential amino acid synthesized by multiple endogenous sources, including serine, choline, and threonine. Structurally, it is the simplest amino acid. Glycine is involved in many reactions in the body, especially in the nervous system, where it functions as a neurotransmitter (excitatory in the cortex, inhibitory in the brainstem and the spinal cord; see Chapter 105.11). Its main catabolic pathway requires the *glycine cleavage system,* a pyridoxal phosphate–dependent, mitochondrial enzyme complex that converts glycine to carbon dioxide and ammonia and transfers α-carbon to tetrahydrofolate (see Fig. 105.8). The glycine cleavage system is composed of four proteins: P protein (glycine decarboxylase), H protein, T protein, and L protein, which are encoded by four different genes.

HYPOGLYCINEMIA

Defects in the biosynthetic pathway of serine (see Chapter 105.8) cause a deficiency of glycine in addition to that of serine in body fluids, especially in the CSF. Isolated primary deficiency of glycine has not been reported.

HYPERGLYCINEMIA

Elevated levels of glycine in body fluids occur in propionic acidemia, methylmalonic acidemia, isovaleric acidemia, and β-ketothiolase deficiency, which are collectively referred to as **ketotic hyperglycinemia** because of the coexistence of acidosis and ketosis. The pathogenesis of hyperglycinemia in these disorders is not understood. Inhibition of the glycine cleavage enzyme system by the various organic acids and post-translational modification has been shown to occur in some of these biochemical disorders. The term **nonketotic hyperglycinemia (NKH)** is reserved for the clinical condition caused by the genetic deficiency of the *glycine cleavage enzyme system* (GCS, see Fig. 105.8). In this condition, hyperglycinemia is present without ketosis.

NONKETOTIC HYPERGLYCINEMIA (GLYCINE ENCEPHALOPATHY)

Four forms of NKH have been identified: neonatal, infantile, late onset, and transient. NKH is an autosomal recessive disorder caused by biallelic pathogenic variants in either of three genes, *GLDC* (encodes P protein), *AMT* (encodes T protein), and *GCSH* (encodes H protein). The L-protein gene *(DLD)* encodes dihydrolipoamide dehydrogenase, the E3 component of α-ketoacid dehydrogenase complexes, and is discussed in Chapter 105.6. Birth prevalence of NKH is ~1:75,000, but a high frequency of the disorder has been noted in Northern Finland (1:12,000 live births), suggesting that this disorder is likely underdiagnosed in some regions of the world.

NKH should be differentiated from the GCS cofactor deficiency caused by the deficiency of lipoate resulting from biallelic pathogenic variants in genes involved in lipoate synthesis (*LIAS, LIPT2, BOLA3, GLRX5, IBA57,* and *NFU1*).

Neonatal Nonketotic Hyperglycinemia

This is the most common form of NKH. Clinical manifestations become apparent in the first few days of life (between 6 hours and 8 days after birth). Poor feeding, failure to suck, lethargy, and profound hypotonia may progress rapidly to a deep coma, apnea, and death. Convulsions, especially myoclonic seizures, and hiccups are common.

Laboratory findings reveal moderate to severe hyperglycinemia (as high as eight times the upper reference range) and hyperglycinuria. The unequivocal elevation of glycine concentration in CSF (15-30 times the upper reference range) and the high ratio of glycine concentration in CSF to that in plasma (a value >0.08, reference value <0.02) are diagnostic of NKH. Affected patients' blood pH is usually normal. The plasma acylcarnitine profile and urine organic acid assay reveal no abnormalities. CSF serine levels can be low.

Approximately 30% of NKH infants die despite supportive therapy. Those who survive develop profound intellectual disability and intractable seizure disorders (myoclonic and/or grand mal seizures). Hydrocephalus, requiring shunting, and pulmonary hypertension have been noted in survivors. Transient hyperglycemia may prompt evaluation for biochemical phenocopies of NKH (e.g., organic acidemias), brain imaging studies to evaluate for intracerebral hemorrhage or hypoxic-ischemic injury, and ultimately may require molecular studies of *AMT, GLDC,* and *GCSH*.

Transient Nonketotic Hyperglycinemia

Most clinical and laboratory manifestations of transient NKH are indistinguishable from those of the neonatal form. By 2-8 weeks of age, however, a complete clinical recovery may occur, and the elevated glycine levels in plasma and CSF normalize after the patient stops a glycine-lowering medication. Some of these patients develop normally with no neurologic sequelae, but intellectual disability has been noted in others. The etiology of this condition is not known, but it is thought to be a consequence of immaturity of the enzyme system; genetic testing is normal. Transient hyperglycemia should prompt consideration of additional biochemical studies; brain imaging; and molecular studies to evaluate for pathogenic variants in *AMT, GLDC,* and *GCSH*.

Infantile Nonketotic Hyperglycinemia

In infantile NKH, previously healthy-appearing infants develop signs and symptoms of neonatal NKH after 6 months of age. Seizures and hypotonia are common presenting signs. Infantile NKH appears to be a milder form of neonatal NKH; infants usually survive, and intellectual

disability is not as profound as in the neonatal form. Laboratory findings in patients with infantile NKH are identical to those seen in neonatal NKH.

Late-Onset Nonketotic Hyperglycinemia

Clinical manifestations of this atypical form of NKH include progressive spastic diplegia, optic nerve atrophy, and choreoathetotic movements. Age of onset has been between 2 and 33 years. Symptoms of delirium, chorea, and vertical gaze palsy may occur episodically in some patients during an intercurrent infection. Mental development is usually normal, but mild cognitive impairment and infrequent seizures have been reported in some patients.

Laboratory findings in late-onset NKH are similar but not as pronounced as in neonatal NKH.

All forms of NKH should be differentiated from *ketotic* hyperglycinemia, pyridox(am)ine phosphate oxidase (PNPO) deficiency, ingestion of valproic acid, and transient glycine encephalopathy. Valproic acid can moderately increase blood, CSF, and urinary concentrations of glycine. Repeat assays after discontinuation of the drug will help establish the diagnosis.

Diagnosis and Treatment

A diagnosis of NKH can be suspected based on the findings of elevated glycine in plasma or CSF and the abnormal CSF/plasma ratio of glycine. The diagnosis is confirmed using molecular analysis of the NKH-related genes (*AMT, GLDC,* and *GCSH*). Rarely, enzymatic assay on liver specimens is necessary to establish the diagnosis. Enzyme activity in the neonatal form is close to zero, whereas in the other forms, some residual activity is present. In most patients with neonatal NKH, the enzyme defect resides in the P protein (75%). Defects in the T protein account for approximately 20% of cases, whereas <1% are caused by pathogenic variants in the H protein.

Prenatal diagnosis can be accomplished by identifying known familial pathogenic variants in the affected gene or by performing an assay of the enzyme activity in chorionic villus biopsy specimens.

No effective treatment is currently available. Exchange transfusion, dietary restriction of glycine, and administration of sodium benzoate or folate have not altered the neurologic outcome in severe forms of NKH. Patients with attenuated NKH may experience clinical improvement from enteral sodium benzoate. Drugs that counteract the effect of glycine on neuronal cells, such as dextromethorphan and felbamate, have shown some beneficial effects in patients with the mild forms of the condition.

SARCOSINEMIA

Increased concentrations of sarcosine (*N*-methylglycine) are observed in both blood and urine of probands affected by sarcosine dehydrogenase complex deficiency. This autosomal recessive metabolic condition is caused by a defect in sarcosine dehydrogenase, the enzyme that converts sarcosine to glycine (see Fig. 105.8) and is encoded by *SARDH*. No consistent clinical picture has been attributed to sarcosinemia.

PRIMARY TRIMETHYLAMINURIA

Trimethylamine is normally produced by intestinal bacteria from the breakdown of dietary choline and trimethylamine oxide by bacteria. Egg yolk and liver are the main sources of choline, and fish is the major source of trimethylamine oxide. Trimethylamine is absorbed and oxidized in the liver by trimethylamine oxidase (a flavin-containing monooxygenase encoded by *FMO3*) to trimethylamine oxide, which is odorless and excreted in the urine (see Fig. 105.8). Deficiency of this enzyme results in massive excretion of trimethylamine in urine. There is a body odor that resembles that of rotting fish, which may have significant psychosocial ramifications. Transient symptomatic trimethylaminuria can occur in normal individuals after ingestion of large quantities of the previously mentioned foods.

Treatment with oral activated charcoal and short courses of oral metronidazole, neomycin, or lactulose cause temporary reduction in body odor. Restriction of fish, eggs, liver, and other sources of choline (e.g., nuts, grains) in the diet significantly reduces the odor. Topical use of acidic soaps (pH 5.5) can also help control the odor.

HYPEROXALURIA AND OXALOSIS

Normally, oxalic acid is derived mostly from oxidation of glyoxylic acid and, to a lesser degree, from oxidation of ascorbic acid (see Fig. 105.8). Glyoxylic acid is formed from oxidation of glycolic acid and glycine in the peroxisomes and catabolism of **hydroxyproline** in the mitochondria mediated by 4-hydroxy-2-oxoglutarate aldolase 1 (encoded by *HOGA1*), the underlying cause of **primary hyperoxaluria type 3** (Fig. 105.9). Vegetables and foods containing oxalic acid, such as spinach, rhubarb, and almond milk, are the main *exogenous* sources of glycolic and oxalic acids; most of glyoxylic and oxalic acids are produced endogenously. Normally, a major portion of glyoxylate produced in the body is shuttled to peroxisomes, where it is converted to glycine by the action of the enzyme alanine:glyoxylate transaminase (AGT encoded by *AGXT*). Deficiency of this enzyme causes **primary hyperoxaluria** type 1. Most of the remaining glyoxylate in the cytosol is reduced to glycolate by the action of the enzyme glyoxylate reductase/

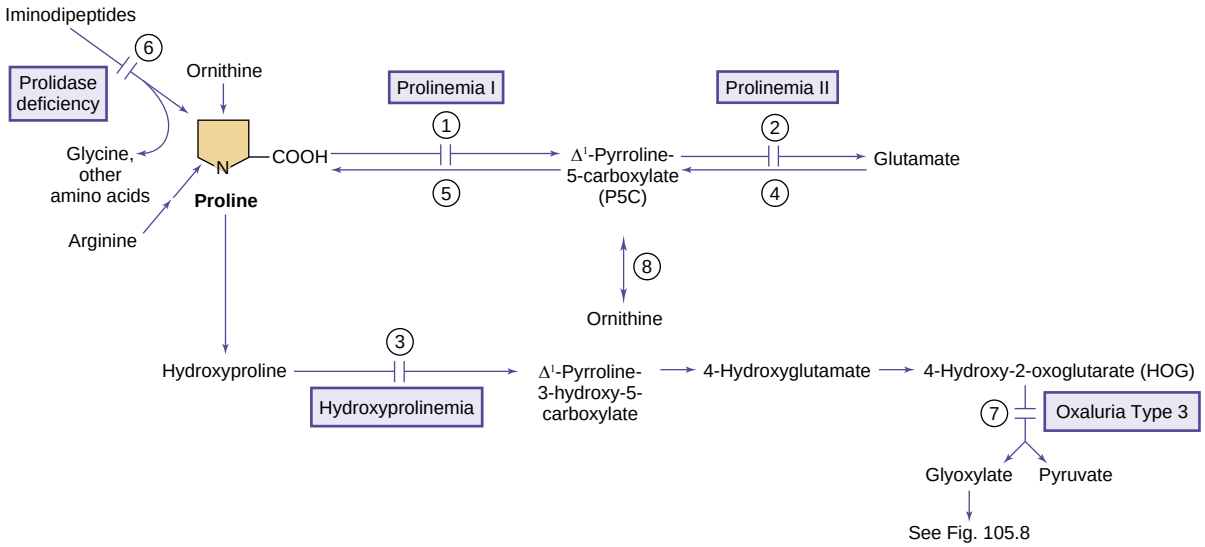

Fig. 105.9 Pathways in the metabolism of proline. **Enzymes:** *(1)* Proline oxidase (dehydrogenase), *(2)* Δ^1-pyrroline-5-carboxylic acid (P5C) dehydrogenase, *(3)* hydroxyproline oxidase, *(4)* Δ^1-pyrroline-5-carboxylic acid (P5C) synthase, *(5)* Δ^1-pyrroline-5-carboxylic acid (P5C) reductase, *(6)* prolidase, *(7)* 4-hydroxyoxoglutarate aldolase one (HOGA1), *(8)* ornithine aminotransferase.

hydroxypyruvate reductase (GR/HPR encoded by *GRHPR*). Deficiency of this enzyme causes **primary hyperoxaluria type 2**. These pathways protect the body from excessive production of oxalic acid (see Fig. 105.8). Any glyoxylate that cannot be disposed of through these pathways is readily converted to oxalic acid by the action of the enzyme lactate dehydrogenase (LDH). Oxalic acid cannot be further metabolized in humans and is excreted in the urine as oxalates. Calcium oxalate is relatively insoluble in water and precipitates in tissues (kidneys and joints) if its concentration increases in the body.

Secondary hyperoxaluria has been observed in pyridoxine deficiency (cofactor for alanine:glyoxylate transaminase), in patients with IBD, extensive resection of the small bowel or jejunoileal bypass *(enteric hyperoxaluria)*, after ingestion of ethylene glycol or high doses of vitamin C, and after administration of the anesthetic agent methoxyflurane (which can be catabolized to oxalic acid as one of its by-products). Acute, fatal hyperoxaluria may develop after ingestion of plants with high oxalic acid content (e.g., sorrel) or intentional ingestion of oxalic acid. Precipitation of calcium oxalate in tissues causes hypocalcemia, liver necrosis, renal failure, cardiac arrhythmia, and death. The lethal dose of oxalic acid is estimated at 5-30 g.

Primary hyperoxaluria is a group of disorders in which large amounts of oxalates accumulate in the body. Three types of primary hyperoxaluria have been identified to date. The term **oxalosis** refers to deposition of calcium oxalate in parenchymal tissues.

Primary Hyperoxaluria Type 1

This rare autosomal recessive condition (prevalence of 1 in 120,000 live births in Europe) is the most common form of primary hyperoxaluria and can be seen in in ~1% of children diagnosed with end-stage renal disease. Primary hyperoxaluria type 1 is caused by deficiency of the peroxisomal enzyme alanine:glyoxylate transaminase *(AGXT)*, which is expressed almost exclusively in the liver peroxisomes and requires pyridoxine (vitamin B_6) as a cofactor. In the absence of this enzyme, glyoxylic acid cannot be converted to glycine and is transferred to the cytosol, where it is oxidized to oxalic acid (see earlier and Fig. 105.8).

The age of presentation varies widely, from the neonatal period to late adulthood. The majority of patients become symptomatic in late childhood or early adolescence. In about 20% of cases, symptoms develop before the infant's first birthday. The initial clinical manifestations are related to renal stones and nephrocalcinosis. Renal colic and asymptomatic hematuria lead to a gradual deterioration of renal function, manifested by growth retardation and uremia. If the disorder is left untreated, most patients die before 20 years of age from renal failure. Other frequent manifestations of the disease include failure to thrive, short stature, arterial calcifications, arrhythmia, heart failure, hypothyroidism, and skin nodules. Acute arthritis is a rare manifestation and can be misdiagnosed as gout because uric acid is often elevated in patients with type 1 hyperoxaluria, driven in part by the worsening renal function. Crystalline retinopathy and optic neuropathy causing visual loss have been reported.

A marked increase in urinary excretion of oxalate (typical excretion: 10-50 mg/day) is the most important laboratory finding. The presence of oxalate crystals in urinary sediment is rarely helpful for diagnosis because such crystals can also be seen in otherwise healthy individuals. Urinary excretion of glycolic acid and glyoxylic acid is increased in most, but not all, patients. Diagnosis can be confirmed by identification of biallelic pathogenic variants in the *AGXT* gene or by performing an enzymatic assay in liver specimens.

The **diagnosis** of primary hyperoxaluria type 1 can be suspected in patients presenting with recurrent renal stones, nephrocalcinosis, and oxalate crystals in the urine after ruling out possible secondary causes (e.g., gastrointestinal disorders or dietary causes). Laboratory studies will reveal elevated urinary oxalate excretion, high urinary glycolate, and elevated plasma oxalate. Confirmatory testing of *AGXT* as a single gene or part of a multigene panel will secure the ultimate diagnosis. The most common pathogenic variant in patients with high residual enzyme activity (c.508G>A, p.Gly170Arg) results in mislocalization of the enzyme to mitochondria instead of peroxisomes, thus leading to the loss of in vivo function. **Prenatal diagnosis** has been achieved by DNA analysis of chorionic villus samples when biallelic pathogenic variants are known.

Treatment focuses on the reduction of oxalic acid production and on improving calcium oxalate disposal. Patients with primary hyperoxaluria type 1 should receive a 3-month trial of pyridoxine treatment to establish pyridoxine responsiveness. In up to 30% of patients (e.g., those homozygous for the *AGXT* pathogenic variant c.508G>A), administration of large doses of pyridoxine can reduce the plasma level and urinary excretion of oxalate. To increase calcium oxalate disposal and prevent nephrolithiasis, high oral fluid intake (2-3 L/m^2/day while controlling for fluid balance), urine alkalinization, phosphate supplementation, monitoring of vitamin C and vitamin D intake, and avoidance of drugs that can increase urinary calcium excretion (e.g., loop diuretics) are recommended. Urinary stones should be managed by experienced urologists, as excessive surgical trauma may contribute to renal dysfunction. Renal function replacement strategies (e.g., hemodialysis) are used in some patients (e.g., to bridge patients to transplant or when transplant is not a viable option).

Organ **transplantation** has emerged as the most definitive treatment. The decision to undergo kidney, liver, or liver-kidney transplant is complex, and referral rates may vary from one medical center to another. Except for older patients with the pyridoxine-responsive form of disease, renal transplantation alone in patients with renal failure may not improve the outcome, because oxalosis can recur in the transplanted kidney. Combined liver-kidney transplants have resulted in a significant decrease in plasma and urinary oxalate and thus may be the most effective treatment strategy, particularly in children.

Primary Hyperoxaluria type 2 (L-Glyceric Aciduria)

This rare autosomal recessive condition is caused by a deficiency of the glyoxylate reductase–hydroxypyruvate reductase enzyme complex encoded by *GRHPR* (see Fig. 105.8). A deficiency in the activity of this complex results in accumulation of two intermediate metabolites: hydroxypyruvate (the ketoacid derivative of serine) and glyoxylic acid. Both these compounds are further metabolized by LDH to L-glycerate and oxalate, respectively. A high prevalence of this disorder is reported in the Saulteaux-Ojibway Indians of Manitoba.

Primary hyperoxaluria type 2 results in the deposition of calcium oxalate in the renal parenchyma and urinary tract. Renal stones presenting with renal colic and hematuria may develop before age 2 years. Renal failure is less common in this condition than in primary hyperoxaluria type 1.

Urinary testing reveals large amounts of L-glyceric acid in addition to high levels of oxalate. Urinary L-glyceric acid is considered a pathognomonic finding in primary hyperoxaluria type 2. Urinary excretion of glycolic acid and glyoxylic acid is not increased. The presence of L-glyceric acid without increased levels of glycolic and glyoxylic acids in urine differentiates this type from type 1 hyperoxaluria. The diagnosis can be confirmed by molecular analysis of *GRHPR* or by the enzyme assay in liver biopsy.

The principles of therapy are similar to those in primary hyperoxaluria type 1. Renal transplant is used in some patients; experience with kidney-liver transplantation is limited at this time.

Primary Hyperoxaluria Type 3

Approximately 10% of patients with primary hyperoxaluria have deficiency of 4-hydroxy-2-oxoglutarate aldolase 1 (HOGA1), the underlying cause of hyperoxaluria type 3. The enzyme is encoded by *HOGA1*. This mitochondrial enzyme catalyzes a step in the metabolic pathway of hydroxyproline that generates pyruvate and glyoxylate from 4-hydroxy-2-oxoglutarate (HOG; see Figs. 105.8 and 105.9). In vitro studies show inhibition of glyoxylate reductase–hydroxypyruvate reductase enzyme activity by a high concentration of HOG that accumulates in patients with hyperoxaluria type 3. HOGA1 deficiency results in a biochemical phenotype similar to primary hyperoxaluria type 2 (see Fig. 105.8).

Patients with primary hyperoxaluria type 3 usually present with calcium oxalate kidney stones in early childhood, but asymptomatic older siblings have also been identified. Gradually, renal function may

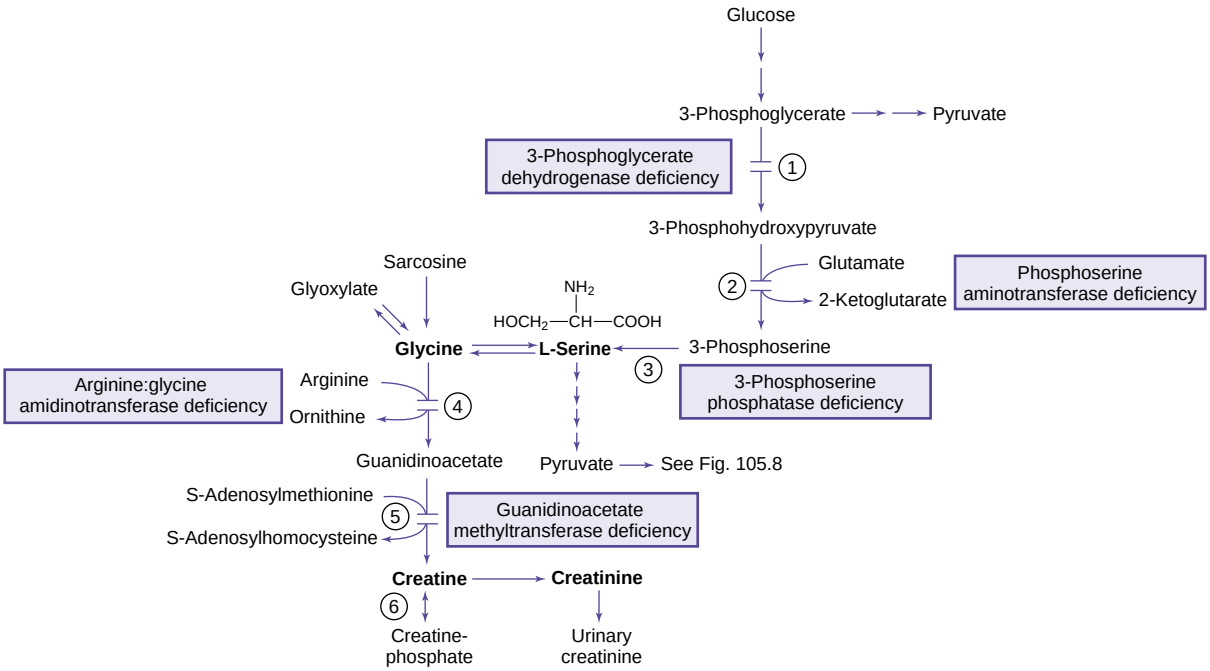

Fig. 105.10 Biosynthesis of serine and creatine. **Enzymes:** *(1)* 3-Phosphoglycerate dehydrogenase, *(2)* 3-phosphoserine aminotransferase, *(3)* 3-phosphoserine phosphatase, *(4)* arginine:glycine amidinotransferase (AGAT), *(5)* guanidinoacetate methyltransferase (GAMT), *(6)* creatine kinase.

decline, infrequently resulting in end-stage renal disease. Increased levels of HOG in urine, serum, and liver biopsy samples of these patients are the distinguishing feature of this disorder. **Treatment** involves high oral fluid intake, management of oral citrate or phosphate intake to prevent calcium oxalate renal stone formation, and avoidance of dehydration to prevent acute kidney injury. In severe forms of this disorder, dialysis and transplantation may be required to address the end-stage renal disease.

Creatine Deficiency Disorders

Creatine is synthesized mainly in the liver, pancreas, and kidneys and to a lesser degree in the brain from arginine and glycine and is transported to muscles and the brain, where there is high activity of the enzyme creatine kinase (Fig. 105.10). Phosphorylation and dephosphorylation of creatine in conjunction with adenosine triphosphate and diphosphate provide high-energy phosphate transfer reactions in these organs. Creatine is nonenzymatically metabolized to creatinine at a relatively constant daily rate and is excreted in the urine. Three genetic conditions are known to cause creatine deficiency in the brain and other tissues. Two enzymes, arginine:glycine amidinotransferase (see Fig. 105.10; **AGAT**, encoded by *GATM*) and guanidinoacetate methyltransferase (**GAMT**, encoded by *GAMT*), are involved in the biosynthesis of creatine. Both conditions may respond to creatine supplementation, especially when the treatment is started at an early age. The third condition, an X-linked inherited defect, is caused by a deficiency of the **creatinine transporter** (CRTR, encoded by *SLC6A8*) mediating uptake of creatine by the brain and muscle. A CRTR defect is the most common cause of creatine deficiency, accounting for up to 1–2% of males with intellectual disability of unknown cause.

Clinical manifestations of the three defects overlap, relate to the brain and muscle, and may appear in the first few weeks or months of life. Developmental delay, intellectual disability, speech delay, psychiatric symptoms (autism and psychosis), hypotonia, ataxia, and seizures are common findings. Dystonic movements have been documented in GAMT and CRTR deficiency.

Laboratory findings include decreased creatine in plasma in patients with AGAT and GAMT defects. Plasma creatinine level alone is insufficient to diagnose these disorders. Secondary to impaired reabsorption of creatine in kidneys, the urinary ratio of creatine to creatinine is increased in male patients with a CRTR defect but can also be mildly elevated in female carriers. Marked elevations of guanidinoacetate in the blood, urine, and especially in CSF are diagnostic of GAMT defects. In contrast, low levels of guanidinoacetate can be found in body fluids in the AGAT defect. Evidence of creatine and creatine phosphate deficiency (in all three defects) and high levels of guanidinoacetate (in the GAMT defect) in the brain can be demonstrated by magnetic resonance spectroscopy (MRS). Brain MRI may show signal hyperintensity in the globus pallidus. Diagnosis of AGAT deficiency or GAMT deficiency may be confirmed by DNA analysis or by measuring enzymatic activity in cultured fibroblasts (GAMT) or lymphoblasts (AGAT). The diagnosis of CRTR deficiency can be confirmed by DNA analysis or a creatine uptake assay in fibroblasts.

The outcomes of **treatment** are age-dependent, and the best outcomes are seen when treatment is started in the neonatal period or presymptomatically. In AGAT-deficient patients, oral creatine monohydrate (up to 400-800 mg/kg/day) can improve muscle weakness, seizures, and neurocognitive outcomes in some patients. In GAMT-deficient patients, supplementation with oral creatine monohydrate (up to 400-800 mg/kg/day), ornithine (up to 400-800 mg/kg/day), and dietary arginine restriction may result in improved muscle tone and neurocognitive development and may alleviate seizures. In CRTR-deficient patients, administration of creatine monohydrate and its precursors (arginine and glycine) may improve seizures and neurocognitive outcomes in some patients.

105.8 Serine Deficiency Disorders (Serine Biosynthesis and Transport Defects)

Oleg A. Shchelochkov and Charles P. Venditti

Serine is a nonessential amino acid supplied through dietary sources and through endogenous synthesis, mainly from glucose and glycine. The endogenous production of serine comprises an important portion of the daily requirement of this amino acid, especially in the synaptic junctions, where it contributes to phospholipid metabolism of D-serine and glycine, both of which are involved in neurotransmission (see Chapter 105.11). Consequently, deficiency of any of the enzymes

involved in the biosynthesis of serine or its transport causes neurologic manifestations. The clinical spectrum of serine deficiency disorders ranges widely and varies from **Neu-Laxova syndrome** on the severe end of spectrum to epilepsy and developmental delay on the milder end. Affected patients respond favorably to oral supplementation with serine and glycine when treatment is initiated very early in life. Figures 105.8 and 105.10 show the metabolic pathway for the synthesis and catabolism of serine.

3-PHOSPHOGLYCERATE DEHYDROGENASE DEFICIENCY

3-Phosphoglycerate dehydrogenase (**PHGDH** encoded by *PHGDH*) deficiency has a broad range of symptoms and ages of presentation. **Neu-Laxova syndrome type 1**, an autosomal recessive condition, is on the most severe end of the spectrum, presenting prenatally with intrauterine growth restriction and congenital anomalies, including dysmorphic facial features, microcephaly, CNS malformations, limb deformities, and ichthyosis. Most patients with this form are stillborn or have early neonatal mortality. The infantile form of PHGDH deficiency can present with feeding problems, failure to thrive, vomiting, irritability, seizures, severe developmental delay, and hypertonia progressing to spastic quadriplegia. Nystagmus, cataracts, hypogonadism, and megaloblastic anemia have been observed in some affected infants. Patients with a milder form of this disorder experience cognitive impairment, behavioral problems, sensorineural polyneuropathy, and childhood-onset seizures.

Laboratory findings include low fasting levels of serine and glycine in plasma and very low levels of serine and glycine in CSF. No abnormal organic acid metabolite is found in the urine. MRI of the brain shows cerebral atrophy with enlarged ventricles, significant attenuation of white matter, and impaired myelination. **Diagnosis** can be confirmed by DNA analysis or by measurement of the enzyme activity in cultured fibroblasts. **Treatment** with high doses of serine (200-700 mg/kg/day orally) and glycine (200-300 mg/kg/day) normalizes the serine levels in the blood and CSF. When started postnatally, this treatment may improve seizures, spasticity, and brain myelination. One case report suggests that developmental delay may be prevented if the treatment commences in the first days of life or prenatally.

If familial pathogenic variants are known, molecular **prenatal diagnosis** is possible. Administration of serine to a mother carrying an affected fetus was associated with stabilization of the fetal head circumference, as evidenced by ultrasound. Treatment with supplemental serine continued postnatally, and the patient remained normal neurologically at 4 years of age. The favorable response of this condition to a relatively straightforward treatment makes this diagnosis an important consideration in any child with microcephaly and neurologic defects such as psychomotor delay or a seizure disorder. Measurements of serine and glycine in the CSF are critical for diagnosis because mild decreases of these amino acids in the plasma can be easily overlooked.

PHOSPHOSERINE AMINOTRANSFERASE DEFICIENCY

Phosphoserine aminotransferase 1 (**PSAT1** encoded by *PSAT1*) catalyzes conversion of 3-phosphohydroxypyruvate to 3-phosphoserine (see Fig. 105.10). Deficiency of this enzyme, an autosomal recessive disorder, may present in the neonatal period with poor feeding, cyanotic episodes, and irritability and may progress to intractable, multifocal seizures and microcephaly. Brain imaging may reveal generalized cerebral and cerebellar atrophy. Laboratory studies done on postprandial plasma samples may reveal normal or mildly decreased levels of serine and glycine. Serine and glycine levels are usually more depressed on the CSF amino acid analysis. **Treatment** with serine and glycine as outlined earlier may result in clinical improvement.

3-PHOSPHOSERINE PHOSPHATASE DEFICIENCY

3-Phosphoserine phosphatase catalyzes the final step in the L-serine synthesis, converting 3-phosphoserine to L-serine. Deficiency of this enzyme results in an autosomal recessive disorder with clinical and biochemical findings indistinguishable from the PHGDH and PSAT1 deficiencies. The disorder is caused by biallelic pathogenic variants in *PSPH*.

105.9 Proline

Oleg A. Shchelochkov and Charles P. Venditti

Proline is a nonessential amino acid synthesized endogenously from glutamic acid, ornithine, and arginine (see Fig. 105.9). Proline and hydroxyproline are found in high concentrations in collagen. Normally, neither of these amino acids is found in large quantities in urine. Excretion of proline and hydroxyproline as *iminopeptides* (dipeptides and tripeptides containing proline or hydroxyproline) is increased in disorders of accelerated collagen turnover, such as rickets or hyperparathyroidism. Proline is also found in synapses, where it can interact with glycine and glutamate receptors (see Chapter 105.11). The catabolic pathway of proline and hydroxyproline produces glyoxylic acid, which can be further metabolized to glycine or oxalic acid (see Fig. 105.8).

Accumulation of proline in tissues is associated with disorders of hyperprolinemia type 1 and hyperprolinemia type 2. Two types of primary hyperprolinemia have been described. Reduced de novo synthesis of proline may manifest with **cutis laxa** (see Fig. 700.8) with **progeroid features** or **spastic paraplegia**.

HYPERPROLINEMIA TYPE I

This rare autosomal recessive condition is caused by a deficiency of proline oxidase (proline dehydrogenase; see Fig. 105.9). Most patients with hyperprolinemia type 1 appear asymptomatic, although some may present with intellectual disability, seizures, and behavioral problems. Hyperprolinemia may also be a risk factor for autism spectrum disorders and schizophrenia. The nature of such a wide phenotypic range in this biochemical condition is incompletely understood. The gene encoding proline oxidase *(PRODH)* is mapped to 22q11.2 within the critical region for velocardiofacial syndrome. Laboratory studies reveal high concentrations of proline in plasma, urine, and CSF. Increased urinary excretion of hydroxyproline and glycine is also present, which could be related to saturation of the shared tubular reabsorption mechanism due to massive prolinuria.

No effective treatment has yet emerged. Restriction of dietary proline causes a modest improvement in plasma proline but with no proven clinical benefit.

HYPERPROLINEMIA TYPE II

This is a rare autosomal recessive condition caused by the deficiency of Δ^1-pyrroline-5-carboxylate dehydrogenase (aldehyde dehydrogenase 4, *ALDH4A1*; see Fig. 105.9). Intellectual disability and seizures (usually precipitated by an intercurrent infection) have been reported in affected children, but asymptomatic patients have also been described. The cause for such disparate clinical outcomes is incompletely understood.

Laboratory studies reveal increased concentrations of proline and Δ^1-pyrroline-5-carboxylate (P5C) in blood, urine, and CSF. The presence of P5C differentiates this condition from hyperprolinemia type I. An increased level of P5C in body fluids, especially in the CNS, appears to antagonize vitamin B_6 and leads to vitamin B_6 dependency (see Chapter 105.14). Vitamin B_6 dependency may be the main cause of seizures and neurologic findings in this condition and can explain the variability in clinical manifestations in different patients. **Treatment** with high doses of vitamin B_6 is recommended.

PROLIDASE DEFICIENCY

During collagen degradation, imidodipeptides are formed and are normally cleaved by tissue prolidase. Prolidase deficiency, an autosomal recessive condition caused by biallelic pathogenic variants in *PEPD,* results in the accumulation of imidodipeptides in body fluids. The age at onset varies from 6 months to the third decade of life.

Clinical manifestations vary and include recurrent, severe, and painful skin ulcers typically found on the hands and legs. Other skin lesions may precede ulcers by several years and may include a scaly erythematous maculopapular rash, purpura, and telangiectasia. Most ulcers become infected. Healing of the ulcers may take months. Other findings include developmental delays, intellectual disability, organomegaly, anemia, thrombocytopenia, and immune dysfunction resulting in increased susceptibility to infections (recurrent otitis media, sinusitis, respiratory infection, splenomegaly). Some patients have craniofacial abnormalities such as ptosis, ocular proptosis, hypertelorism, small beaked nose, and prominent cranial sutures. Asymptomatic cases have also been reported. Increased incidence of systemic lupus erythematosus has been noted in children. High levels of urinary excretion of imidodipeptides are diagnostic. The diagnosis can be confirmed using DNA analysis. Enzyme assay may be performed in erythrocytes or cultured skin fibroblasts.

Treatment of prolidase deficiency is supportive. Infectious complications can be fatal and warrant close and proactive antibiotic management. Oral supplementation with proline, ascorbic acid, and manganese and topical proline and glycine have not been found to be consistently effective in all patients.

DISORDERS OF DE NOVO PROLINE SYNTHESIS

De novo synthesis of proline and ornithine from glutamate appears to be critical in the normal biology of connective tissue and to maintain the urea cycle in a repleted state. Correspondingly, clinical manifestations of these disorders encompass connective tissue abnormalities, nervous system abnormalities, and variable biochemical abnormalities reflecting urea cycle dysfunction. Clinical and laboratory findings associated with the deficient function of Δ^1-P5C synthase (see Fig. 105.9), encoded by *ALDH18A1,* and P5C, reductase encoded by *PYCR1,* are discussed.

Deficient activity of P5C synthase has been associated with several phenotypes, including **de Barsy syndrome**, characterized by cataracts, growth restriction, intellectual disability, a prematurely aged appearance (progeroid features), and cutis laxa. Some patients may show pyramidal signs. Skin biopsy may reveal decreased size of elastic fibers and collagen abnormalities. Brain imaging studies show cortical atrophy, ventriculomegaly, and reduced creatine. Laboratory findings include reduced levels of proline, ornithine, citrulline, and arginine as well as mild fasting hyperammonemia. Patients may show only intermittent abnormalities on the plasma amino acid profile, likely related to the time of blood sampling in relation to the last meal. Interestingly, both autosomal recessive and autosomal dominant forms of inheritance have been described. The diagnosis can be suspected in a patient presenting with cutis laxa, developmental delay, mild hyperammonemia, and characteristic amino acid abnormalities. The diagnosis can be confirmed using molecular DNA analysis or the glutamine loading test on skin fibroblasts. Treatment is supportive, although supplementation with citrulline or arginine to address hyperammonemia and cerebral creatine depletion have been proposed.

Biallelic pathogenic variants in *PYCR1* result in the abnormal function of the mitochondrial Δ^1-pyrroline-5-carboxylate reductase, which catalyzes the last step in the synthesis of proline from P5C. The most consistent finding in patients carrying proven pathogenic variants in *PYCR1* include triangular facies, cutis laxa **(de Barsy–like syndrome)**, joint hypermobility, wrinkled skin, gerodermia osteodysplastica, and progeroid features. Skin biopsy reveals reduction of the elastic fibers and infiltration with inflammatory cells. Some patients may have epilepsy, developmental delays, intellectual disability, cataracts, osteopenia, and failure to thrive. However, many of the affected families are consanguineous, thus complicating interpretation of the phenotype. Of note, plasma amino acid analysis reveals no specific abnormalities. The diagnosis depends on the recognition of the skin findings and can be confirmed using molecular DNA analysis. Available pedigrees of families affected by *PYCR1*-related disorder supports the autosomal recessive mode of inheritance.

105.10 Glutamic Acid

Oleg A. Shchelochkov and Charles P. Venditti

Glutamic acid and its amide derivative glutamine have a wide range of functions in the body. *Glutamate* plays numerous biologic roles, functioning as a neurotransmitter, an intermediate compound in many fundamental biochemical reactions, and a precursor of an inhibitory neurotransmitter, γ-aminobutyric acid (GABA) (see Chapter 105.11). Another major product of glutamate is *glutathione* (γ-glutamylcysteinylglycine). This ubiquitous tripeptide, with its function as the major antioxidant in the body, is synthesized and degraded through a complex cycle called the γ-glutamyl cycle (Fig. 105.11). Because of its free sulfhydryl (–SH) group and its abundance in the cell, glutathione protects other sulfhydryl-containing compounds (e.g., enzymes, coenzyme A) from oxidation. It is also involved in the detoxification of peroxides, including hydrogen peroxide, and in keeping the intracellular milieu in a reduced state. In addition, glutathione participates in amino acid transport across the cell membrane through the γ-glutamyl cycle.

One of the biochemical manifestations of γ-glutamyl cycle deficiency is increased urinary excretion of 5-oxoproline, which could be the result of both genetic and nongenetic causes. 5-Oxoprolinemia should be routinely considered in the differential diagnosis of **high–anion gap metabolic acidosis** (HAGMA). Two metabolic disorders can present with massive 5-oxoprolinuria: **glutathione synthetase deficiency** and **5-oxoprolinase deficiency** (see Fig. 105.11). However, a more common clinical scenario is a transient and mild urinary elevation of 5-oxoproline that can be seen in a variety of metabolic and acquired conditions, such as exposure to acetaminophen and some hydrolyzed-protein formulas, severe burns, Stevens-Johnson syndrome, homocystinuria, urea cycle defects, and tyrosinemia type I.

GLUTATHIONE SYNTHETASE DEFICIENCY

Three forms of this rare autosomal recessive condition have been reported. In the **mild form**, glutathione synthetase deficiency causes glutathione deficiency in erythrocytes. These patients present with hemolytic anemia without chronic metabolic acidosis and demonstrate high residual activity of glutathione synthetase on enzymatic testing. A **moderate form** has also been observed in which the hemolytic anemia is associated with variable degrees of metabolic acidosis and 5-oxoprolinuria. Its **severe form** is distinguished by the presence of hemolytic anemia accompanied by severe acidosis, massive 5-oxoprolinuria, and neurologic manifestations.

Glutathione Synthetase Deficiency, Moderate and Severe Forms

Affected newborn infants with severe and moderate forms of glutathione synthetase deficiency usually develop acute symptoms of metabolic acidosis, jaundice, and mild to moderate hemolytic anemia in the first days of life. Chronic acidosis continues after recovery. Similar episodes of life-threatening acidosis may occur during an infection (e.g., gastroenteritis) or after a surgical procedure. Progressive neurologic damage develops with age, manifested by intellectual disability, spastic tetraparesis, ataxia, tremor, dysarthria, and seizures. Susceptibility to infections, presumably because of granulocyte dysfunction, is observed in some patients. Patients with the moderate form of glutathione synthetase deficiency have milder acidosis and less 5-oxoprolinuria than is seen in the severe form, with few neurologic manifestations.

Laboratory findings include metabolic acidosis, mild to moderate degrees of hemolytic anemia, and 5-oxoprolinuria. High concentrations of 5-oxoproline are also found in the blood. The urinary and blood levels of 5-oxoproline are less pronounced in patients with the moderate form of the condition. The glutathione content of erythrocytes is markedly decreased. Increased synthesis of 5-oxoproline in this disorder is thought to be the result of the conversion of γ-glutamylcysteine to 5-oxoproline by the enzyme γ-glutamyl cyclotransferase (see Fig. 105.11). γ-Glutamylcysteine production increases greatly because the normal inhibitory effect of glutathione on the γ-glutamylcysteine synthetase enzyme is removed.

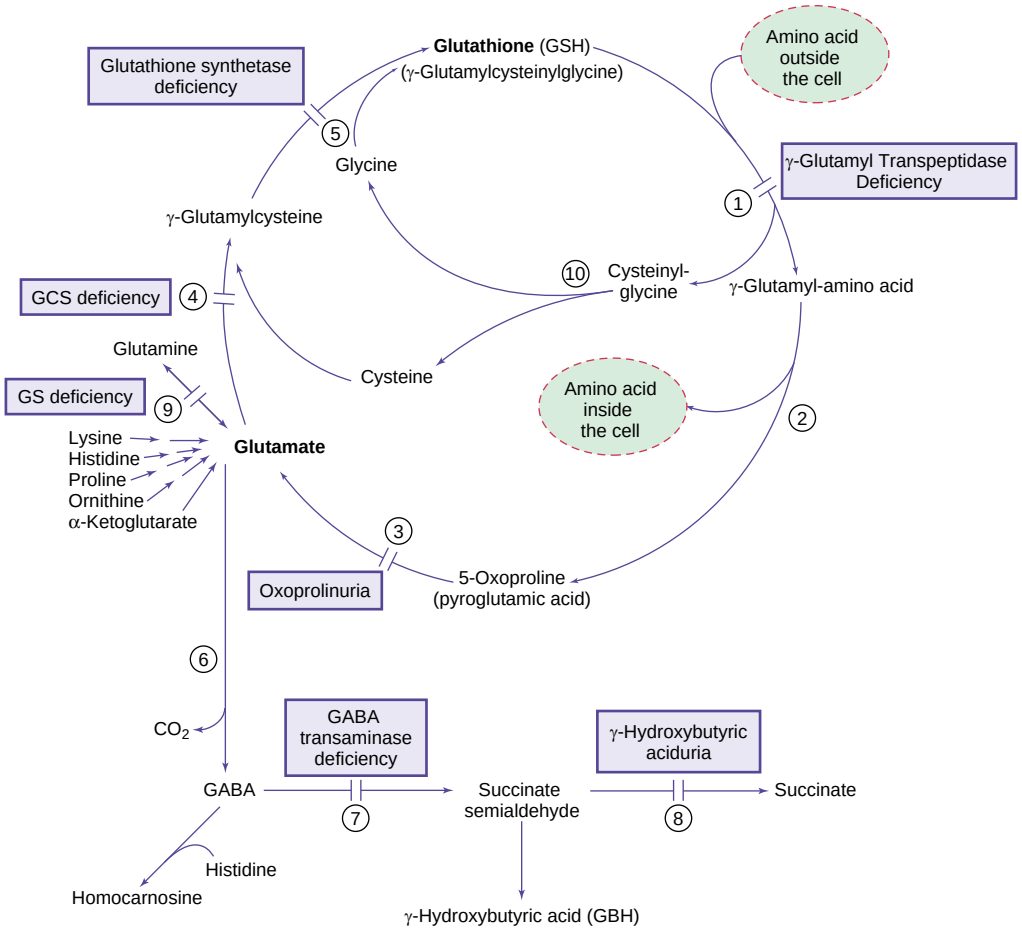

Fig. 105.11 The γ-glutamyl cycle and related pathways. Defects of the glutathione (GSH) synthesis and degradation are noted. **Enzymes:** *(1)* γ-Glutamyl transpeptidase (GGT), *(2)* γ-glutamyl cyclotransferase, *(3)* 5-oxoprolinase, *(4)* γ-glutamyl-cysteine synthetase, *(5)* glutathione synthetase, *(6)* glutamate decarboxylase, *(7)* γ-aminobutyric acid (GABA) transaminase, *(8)* succinate-semialdehyde dehydrogenase, *(9)* glutamine synthetase, *(10)* dipeptidase.

Treatment of acute attack includes hydration, correction of acidosis (by infusion of sodium bicarbonate), and measures to correct anemia and hyperbilirubinemia. Chronic administration of alkali is usually needed indefinitely. Supplementation with vitamin C, vitamin E, and selenium is recommended. Drugs and oxidants known to cause hemolysis and stressful catabolic states should be avoided. Oral administration of glutathione analogs has been tried with variable success.

Prenatal diagnosis can be achieved by the measurement of 5-oxoproline in amniotic fluid, by enzyme analysis in cultured amniocytes or chronic villus samples, or by *GSS* gene analysis. Successful pregnancy in an affected female (moderate form) has been reported, with favorable outcomes for both mother and infant.

Glutathione Synthetase Deficiency, Mild Form

The mild form has been reported in only a few patients. Mild to moderate hemolytic anemia has been the only clinical finding. Splenomegaly has been reported in some patients. Cognitive development is normal. Chronic metabolic acidosis typically is not seen. Some patients can have increased concentrations of 5-oxoproline in the urine. Biallelic pathogenic variants in *GSS*, the gene encoding the enzyme, appear to decrease the half-life of the enzyme, causing an increased rate of protein turnover without affecting its catalytic function. The expedited rate of enzyme turnover caused by these pathogenic variants is of little or no consequence for tissues with protein synthetic capability. However, inability of mature erythrocytes to synthesize protein results in glutathione deficiency in the erythrocytes. **Treatment** is that of hemolytic anemia and avoidance of drugs and oxidants that can trigger the hemolytic process.

All forms of glutathione synthetase deficiency are inherited as an autosomal recessive trait. **Diagnosis** can be confirmed by *GSS* gene analysis or enzyme activity in erythrocytes or skin fibroblasts.

5-Oxoprolinase Deficiency

More than 20 patients with 5-oxoprolinuria (4-10 g/day) caused by 5-oxoprolinase (see Fig. 105.11) deficiency *(OPLAH)* have been described. No specific clinical picture has yet emerged; completely asymptomatic affected individuals have also been identified. It is therefore not clear whether 5-oxoprolinase deficiency is of any clinical consequence. No treatment is currently recommended.

γ-Glutamylcysteine Synthetase Deficiency (Glutamate-Cysteine Ligase Deficiency)

γ-Glutamylcysteine synthetase deficiency is an autosomal recessive disorder caused by biallelic pathogenic variants in *GCLC*. Only a few patients with this enzyme deficiency have been reported. The most consistent clinical manifestation has been mild chronic hemolytic anemia. Acute attacks of hemolysis have occurred after exposure to sulfonamides. Peripheral neuropathy and progressive spinocerebellar degeneration have been noted in two siblings in adulthood. Laboratory findings of chronic hemolytic anemia were present in all patients. Generalized aminoaciduria is also found because the γ-glutamyl cycle is involved in amino acid transport in cells (see Fig. 105.11). **Treatment** focuses on the management of hemolytic anemia and avoidance of drugs and oxidants that may trigger the hemolytic process.

γ-GLUTAMYL TRANSPEPTIDASE DEFICIENCY (GLUTATHIONEMIA)

γ-Glutamyl transpeptidase (GGT) is expressed in any cell that has secretory or absorptive functions. It is especially abundant in the kidneys, pancreas, intestines, and liver. The enzyme is also present in the bile. Measurement of GGT in the blood is frequently performed to evaluate for liver and bile duct diseases.

GGT deficiency causes elevation in glutathione concentrations in body fluids, but the cellular levels remain normal (see Fig. 105.11). Because only a few patients with GGT deficiency have been reported, the scope of clinical manifestations has not yet been defined. Mild to moderate intellectual disability and severe behavioral problems were observed in three patients. However, one of two sisters with this condition had normal intelligence as an adult, and the other had Prader-Willi syndrome.

Laboratory findings include marked elevations in urinary glutathione (up to 1 g/day), γ-glutamylcysteine, and cysteine. None of the reported patients have had generalized aminoaciduria, a finding that would have been expected to occur in this enzyme deficiency (see Fig. 105.11).

Diagnosis can be confirmed by measurement of the enzyme activity in leukocytes or cultured skin fibroblasts. *No effective treatment has been proposed.* The condition is inherited as an apparent autosomal recessive trait. The γ-glutamyl transpeptidases represent a large family of enzymes encoded by at least seven genes.

GENETIC DISORDERS OF METABOLISM OF γ-AMINOBUTYRIC ACID

See Chapter 105.11.

105.11 Disorders of Neurotransmitter Metabolism

Oleg A. Shchelochkov and Charles P. Venditti

Neurotransmitters are chemical substances released from the axonal end of excited neurons at the synaptic junctions; they mediate initiation, amplification, or inhibition of neural impulses. Several amino acids and their metabolites act as neurotransmitters in the central and peripheral nervous system. Pathogenic variants in genes responsible for the synthesis, transport, or degradation of these substances may cause conditions that manifest neurologic and/or psychiatric abnormalities (Table 105.3). Previously, children affected by disorders of neurotransmitters have been given syndromic diagnoses such as cerebral palsy, epilepsy, parkinsonism, dystonia, or autism. Diagnosis, in most cases, requires specialized laboratory studies of the CSF, because some of the neurotransmitters generated in the CNS, dopamine and serotonin, do not cross the BBB, and their abnormal concentrations are not detected in the serum or urine.

TYROSINE HYDROXYLASE DEFICIENCY (INFANTILE PARKINSONISM, AUTOSOMAL RECESSIVE DOPA-RESPONSIVE DYSTONIA, AUTOSOMAL RECESSIVE SEGAWA SYNDROME)

Tyrosine hydroxylase catalyzes the formation of L-dopa from tyrosine. Deficiency of this enzyme results in deficiencies of dopamine and norepinephrine (see Fig. 105.2 and Fig. 105.12). The differential diagnosis includes a wide range of inherited dystonias, including autosomal dominant dystonia caused by GTP cyclohydrolase 1 deficiency.

Clinical manifestations range from mild to very severe. In general, two phenotypes have been recognized. In the **mild** form (dopa-responsive dystonia, or **type A**), symptoms of unilateral limb dystonia causing gait incoordination and postural tremor occur in childhood and worsen with age when the condition remains untreated. Diurnal variation of symptoms (worse at the end of the day) may be present. Cognitive development is usually normal.

In the **severe** form of tyrosine hydroxylase deficiency (infantile parkinsonism, infantile encephalopathy, or **type B**), the clinical manifestations occur at birth or shortly thereafter and include microcephaly, developmental delay, involuntary movements of the limbs with spasticity, dystonia, ptosis, expressionless face, oculogyric crises (upward eye-rolling movements), and autonomic dysfunction (temperature instability, excessive sweating, hypoglycemia, salivation, tremor, gastrointestinal reflux, constipation). Brisk reflexes, myoclonus, athetosis, and distal chorea may be present. The patient with the severe form usually shows incomplete response to treatment with L-dopa and is prone to developing L-dopa–induced dyskinesia as a side effect.

Laboratory findings include reduced levels of dopamine and its metabolite homovanillic acid (HVA) and normal concentrations of tetrahydrobiopterin (BH_4), neopterin, and 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of serotonin) in the CSF. Serum prolactin levels are usually elevated. These findings are not diagnostic of the condition; diagnosis should be established by molecular gene analysis.

Treatment with L-dopa/carbidopa results in significant clinical improvement in most patients, but the severe forms are invariably associated with L-dopa–induced dyskinesias. To minimize the side effects of therapy, treatment should be started with a low dose and, if needed, increased very slowly. Other therapeutic interventions include anticholinergics, serotonergic agents, and monoamine oxidase (MAO) B inhibitors, including amantadine, biperiden, and selegiline. Bilateral subthalamic nucleus deep brain stimulation has shown clinical efficacy in one case. Tyrosine hydroxylase deficiency is inherited as an autosomal recessive trait. Molecular testing for pathogenic variants in the *TH* gene is available clinically.

AROMATIC L-AMINO ACID DECARBOXYLASE DEFICIENCY

Aromatic L-amino acid decarboxylase (AADC encoded by *DDC*) is a vitamin B_6–dependent enzyme that catalyzes the decarboxylation of both 5-hydroxytryptophan to form serotonin (see Fig. 105.5 and Fig. 105.12) and L-dopa to generate dopamine (see Fig. 105.2 and Fig. 105.12). **Clinical manifestations** of this autosomal recessive disorder reflect the reduced availability of dopamine and serotonin. Poor feeding, lethargy, hypotension, hypothermia, oculogyric crises, and ptosis have been observed in affected neonates. Clinical findings in infants and older children include developmental delay, truncal hypotonia with hypertonia of limbs, oculogyric crises, extrapyramidal movements (choreoathetosis, dystonia, myoclonus), and autonomic abnormalities (sweating, salivation, irritability, temperature instability, hypotension). Symptoms may have a diurnal variation, becoming worse by the end of the day.

Laboratory findings include decreased concentrations of dopamine and serotonin and their metabolites (HVA, 5-HIAA, norepinephrine, vanillylmandelic acid [VMA]) and increased levels of 5-hydroxytryptophan, L-dopa, and its metabolite (3-*O*-methyldopa) in body fluids, especially in CSF. Elevated serum concentrations of prolactin (the result of dopamine deficiency) have also been observed. Brain MRI reveals cerebral atrophy with degenerative changes in the white matter. A urine screening program, focused on 3-*O*-methyl-dopa and VMA, has demonstrated diagnostic promise in high-disease-prevalence populations.

Treatment with neurotransmitter precursors has produced limited clinical improvement. Dopamine and serotonin have no therapeutic value because of their inability to cross the BBB. Nonergot dopamine agonists, MAO inhibitors (tranylcypromine), serotonergic agents, and high doses of pyridoxine/pyridoxal phosphate, a cofactor for the AADC enzyme, are preferred. The demonstration of putamen-directed gene therapy with an adeno-associated viral vector has shown some benefit in patients. Preimplantation genetic diagnosis after in vitro fertilization has been achieved in the high-prevalence Taiwanese population.

TETRAHYDROBIOPTERIN DEFICIENCY

See Chapter 105.1.

Tetrahydrobiopterin (BH_4) is the enzymatic cofactor for phenylalanine hydroxylase (see Fig. 105.1 and Fig. 105.12), tyrosine hydroxylase

Table 105.3 Neurotransmitter Disorders Affecting Biogenic Amines and GABA Metabolism and Transport: Biomarker Assessment in Biologic Fluids

CSF MARKER	DISEASE OMIM[A]/GENE	BIOCHEMICAL PATTERN
Biogenic amines	TH deficiency 191290/*TH*	*CSF*:↓ HVA, MHPG, and HVA/5-HIAA ratio
	AADC deficiency 107930/*DDC*	*CSF*: ↓↓ HVA and 5-HIAA; ↑↑ 3OMD and 5HTP *Urine*: ↑ vanillactate; *blood*: ↑ 3OMD
	MAOA deficiency 309850/*MAO-A*	*CSF*: ↓↓ 5-HIAA and HVA *Plasma/urine*: ↑ catecholamines and serotonin
	DBH deficiency 609312/*DBH*	*CSF*: ↑ HVA, HVA/5-HIAA ratio, ↓ MHPG[a] *Urine/plasma*: ↓↓ norepinephrine and epinephrine; ↑ dopamine and DOPAC
	DAT1 deficiency 126455/*SLC6A3*	*CSF*: ↑ HVA and HVA/5-HIAA ratio
	VMAT2 deficiency 193001/SLC18A2	*Urine*: ↑ HVA and 5-HIAA ↓ Norepinephrine and dopamine

[a]Expected values.

↑: Increased values compared with reference aged values; ↓: decreased values compared with reference aged values.

5-HIAA, 5-Hydroxyindoleacetic acid; AADC, aromatic L-amino acid decarboxylase; BP, biopterin; CSF, cerebrospinal fluid; DBH, dopamine β-hydroxylase; DOPAC, dihydroxyphenylacetic acid; GHB, γ-hydroxybutyrate; GTPCH-I, guanosine triphosphate cyclohydrolase-I; HVA, homovanillic acid; MAOA, monoamine oxidase A; MHPG, 3-methoxy-4-hydroxyphenylethyleneglycol; NP, neopterin; SP, sepiapterin; SR, sepiapterin reductase; SSADH, succinic semialdehyde dehydrogenase; TH, tyrosine hydroxylase.

From García-Cazorla À, Artuch R. Neurotransmitter disorders. In Rosenberg RN, Pascual JM, eds. *Rosenberg's Molecular and Genetic Basis of Neurological and Psychiatric Disease*, 6th ed. Vol. 1. London: Elsevier; 2020: Table. 67.1.

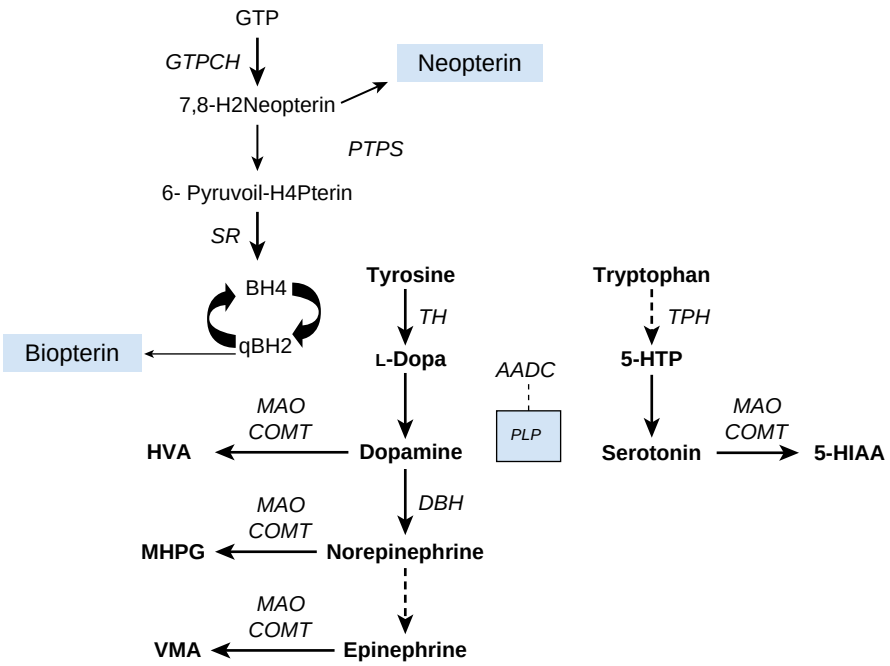

Fig. 105.12 Metabolic pathways of monoamines. The first step in their formation is catalyzed by amino acid–specific hydroxylases, which require tetrahydrobiopterin (BH_4) as a cofactor. The synthesis of BH_4 comes from GTP, and it is initiated by the enzyme GTPCH-I, which forms dihydroneopterin triphosphate. Levodopa and 5-HTP are metabolized by a common B_6-dependent AADC into dopamine and serotonin. MAOA catabolizes adrenaline and noradrenaline to VMA and MHPG. This enzyme is also involved in the catabolism of both dopamine into HVA and serotonin into 5-HIAA. 5-HIAA, 5-Hydroxyindoleacetic acid; 5-HTP, 5-hydroxytryptophan; AADC, aromatic l-amino acid decarboxylase; GTP, guanosine triphosphate; GTPCH-I, GTP cyclohydrolase-1; HVA, homovanillic acid; MAOA, monoamine oxidase A; MHPG, 3-methoxy-4-hydroxyphenylethyleneglycol; VMA, vanillylmandelic acid. (*From García-Cazorla À, Artuch R. Neurotransmitter disorders. In: Rosenberg RN, Pascual JM, eds. Rosenberg's Molecular and Genetic Basis of Neurological and Psychiatric Disease, 6th ed. Vol. 1. London: Elsevier; 2020: Fig. 67.1.*)

(see Fig. 105.2 and 105.12), tryptophan hydroxylase (see Fig. 105.5 and 105.12), and nitric oxide synthase. It is synthesized from GTP in many tissues (see Fig. 105.1). Deficiencies of enzymes involved in the biosynthesis of BH_4 result in inadequate production of this cofactor, which causes deficiencies of monoamine neurotransmitters with or without concomitant hyperphenylalaninemia.

Tetrahydrobiopterin Deficiency with Hyperphenylalaninemia

See Chapter 105.1.

Tetrahydrobiopterin Deficiency Without Hyperphenylalaninemia

GTP Cyclohydrolase 1 Deficiency (Hereditary Progressive Dystonia, Autosomal Dominant Dopa-Responsive Dystonia, Autosomal Dominant Segawa Syndrome)

Guanosine triphosphate (GTP) cyclohydrolase 1 catalyzes the first and rate-limiting step in the biopterin biosynthesis pathway (see Fig. 105.1). This form of dystonia, caused by GTP cyclohydrolase 1 deficiency *(GCH1)*, has an autosomal dominant mode of inheritance and is more common in females than in males (4:1 ratio) (see Chapter 637.4). **Clinical manifestations** usually start in early childhood with tremor and dystonia of the lower limbs **(toe gait)**, which may spread to all extremities within a few years. Torticollis, dystonia of the arms, and poor coordination may precede dystonia of the lower limbs. Early development is generally normal. Symptoms have an impressive diurnal variation, becoming worse by the end of the day and improving with sleep. Autonomic instability is common. Parkinsonism may also be present or develop with advancing age. Late presentation in adult life has also been reported, associated with **action dystonia** ("writer's cramp"), torticollis, or generalized rigid hypertonia with tremor but without postural dystonia. Additionally, limited data on adults suggest symptoms related to serotonin deficiency (sleep disturbance, cognitive impairment, impulsivity).

Laboratory findings show reduced levels of BH_4 and neopterin in the CSF without hyperphenylalaninemia (not to be confused with the autosomal recessive form of BH_4-deficient hyperphenylalaninemia, see Chapter 105.1). Dopamine and its metabolite (HVA) may also be reduced in CSF. The serotonergic pathway is less affected by this enzyme deficiency; thus concentrations of serotonin and its metabolites are usually normal. Plasma phenylalanine is normal, but an oral phenylalanine loading test (100 mg/kg) produces an abnormally high plasma phenylalanine level with an elevated phenylalanine/tyrosine ratio. The ratio, obtained 2-3 hours after the load, in combination with urine neopterin level, has optimal diagnostic specificity and sensitivity. The existence of asymptomatic carriers indicates that other factors or genes may play a role in pathogenesis. Asymptomatic carriers may be identified using molecular testing or by the phenylalanine loading test. **Diagnosis** is confirmed by demonstrating reduced levels of BH_4 and neopterin in CSF, measurement of the enzyme activity, and molecular genetic analysis of *GCH1* (see Chapter 105.1). Clinically, the condition should be differentiated from other causes of dystonias and childhood parkinsonism, especially tyrosine hydroxylase, sepiapterin reductase, and aromatic amino acid decarboxylase deficiencies.

Treatment with L-dopa/carbidopa usually produces dramatic clinical improvement. Oral administration of BH_4 is also effective but is rarely used.

Sepiapterin Reductase Deficiency

Sepiapterin reductase (encoded by *SPR*) is involved in the conversion of 6-pyruvoyl-tetrahydropterin to BH_4. It also participates in the salvage pathway of BH_4 synthesis (see Fig. 105.1 and Fig. 105.12). Sepiapterin reductase deficiency, an autosomal recessive condition, results in accumulation of 6-lactoyl-tetrahydropterin, which can be converted to sepiapterin nonenzymatically. The majority of sepiapterin is metabolized to BH_4 through the salvage pathway in peripheral tissues (see Fig. 105.1 and Fig. 105.12), but because of the low activity of dihydrofolate reductase in the brain, the amount of BH_4 remains insufficient for proper synthesis of dopamine and serotonin. This explains the absence of hyperphenylalaninemia and the often-delayed diagnosis.

Clinical manifestations in severely affected patients usually appear within a few months of life. Cardinal manifestations include paroxysmal stiffening, oculogyric crises, and hypotonia. Additional findings include motor and language delays, weakness, limb hypertonia, dystonia, hyperreflexia, and early-onset parkinsonism. The symptoms usually have a diurnal variation. Misdiagnosis as cerebral palsy is common, and a wide variability of symptoms has been reported. **Diagnosis** is established by measurement of CSF neurotransmitters and pterin metabolites, which reveal decreased dopamine, HVA, norepinephrine, and 5-HIAA and marked elevations of sepiapterin and dihydrobiopterin. The serum concentration of prolactin may be elevated. The phenylalanine loading test may have diagnostic utility, but it is being replaced by molecular genetic analysis, which can confirm the diagnosis. **Treatment** with slowly increasing doses of L-dopa/carbidopa and 5-hydroxytryptophan usually produces dramatic clinical improvement.

DOPAMINE β-HYDROXYLASE DEFICIENCY

Dopamine β-hydroxylase catalyzes the conversion of dopamine to norepinephrine (see Fig. 105.2 and Fig. 105.12). The deficiency of this enzyme results in reduced or absent synthesis of norepinephrine, leading to dysregulation of the sympathetic function. Infants and children may present with difficulty opening the eyes, ptosis, hypotension, hypothermia, hypoglycemia, and nasal stuffiness. Adult patients may present with profound deficits of autonomic regulation, resulting in severe orthostatic hypotension, and sexual dysfunction in males. Presyncopal symptomatology includes dizziness, blurred vision, dyspnea, nuchal discomfort, and chest pain; olfactory function remains relatively intact. The **diagnosis** can be aided by performing autonomic function testing (measurement of the sinus arrhythmia ratio, blood pressure studies during controlled hyperventilation, Valsalva maneuver, cold pressor, handgrip exercise). **Laboratory findings** include decreased or absent norepinephrine and epinephrine and their metabolites, with elevated levels of dopamine and its metabolite (HVA), in plasma, CSF, and urine. Elevated plasma dopamine may be pathognomonic for this disease. MRI of the brain shows decreased brain volume, consistent with the neurotrophic role of norepinephrine. **Treatment** with L-dihydroxyphenylserine, which is converted to norepinephrine directly in vivo by the action of AADC, leads to significant improvement in orthostatic hypotension and normalizes noradrenaline and its metabolites. The condition is inherited as an autosomal recessive trait. Dopamine β-hydroxylase is encoded by *DBH*.

MONOAMINE OXIDASE A DEFICIENCY

The human genome encodes two MAO isoenzymes: MAO A and MAO B. Both enzymes catalyze oxidative deamination of most biogenic amines in the body, including serotonin (see Fig. 105.5 and Fig. 105.12), norepinephrine, epinephrine, and dopamine (see Fig. 105.2 and Fig. 105.12). The genes for both isoenzymes are on the X chromosome (Xp11.3). A deletion of both genes can also encompass a neighboring gene, *NDP,* resulting in a contiguous deletion syndrome, which can present as an atypical **Norrie disease** (see Chapter 640). Male patients with MAO A deficiency manifest borderline intellectual deficiency and impaired impulse control. The consequences of the isolated MAO B deficiency are incompletely understood. Combined MAO A and B deficiency causes severe intellectual disability and behavioral problems and can be associated with pronounced laboratory abnormalities (e.g., fourfold to sixfold serotonin elevation in physiologic fluids, elevated *O*-methylated amine metabolites, and reduced deamination products [VMA, HVA]). Dietary intervention (low tyramine, phenylethylamine, and L-dopa/dopamine intake) did not improve patients' blood serotonin levels. Inheritance of MAO deficiency is X-linked. **Treatment** of MAO A deficiency is supportive.

DISORDERS OF GABA METABOLISM

GABA is the main inhibitory neurotransmitter synthesized in the synapses through decarboxylation of glutamic acid by glutamate decarboxylase (GAD). The same pathway is responsible for production of GABA in other organs, especially the kidneys and the β cells of the pancreas. The GAD enzyme requires pyridoxine (vitamin B_6) as a cofactor.

Two GAD enzymes, GAD1 (GAD_{67}) and GAD2 (GAD_{65}), have been identified. **GAD1** is the main enzyme in the brain, and **GAD2** is the major enzyme in the β cells. Antibodies against GAD_{65} and GAD_{67} have been implicated in the development of type 1 diabetes and **stiff-person syndrome**, respectively. GABA is catabolized to succinic acid by two enzymes: GABA transaminase and succinic semialdehyde dehydrogenase (SSADH) (see Figs. 105.11 and 105.12).

GABA Transaminase Deficiency

Clinical manifestations in the two index infant siblings included severe developmental delay and intellectual disability, hypotonia, hyperreflexia, lethargy, refractory seizures, and increased linear growth likely related to GABA-mediated increased secretion of growth hormone. Increased concentrations of GABA and β-alanine were found in the CSF (see Fig. 105.11 and Fig. 105.12). Evidence of leukodystrophy was noted in the postmortem examination of the brain. A third patient showed severe psychomotor retardation, recurrent episodic lethargy, and intractable seizures with comparable CSF metabolite abnormalities to those of the index probands. GABA transaminase deficiency is demonstrated in the brain and lymphocytes. **Treatment** is symptomatic. Intervention with vitamin B_6, the cofactor for the enzyme, was without therapeutic benefit. The condition is inherited in the autosomal recessive manner and caused by biallelic pathogenic variants in *ABAT*.

Succinic Semialdehyde Dehydrogenase Deficiency (β-Hydroxybutyric Aciduria)

Clinical manifestations of SSADH deficiency, an autosomal recessive disorder, usually begin in infancy with developmental delays with a disproportionate deficit in expressive language, hypotonia, and ataxia; seizures occur in approximately 50% of patients (see Fig. 105.11 and Fig. 105.12). Many patients also carry the diagnosis of **autism spectrum disorder**. Neuropsychiatric comorbidity (especially oppositional defiance, obsession-compulsion, and hyperactivity) can be disabling, particularly in adolescents and adults. Abnormal EEG findings include background slowing and generalized spike-wave paroxysms, with variable lateralization in hemispheric onset and voltage predominance. Photosensitivity and electrographic status epilepticus of sleep have been reported in combination with difficulties in sleep maintenance and excessive daytime somnolence. Brain MRI shows an increased T2-weighted hyperintensity involving the globus pallidi, cerebellar dentate nuclei, and subthalamic nuclei, usually in a bilaterally symmetric distribution.

The biochemical hallmark, γ-hydroxybutyric acid (GHB), is elevated in physiologic fluids (CSF, plasma, urine) in all patients. Increased concentrations of GABA are also found in the CSF. Heightened diagnostic suspicion evolves through documentation of elevated urinary GHB, and confirmation is achieved by molecular genetic testing.

Effective **treatment** is lacking. Vigabatrin (a GABA-transaminase inhibitor) has been employed empirically, with mixed outcomes, and there is concern with its use, as it further elevates CNS GABA in an already hyper-GABAergic disorder. Additionally, vigabatrin can cause constriction of the visual field, and long-term use is contraindicated.

SSADH is encoded by *ALDH5A1,* and inheritance follows an autosomal recessive pattern. **Prenatal diagnosis** has been achieved by measurement of GHB in the amniotic fluid, assay of the enzyme activity in the amniocytes, chorionic villus sampling, or DNA analysis.

DEFECTS IN NEUROTRANSMITTER TRANSPORTER PROTEINS

More than 20 different proteins are involved in transporting neurotransmitters across the neuronal membranes. The main function of most of these transporters is to remove excess neurotransmitters from the synaptic junction into the presynaptic neurons (reuptake). This recycling process not only regulates the precise effect of neurotransmitters at the synaptic junction but also resupplies the presynaptic neurons with neurotransmitters for future use. A few transporter proteins are involved in shuttling neurotransmitters from the neuronal cytoplasm across the membrane of synaptic vesicles for storage (vesicular transporters). On neuronal stimulation, these vesicles release a bolus of neurotransmitters through exocytosis. As expected, pathogenic variants in transporter proteins interfere with the proper reuptake and storage of neurotransmitters and may result in clinical manifestations similar to those seen in deficiencies of neurotransmitter metabolism. Several conditions caused by pathogenic variants of neurotransmitter protein transporters have been described, including dopamine transporter protein deficiency and dopamine-serotonin vesicular transporter disease.

SLC6A3-Related Dopamine Transporter Protein Deficiency

This transporter protein is involved in the reuptake of dopamine by the presynaptic neurons, and its deficiency causes depletion of dopamine and thus a dopamine-deficient state. The dopamine transporter protein (DAT) is encoded by *SLC6A3*. Children with biallelic pathogenic variants in *SLC6A3* present with symptoms of infantile **parkinsonism-dystonia syndrome**. Irritability and feeding difficulties start shortly after birth and progress to hypotonia, lack of head control, parkinsonism, dystonia, and global developmental delay by early infancy. Brain MRI usually shows no abnormalities.

CSF examination reveals elevation of HVA and a normal level of 5-HIAAs. The urinary level of HVA and serum concentration of prolactin are increased. Diagnosis can be established by demonstrating loss-of-function pathogenic variants in the *SLC6A3* gene.

Dopamine-Serotonin Vesicular Transporter Disease (Vesicular Monoamine Transporter Deficiency)

This autosomal recessive condition is caused by pathogenic variants in the *SLC18A2* gene. This gene encodes the vesicular monoamine transporter 2 (VMAT2) involved in transporting dopamine and serotonin from the cytoplasm into the synaptic storage vesicles located in the axonal terminals of the presynaptic neurons. Most affected children presented in the first year of life with symptoms consistent with deficiencies of dopamine (hypotonia progressing into dystonia, parkinsonism, oculogyric crises), serotonin (sleep and psychiatric disturbances), and norepinephrine-epinephrine (excessive sweating, tremors, temperature instability, postural hypotension, ptosis). Neurocognitive delays become apparent in the first year of life. No diurnal variation of the symptoms was noted. Brain imaging studies were within normal limits. Changes in the levels of CNS neurotransmitters and their metabolites have been inconsistent.

The phenotype resembles that seen in AADC and BH_4 deficiencies. Diagnosis requires demonstration of biallelic pathogenic variants in *SLC18A2*. **Treatment** with L-dopa/carbidopa caused exacerbation of symptoms, whereas pramipexole, a dopamine receptor agonist, has resulted in a promising clinical response.

HISTIDINE DECARBOXYLASE DEFICIENCY

Decarboxylation of histidine by histidine decarboxylase produces histamine, which functions as a neurotransmitter in the brain. Deficiency of this enzyme (expressed mainly in the posterior hypothalamus) results in deficiency of histamine in the CNS and in one family has been reported as an autosomal dominant form of Tourette syndrome (see Chapter 105.13).

HYPERPROLINEMIA

Intellectual disability and seizures are common findings in most patients with hyperprolinemia types I and II. Patients with **type I** hyperprolinemia typically show a benign clinical course but could have an increased risk of developing schizophrenia. The contribution of increased concentrations of proline to the mechanisms of schizophrenia, however, remains unclear. The neurologic abnormalities observed in hyperprolinemia **type II** are mainly caused by development of vitamin B_6 dependency in this condition (see Chapter 105.9). Dietary intervention in hyperprolinemia type I and II is neither feasible nor recommended.

3-PHOSPHOGLYCERATE DEHYDROGENASE DEFICIENCY

See Chapter 105.8.

PHOSPHOSERINE AMINOTRANSFERASE DEFICIENCY

See Chapter 105.8.

NONKETOTIC HYPERGLYCINEMIA

See Chapter 105.7.

105.12 Urea Cycle and Hyperammonemia (Arginine, Citrulline, Ornithine)

Oleg A. Shchelochkov and Charles P. Venditti

Catabolism of amino acids results in the production of free ammonia, which in high concentrations is toxic to the CNS. Mammals detoxify ammonia to urea through a series of reactions known as the **urea cycle** (Fig. 105.13). It is composed of five enzymes: carbamoyl phosphate synthetase 1 **(CPS1)**, ornithine transcarbamylase **(OTC)**, argininosuccinate synthetase **(ASS)**, argininosuccinate lyase **(ASL)**, and arginase 1 **(ARG1)**. A sixth enzyme, *N*-acetylglutamate (NAG) synthetase **(NAGS)**, catalyzes synthesis of NAG, an obligatory activator (effector) of the CPS1 enzyme. Individual deficiencies of these enzymes have been observed and, with an overall estimated prevalence of 1 in 35,000 live births, they are the most common genetic causes of hyperammonemia in infants (Table 105.4).

GENETIC CAUSES OF HYPERAMMONEMIA

Hyperammonemia, sometimes severe, occurs in inborn errors of metabolism other than the urea cycle defects (Table 105.5; see also Table 104.5). The mechanisms of hyperammonemia in some of these conditions are diverse and include accumulation of toxic metabolites (e.g., organic acids), impaired transport of urea cycle intermediates (e.g., HHH syndrome), or depletion of urea cycle intermediates (e.g., lysinuric protein intolerance), leading to compromised function of the urea cycle.

CLINICAL MANIFESTATIONS OF HYPERAMMONEMIA

In the **neonatal period**, symptoms and signs are mostly related to brain dysfunction and are similar regardless of the cause of the hyperammonemia. The affected infant appears healthy at birth but becomes symptomatic in the first days of life, often following the introduction of dietary protein. Refusal to eat, vomiting, tachypnea, and lethargy can quickly progress to a deep coma. Seizures are common. Physical examination may reveal hepatomegaly in addition to obtundation. Hyperammonemia can trigger increased intracranial pressure that may be manifested by a bulging fontanelle and dilated pupils.

In **infants and older children**, acute hyperammonemia is manifested by vomiting and neurologic abnormalities such as ataxia, confusion, agitation, irritability, combativeness, and psychosis. These manifestations may alternate with periods of lethargy and somnolence that may progress to coma.

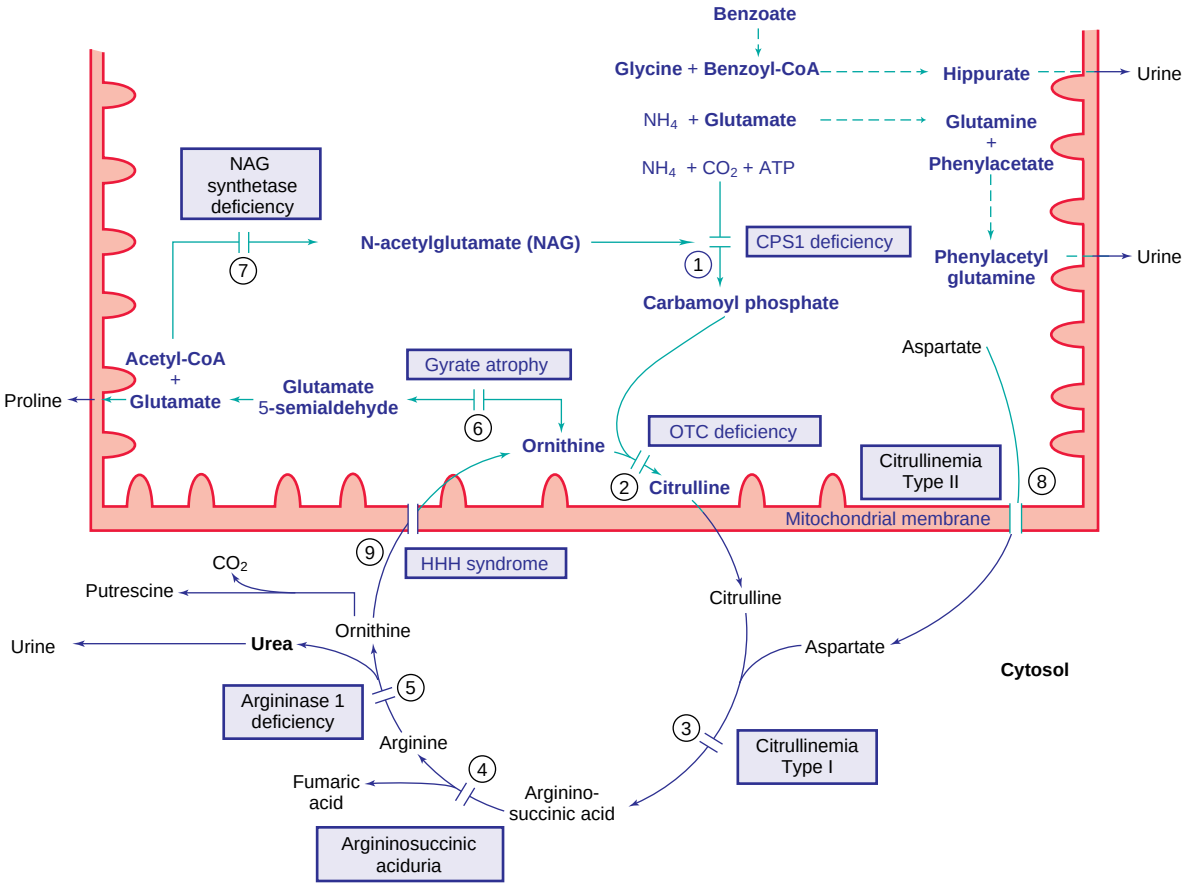

Fig. 105.13 Urea cycle: Pathways for ammonia disposal and ornithine metabolism. Reactions occurring in the mitochondria are depicted in *purple*. Reactions shown with *interrupted arrows* are the alternative pathways for the disposal of ammonia. **Enzymes:** *(1)* Carbamoyl phosphate synthetase type 1 (CPS1), *(2)* ornithine transcarbamylase (OTC), *(3)* argininosuccinate synthetase (ASS), *(4)* argininosuccinate lyase (ASL), *(5)* arginase 1, *(6)* ornithine aminotransferase, *(7)* *N*-acetylglutamate (NAG) synthetase, *(8)* citrin, *(9)* ornithine transporter (ORNT1). Ornithine transporter MIM 238970	*SLC25A15* (AR)	<1:2,000,000	Acute episodic hyperammonemia Liver failure (with or without hyperammonemia) Recurrent vomiting Neurologic presentation (e.g., DD, spasticity) Recurrent	↑ Ornithine ↑ Glutamine ↔-to-↓ citrulline ↑ Urine homocitrulline	*N*-to-↑ orotic acid

AR, Autosomal recessive; DD, developmental delay; FTTDCD, failure to thrive and dyslipidemia caused by citrin deficiency; IV, intravenous; LL, lower limb; NICCD, neonatal intrahepatic cholestasis caused by citrin deficiency; UL, upper limb; XL, X-linked.

From Rossignol F, Ah Mew N, Meltzer MR, Gropman AL. Urea cycle disorders. In: Rosenberg RN, Pascual JM, eds. *Rosenberg's Molecular and Genetic Basis of Neurological and Psychiatric Disease,* 6th ed. Vol. 1. London: Elsevier; 2020: Table 61.1.

Routine laboratory studies show no specific findings when hyperammonemia is caused by defects of the urea cycle enzymes. Blood urea nitrogen is usually low-normal or low in these patients. Some patients may initially present with unexplained elevated serum alanine transaminase (ALT) and aspartate transaminase (AST) and even meet the criteria for acute liver failure. In infants with organic acidemias, hyperammonemia is commonly associated with severe *acidosis* and *ketonuria*. Newborn infants with hyperammonemia are often misdiagnosed as having sepsis; they may succumb without a correct diagnosis. Neuroimaging may reveal cerebral edema. Autopsy may reveal microvesicular steatosis, mild cholestasis, and fibrosis of the liver. Thus because of the nonspecific presentation or urea cycle disorders, it is imperative to measure plasma ammonia levels in any ill infant with severe sepsis, unexplained liver dysfunction, recurrent emesis, or progressive encephalopathy.

DIAGNOSIS

The main criterion for diagnosis is hyperammonemia. Each clinical laboratory should establish its own normal values for blood ammonia. Normal newborn values are higher than those of the older child or adult. Occasionally, levels as high as 100 μmol/L can occur in healthy term infants. An ill infant usually manifests a blood ammonia level >150 μmol/L. Figure 105.14 illustrates an approach to the differential diagnosis of hyperammonemia in the newborn infant. Careful inspection of individual plasma amino acid profiles usually reveals abnormalities that assist in diagnosis. In patients with deficiencies of CPS1, OTC, or NAGS, frequent findings include elevations in plasma glutamine and alanine with concurrent decrements in citrulline and arginine. These disorders cannot be differentiated from one another by plasma amino acid levels alone. A marked increase in urinary orotic acid in patients with OTC deficiency helps differentiate this defect from CPS1 deficiency (see Table 105.4). Differentiation between the CPS1 deficiency and the NAGS deficiency may require molecular analysis of the relevant genes or, infrequently, an assay of the respective enzyme. Significant clinical improvement occurring after oral administration of carbamylglutamate, however, supports the diagnosis of NAGS deficiency. Patients with a deficiency of ASS, ASL, or arginase 1 have marked increases in the plasma levels of citrulline, argininosuccinic

Table 105.6 Treatment of Acute Hyperammonemia in an Infant

1. Provide adequate calories, fluid, and electrolytes intravenously (10% glucose, NaCl* and intravenous lipids 1 g/kg/day). Add minimal amounts of protein, preferably as a mixture of essential amino acids (0.25 g/kg/day) during the first 24 hr of therapy.
2. Give priming doses of the following compounds (to be added to 20 mL/kg of 10% glucose and infused within 1-2 hr):
   - Sodium benzoate 250 mg/kg†
   - Sodium phenylacetate 250 mg/kg†
   - Arginine hydrochloride 200-600 mg/kg as a 10% solution
3. Continue infusion of sodium benzoate† (250-500 mg/kg/day), sodium phenylacetate† (250-500 mg/kg/day), and arginine (200-600 mg/kg/day‡) following the above priming doses. These compounds should be added to the daily intravenous fluid.
4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.

*The concentration of sodium chloride should be calculated to be 0.45–0.9%, including the amount of the sodium in the drugs.
†Sodium from these drugs should be included as part of the daily sodium requirement.
‡The higher dose of the range is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria. Arginine is not recommended in patients with arginase deficiency and in those whose hyperammonemia is secondary to organic acidemia. Sodium benzoate and sodium phenylacetate should be used with caution in patients with organic acidemias.

acid, or arginine, respectively. The combination of hyperammonemia and marked hypercitrullinemia or argininosuccinic acidemia is virtually pathognomonic for these disorders. Additional clinical clues may come from the past medical history. Children with urea cycle defects often self-select a low-protein, high-carbohydrate diet, especially those with late-onset disease or symptomatic females with partial OTC deficiency.

Because of the nonspecific clinical and laboratory findings, mass screening of newborn infants has been implemented in many countries, which can identify patients with ASS, ASL, and arginase 1 deficiencies.

TREATMENT OF ACUTE HYPERAMMONEMIA

The clinical outcome depends mainly on the severity and the duration of hyperammonemia. Serious neurologic sequelae are likely in newborns with severe elevations in blood ammonia (>300 μmol/L) lasting more than 12 hours. Thus acute hyperammonemia should be treated promptly and vigorously. The goal of therapy is to lower the concentration of ammonia. This is accomplished by (1) temporarily restricting dietary sources of ammonia (protein), (2) minimizing endogenous protein breakdown and favoring endogenous protein synthesis by providing adequate calories and essential amino acids, and (3) removal of ammonia from the body in a form other than urea (Table 105.6). Fluid, electrolytes, glucose (10–15%), and lipids (1-2 g/kg/day) should be infused intravenously, together with minimal amounts of protein (0.25 g/kg/day), preferably including essential amino acids. Oral feeding with a low-protein formula (0.5-1.0 g/kg/day) through a nasogastric tube should be started as soon as sufficient improvement is seen.

Because the kidneys clear ammonia poorly, its removal from the body must be expedited by formation of compounds with a high renal clearance. An important advance in the treatment of hyperammonemia has been the introduction of **nitrogen scavenging therapy** by using an exogenous organic acid that conjugates to endogenous nonessential amino acids (glycine and glutamine) to form nontoxic compounds with high renal clearance. The main organic acids used for this purpose are sodium salts of benzoic acid and phenylacetic acid. **Benzoate** forms hippurate through enzymatic conjugation with endogenous glycine in the liver (see Fig. 105.13). Each mole of benzoate removes one mole of ammonia as glycine. **Phenylacetate** enzymatically conjugates with glutamine to form phenylacetylglutamine readily excreted in the urine. One mole of phenylacetate can remove two moles of ammonia as glutamine from the body (see Fig. 105.13). Sodium phenylbutyrate, metabolized to phenylacetate, is the primary oral formulation. For intravenous (IV) use, a combined formulation of benzoate and phenylacetate (Ammonul) is commercially available.

Another valuable therapeutic adjunct is IV infusion of **arginine**, which is effective in all patients except those with arginase deficiency. Arginine administration supplies the urea cycle with ornithine (see Fig. 105.13). In patients with citrullinemia, one mole of arginine reacts with one mole of ammonia as carbamoyl phosphate to form citrulline. In patients with argininosuccinic acidemia, two moles of ammonia (as carbamoyl phosphate and aspartate) react with arginine to form argininosuccinic acid. Citrulline and arginosuccinate are less toxic than ammonia and more readily excreted by the kidneys. In patients with CPS1 or OTC deficiencies, arginine administration is indicated because this amino acid is not produced in sufficient amounts to enable endogenous protein synthesis. For enteral therapy, patients with OTC deficiency benefit from supplementation with *citrulline* (200 mg/kg/day) because one mole of citrulline reacts with one mole of ammonia (through aspartic acid) to form arginine. Administration of arginine or citrulline is contraindicated in patients with **arginase deficiency**, a rare condition in which the spastic diplegia is a much more common presenting feature rather than hyperammonemia. Arginine therapy is of no benefit if hyperammonemia is secondary to an organic acidemia. In a newborn infant with an initial episode of hyperammonemia, arginine should be used until the diagnosis is established (see Table 105.6).

Benzoate, phenylacetate, and arginine may be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery from the acute state occurs. Both benzoate and phenylacetate are usually supplied as concentrated solutions and should be properly diluted (1–2% solution) for IV use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient; this amount should be included in the calculation of the daily sodium requirement. Benzoate and phenylacetate (or the combined formulation) should be used with caution in newborn infants with hyperbilirubinemia because they may displace bilirubin from albumin; however, there are no documented cases of kernicterus (see Chapter 123.4) reported in neonates with hyperammonemia who have received such therapies. In infants at risk, it is advisable to monitor and manage bilirubin levels while considering IV administration of benzoate or phenylacetate.

If the initial ammonia level is <500 μmol/L and if the foregoing therapies fail within 4-6 hours to produce any appreciable change in the blood ammonia level, **hemodialysis** should be considered. For patients

presenting with an ammonia level >500 μmol/L, extracorporeal detoxification is the initial method of ammonia removal. Exchange transfusion has little effect on reducing total body ammonia. It should be used only if dialysis cannot be employed promptly or when the patient is a newborn infant with significant hyperbilirubinemia (see earlier). Hemodialysis dramatically lowers blood ammonia within a few hours, but if it is unavailable or technically unfeasible, peritoneal dialysis may be used as a temporary solution. When hyperammonemia is caused by an organic acidemia and hemodialysis is not available, peritoneal dialysis can be used to remove both the offending organic acid and ammonia.

Oral administration of **neomycin** limits the growth of intestinal bacteria that can produce ammonia. However, this modality is of limited use in urea cycle patients (e.g., affected neonates) in whom reduction of hyperammonemia is an urgent priority. Oral **lactulose** acidifies the intestinal lumen, thereby reducing the diffusion of ammonia across the intestinal epithelium. This agent is of limited applicability in newborns, who have a high risk of acidemia and dehydration.

There may be considerable lag between the normalization of ammonia level and an improvement in the patient's neurologic status. Several days may be needed before the infant becomes fully alert.

There has been interest in the use of **cooling** as a therapeutic adjunct in newborn infants with metabolic encephalopathy such as that caused by hyperammonemia. Clinical studies are in progress to evaluate the efficacy of this approach.

Long-Term Therapy

Once the acute hyperammonemic episode is under control, maintenance therapy should be tailored to address the underlying cause of the hyperammonemia. All patients, regardless of the enzymatic defect, require protein restriction limited to the age-adjusted recommended dietary allowance (RDA). In pediatric patients with urea cycle defects, chronic administration of sodium benzoate (250 mg/kg/day), sodium phenylbutyrate (250-500 mg/kg/day), and arginine (200-400 mg/kg/day) or citrulline (in patients with OTC deficiency, 200-400 mg/kg/day) is effective in maintaining blood ammonia levels within the normal range (doses above are for patients who weigh <20 kg). Arginine and citrulline are contraindicated in patients with argininemia. Patients who have difficulty taking sodium phenylbutyrate can be trialed on glycerol phenylbutyrate. This compound conceals the offensive odor of sodium phenylbutyrate and may help with patient adherence. Benzoate and phenylacetate may lower carnitine levels, but clinical signs of carnitine deficiency or benefit from carnitine supplementation have not yet been demonstrated. These compounds have been used during pregnancy without obvious teratogenic effect. However, experience is still limited, and appropriate caution should be exercised.

Growth parameters, especially head circumference, and nutritional indices (blood albumin, prealbumin, pH, electrolytes, amino acids, zinc, selenium) should be followed closely. Long-term care of these patients is best achieved by a team of experienced professionals (pediatrician, nutritionist, child neurologist, metabolic geneticist). Skin lesions resembling **acrodermatitis enteropathica** (see Chapter 691) have been noted in a few patients with different types of urea cycle defects, presumably resulting from the deficiency of essential amino acids, caused by overzealous dietary protein restriction. Catabolic states (infections, fasting) that may trigger hyperammonemia should be avoided. They must be treated vigorously when they occur. It is important that all children with urea cycle defects avoid valproic acid because this drug can elevate blood ammonia even in some healthy individuals. In patients with CPS1, OTC, or ASS deficiency, acute hyperammonemic attacks may be precipitated by valproate administration.

CARBAMOYL PHOSPHATE SYNTHETASE 1 AND *N*-ACETYLGLUTAMATE SYNTHASE DEFICIENCIES

Without treatment, deficiencies of these two enzymes produce similar clinical and biochemical manifestations (see Figs. 105.13 and 105.14). There is a wide variation in the severity of symptoms and in the age at presentation. In near-complete enzymatic deficiency, symptoms appear during the first few days or even hours of life with signs and symptoms of hyperammonemia (refusal to eat, vomiting, lethargy, convulsion, coma). Increased intracranial pressure is frequent. Late forms (as late as the fourth decade of life) may present as an acute bout of hyperammonemia (lethargy, headache, seizures, psychosis) in a seemingly healthy individual. Coma and death may occur during these episodes. Diagnostic confusion with migraine is common. Intermediate forms with intellectual disability and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

Laboratory findings include hyperammonemia. The plasma amino acid analysis typically shows a marked increase of glutamine and alanine with relatively low levels of citrulline and arginine. These are nondiagnostic changes that occur in hyperammonemia of diverse causes. Urinary orotic acid is usually low or may be absent (see Fig. 105.14).

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier (see Table 105.6). Treatment with oral carbamylglutamate of patients with NAGS deficiency can produce successful rescue of biochemical findings and symptoms. It is therefore important to differentiate between CPS1 and NAGS deficiencies by gene analysis of *CPS1* and *NAGS,* respectively.

CPS1 and NAGS deficiencies are both autosomal recessive conditions; the CPS1 enzyme is normally present in the liver and intestine. Neither of these conditions can be reliably identified by the mass screening of the newborn infants using current approaches.

ORNITHINE TRANSCARBAMYLASE DEFICIENCY

In this X-linked disorder, the hemizygous males are more severely affected than heterozygous females (see Figs. 105.13 and 105.14). The heterozygous females may have a mild form of the disease, but the majority (approximately 75%) remain asymptomatic, although investigations indicate subtle neurologic defects even in females without a discernable history of hyperammonemia. OTC deficiency is the most common form of all the urea cycle disorders, comprising approximately 40% of cases.

Clinical manifestations in a male newborn are usually those of **severe** hyperammonemia (see earlier) occurring in the first few days of life. **Mild forms**, such as in some heterozygous females, characteristically have episodic manifestations, which may occur at any age (usually after infancy). Episodes of hyperammonemia, manifested by vomiting and neurologic abnormalities (e.g., ataxia, mental confusion, agitation, combativeness, frank psychosis), are separated by periods of wellness. These episodes usually occur after ingestion of a high-protein diet or as a result of a catabolic state such as infection. Hyperammonemic coma, cerebral edema, and death may occur during one of these attacks. Cognitive development may proceed normally. Mild to moderate intellectual disability, however, is common. Gallstones have been seen in the survivors, although the mechanism remains unclear.

The major **laboratory finding** during the acute attack is hyperammonemia accompanied by marked elevations of plasma concentrations of glutamine and alanine with low levels of citrulline and arginine. The blood level of urea is usually low. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS1 deficiency (see Fig. 105.14). Orotate may precipitate in urine as pink-colored crystals. In the **mild form**, these laboratory abnormalities may revert to normal between attacks. This form should be differentiated from all the episodic conditions of childhood. Patients with lysinuric protein intolerance (see Chapter 105.14) may demonstrate some features of OTC deficiency, but the former can be differentiated by increased urinary excretion of lysine, ornithine, and arginine and elevated blood concentrations of citrulline.

The prevalence of OTC deficiency is 1 in 56,000 to 1 in 77,000 live births. This condition is not identifiable by the mass screening of newborn infants using current approaches. The **diagnosis** is most conveniently confirmed by *OTC* gene analysis. Many *OTC* pathogenic variants (>300) have been identified. Genotype and degree of enzyme deficiency determine the severity of the phenotype in most cases. Mothers of affected infants are expected to be carriers of the mutant gene unless a de novo pathogenic variant has occurred. A mother who gave birth to two affected male offspring was found to have a normal

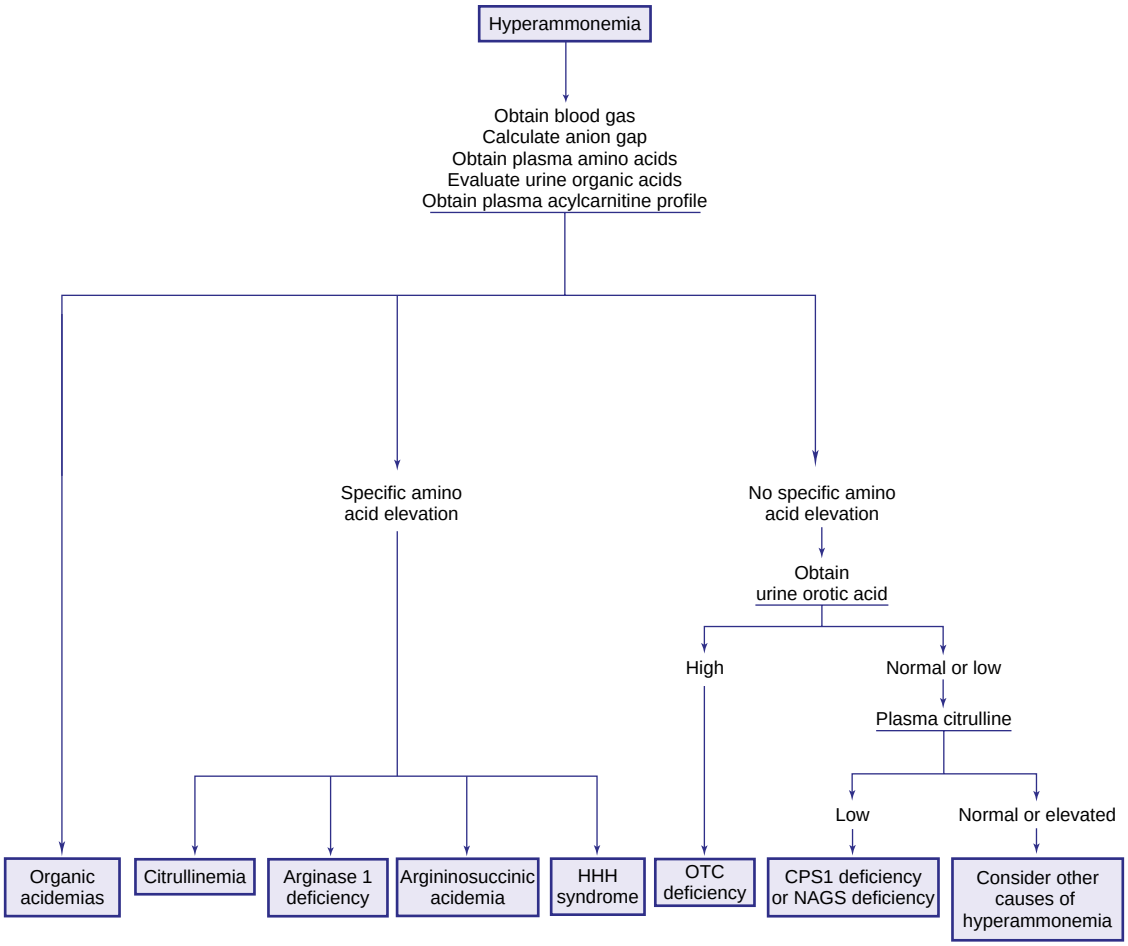

Fig. 105.14 Clinical algorithmic approach to a newborn infant with symptomatic hyperammonemia. CPS1, Carbamoyl phosphate synthetase 1; HHH syndrome, hyperornithinemia-hyperammonemia-homocitrullinemia; NAGS, *N*-acetylglutamate synthetase; OTC, ornithine carbamoyltransferase.

genotype, suggesting that gonadal mosaicism can be seen. As many as 20% of affected patients demonstrate normal results by Sanger sequencing, perhaps because the pathogenic variant involves copy number variants, deep intronic regions, or a promoter sequence. Copy number variants can be evaluated using a chromosomal microarray, and if positive, a contiguous gene deletion should be considered. If the molecular diagnostic approach is negative, a liver biopsy may be indicated. Prenatal diagnosis is feasible by analysis of DNA in amniocytes or chorionic villus samples. Increase in urinary excretion of orotidine after an allopurinol loading test can identify female carriers. Mild cerebral dysfunction may be present in asymptomatic female carriers. The importance of a detailed family history cannot be overemphasized. A history of migraine or protein aversion is common in maternal female relatives of the proband. Indeed, careful scrutiny of the family history may reveal a pattern of unexplained deaths in male newborns in the maternal lineage.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are as outlined earlier. For enteral use, citrulline is used in place of arginine for patients with OTC deficiency. Liver transplantation is a surgical treatment option for patients with severe OTC deficiency.

CITRULLINEMIA

Two clinically and genetically distinct forms of citrullinemia have been described. The classic form (**type I**) is caused by the deficiency of the ASS enzyme. Citrullinemia **type II** is caused by the deficiency of a mitochondrial transport protein called *citrin*. (See Figs. 105.13 and 105.14.)

Citrullinemia Type I (Argininosuccinate Synthetase Deficiency, Classic Citrullinemia)

This condition is caused by the deficiency of ASS (see Fig. 105.13) and has variable clinical manifestations depending on the degree of the enzyme deficiency. Two major forms of the condition have been identified. The **severe** or **neonatal form**, which is most common, appears in the first few days of life with signs and symptoms of hyperammonemia (see earlier). In the **subacute or mild form**, clinical findings such as failure to thrive, frequent vomiting, developmental delay, and dry, brittle hair appear gradually after 1 year of age. Acute hyperammonemia, triggered by an intercurrent catabolic state, may bring the diagnosis to light.

Laboratory findings are similar to those found in patients with OTC deficiency, except that the plasma citrulline concentration is greatly elevated (50-100 times the reference range) (see Fig. 105.14). Urinary excretion of orotic acid is moderately increased; crystalluria may also occur as a result of precipitation of orotates. The diagnosis is confirmed by DNA analysis of *ASS1* or, less frequently, by an assay of enzyme activity in cultured fibroblasts. Prenatal diagnosis is feasible with an enzyme assay in cultured amniotic cells or by DNA analysis of cells obtained from chorionic villus biopsy.

Treatment of acute hyperammonemic attacks and long-term therapy are outlined earlier (see Table 105.6). Plasma concentration of citrulline remains elevated at all times and may increase further after administration of arginine. Patients can do well on a protein-restricted diet in conjunction with sodium benzoate, phenylbutyrate, and arginine therapy. Mild to moderate cognitive impairment is a common sequela, even in a well-treated patient.

Citrullinemia is an autosomal recessive condition caused by biallelic pathogenic variants in *ASS1*. The majority of patients are compound heterozygotes for two different alleles. The prevalence of the condition is 1 in 250,000 live births. The recent introduction of neonatal screening for urea cycle defects has shown that some affected patients are ostensibly asymptomatic even on a regular diet. Long-term follow-up is needed to be certain that these individuals do not sustain neurologic sequelae.

Citrin Deficiency (Citrullinemia Type II)

Citrin (aspartate-glutamate carrier protein) is a mitochondrial transporter encoded by *SLC25A13*. One of this protein's functions is to transport aspartate from mitochondria into cytoplasm and replenish the cytosolic aspartate pool required for converting citrulline to argininosuccinic acid (see Fig. 105.13). If aspartate is unavailable to the cytoplasmic component of the urea cycle, urea will not be formed at a normal rate, and citrulline will accumulate. ASS activity is diminished in the liver of these patients, but no pathogenic variant in the *ASS1* gene has been found. It is postulated that citrin deficiency interferes with translation of the messenger RNA for the ASS enzyme in the liver. The condition initially was reported in Japan (regional prevalence ~1 in 20,000), but many non-Japanese patients have been since identified (worldwide prevalence between 1 in 100,000 and 1 in 230,000). Biallelic pathogenic variants in *SLC25A13* have been associated with three clinical forms of citrin deficiency.

Neonatal Intrahepatic Cholestasis (Citrullinemia Type II, Neonatal Form)

Clinical and laboratory manifestations, which usually start before the infant's first birthday, include cholestatic jaundice with mild to moderate direct (conjugated) hyperbilirubinemia, marked hypoproteinemia, and clotting dysfunction (increased prothrombin time and partial thromboplastin time); increased serum γ-glutamyltransferase and alkaline phosphatase activities; and liver transaminases are usually normal. Plasma concentrations of ammonia and citrulline are usually normal, but moderate elevations have been reported. There may be increases in plasma concentrations of methionine, tyrosine, alanine, and threonine. Elevated levels of serum galactose have been found, even though the enzymes of galactose metabolism are normal. The reason for hypergalactosemia is not clear. Marked elevation in the serum level of α-fetoprotein is also present. These findings resemble those of tyrosinemia type I, but unlike the latter condition, urinary excretion of succinylacetone is not elevated (see Chapter 105.2). Liver biopsy shows fatty infiltration, cholestasis with dilated canaliculi, and a moderate degree of fibrosis. The condition is usually self-limiting, and the majority of infants recover spontaneously by 1 year of age with supportive and symptomatic treatment. Hepatic failure requiring liver transplantation has occurred in a few cases. Although the condition is commonly seen in Japan, the diagnosis should be considered in any case of unexplained neonatal hepatitis with cholestasis. Data on the long-term prognosis and the natural history of the condition are limited; development into the adult form of the condition after several years of a seemingly asymptomatic hiatus has been observed.

Failure to Thrive and Dyslipidemia Due to Citrin Deficiency

Some patients can present between 1 and 10 years of age with peculiar dietary habits favoring high-protein and high-lipid foods. It is accompanied by poor appetite, hypoglycemic episodes, and failure to thrive. Laboratory evaluation may reveal mild hyperammonemia, hypertriglyceridemia, elevated low-density lipoprotein (LDL) cholesterol, and low high-density lipoprotein (HDL) cholesterol levels. This presentation of citrin deficiency in children is often considered a prodromal form of the adult form of citrullinemia type II.

Citrullinemia Type II, Adult Form (Adult-Onset Citrullinemia; Citrullinemia Type II, Mild Form)

Without prior molecular diagnosis or family history, individuals affected by this form of citrullinemia type II (CTLN2) are often identified acutely. A previously healthy individual may present with nonspecific neuropsychiatric symptoms such as disorientation, delirium, delusion, aberrant behavior, tremors, and psychosis. Moderate degrees of hyperammonemia and hypercitrullinemia are present. The age at onset is usually between 20 and 40 years but can happen at any point after age 11 years. Patients who recover from the first episode may have recurrent attacks. Pancreatitis, hyperlipidemia, and hepatoma are major complications among the survivors. Medical **treatment** of CTLN2 has been mostly ineffective to prevent future attacks. A diet enriched in protein and lipids helps restore cytosolic aspartate and stimulate ureagenesis. In confirmed citrin deficiency, a low-protein/high-carbohydrate diet should be avoided. Although liver transplantation appears to be effective in preventing future episodes of hyperammonemia, enteral supplementation with pyruvate, arginine, and medium-chain triglycerides can be tried first to help prevent hyperammonemic episodes and improve growth.

ARGININOSUCCINATE LYASE DEFICIENCY (ARGININOSUCCINIC ACIDURIA)

The severity of the clinical and biochemical manifestations varies considerably (see Figs. 105.13 and 105.14). In the severe form of ASL deficiency, severe hyperammonemia (see earlier) can develop in the first few days of life, and without treatment affected infants can perish. The clinical course of ASL deficiency in patients who survive the initial acute episode is often characterized by intellectual disability, failure to thrive, hypertension, gallstones, liver fibrosis, and hepatomegaly. A common finding in untreated patients is dry and brittle hair (**trichorrhexis nodosa**), although this finding is relatively nonspecific. Acute attacks of severe hyperammonemia may occur during a catabolic state triggered by infections, trauma, or dietary indiscretion. Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, a moderate increase in plasma levels of citrulline (less than in citrullinemia), and a marked increase in the concentration of argininosuccinic acid in plasma, urine, and CSF. The CSF levels are usually higher than those in plasma. The enzyme is present in erythrocytes, the liver, and cultured fibroblasts. **Prenatal diagnosis** is possible by identification of biallelic pathogenic variants in the *ASL* gene or, rarely, by measurement of the enzyme activity in cultured amniotic cells. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this chapter. Intellectual disability, persistent hepatomegaly with mild increases in liver enzymes, and bleeding tendencies as a result of abnormal clotting factors are common sequelae. ASL deficiency is an autosomal recessive disorder with a prevalence of about 1 in 220,000 live births. Early detection is achieved through mass screening of newborn infants.

ARGINASE 1 DEFICIENCY (HYPERARGININEMIA)

Arginase 1 deficiency is an autosomal recessive condition caused by biallelic pathogenic variants in *ARG1* (see Figs. 105.13 and 105.14). Two genetically distinct arginases are present in humans. Arginase 1 (ARG1) is a cytosolic enzyme and is expressed in the liver and can be found in erythrocytes. Arginase 2 (ARG2) is expressed in renal and brain mitochondria. The role of ARG2 is not well understood; its activity in patients with argininemia appears to have no protective effect.

Clinical manifestations of arginase 1 deficiency are somewhat different from other urea cycle enzyme defects, although acute neonatal hyperammonemia presenting with intractable seizures, cerebral edema, and death has also been reported. Outside of the neonatal period, the onset of arginase 1 deficiency often is insidious. The infant can remain asymptomatic in the first few months or years of life. A **progressive spastic diplegia** with scissoring of the lower extremities, choreoathetotic movements, loss of developmental milestones, and failure to thrive in a previously normal infant may suggest the diagnosis. Some children were treated for cerebral palsy before arginase 1 deficiency was confirmed. Intellectual disability is progressive; seizures are common, but episodes of severe hyperammonemia are not as frequent as in the more proximal urea cycle defects. Hepatomegaly may be present.

Laboratory evaluation reveals marked elevations of arginine in plasma and CSF (see Fig. 105.14). Urinary orotic acid can be increased. Determination of amino acids in plasma is a critical step in the diagnosis of argininemia. Guanidino compounds (α-keto-guanidinovaleric acid and α-keto-argininic acid) can be markedly increased in urine. The diagnosis is secured by identification of biallelic pathogenic variants in *ARG1* or, rarely, by assaying arginase activity in erythrocytes.

Treatment consists of a low-protein diet at the age-appropriate RDA. The dietary composition and daily intake of protein should be monitored by frequent plasma amino acid determinations. Supplementation with arginine in ARG1-deficient patients is contraindicated. Sodium benzoate or sodium phenylbutyrate is also effective in controlling hyperammonemia and lowering plasma arginine levels. Liver transplantation has produced promising results, but experience with long-term outcome is limited. Early detection is feasible through mass screening of newborn infants.

TRANSIENT HYPERAMMONEMIA OF THE NEWBORN

The blood concentration of ammonia in a full-term infant can be as high as 100 μmol/L, or two to three times greater than that of the older child or adult. Blood levels approach the adult normal values after a few weeks of life (see Fig. 105.14). Plasma ammonia levels greater than 100 μmol/L should prompt additional diagnostic steps to evaluate for possible genetic causes of hyperammonemia. Infrequently, **severe transient hyperammonemia** can be observed in infants whose diagnostic workup reveals no biochemical abnormalities implicating genes encoding components of the urea cycle. The majority of affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma can develop within 2-3 days of life, and the infant may succumb to the disease if treatment is not started immediately. Laboratory studies reveal marked hyperammonemia (plasma ammonia as high as 4,000 μmol/L) with moderate increases in plasma levels of glutamine and alanine. Plasma concentrations of urea cycle intermediate amino acids are usually normal except for citrulline, which may be moderately elevated. The cause of the disorder is unknown. Urea cycle enzyme activities are normal. **Treatment** of hyperammonemia should be initiated promptly and continued vigorously. Recovery without sequelae has been reported, and hyperammonemia does not recur even with a normal-protein diet.

DISORDERS OF ORNITHINE METABOLISM

Ornithine, a key intermediate of the urea cycle, is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into mitochondria, where it becomes a substrate in reactions catalyzed by OTC forming citrulline. Excess ornithine is catabolized by two enzymes: ornithine aminotransferase, a mitochondrial enzyme converting ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see Fig. 105.13). Two genetic disorders feature **hyperornithinemia**: gyrate atrophy of the retina and hyperammonemia-hyperornithinemia-homocitrullinemia (HHH) syndrome.

Gyrate Atrophy of the Retina and Choroid

This rare, autosomal recessive disorder is caused by biallelic pathogenic variants in *OAT* leading to the deficient activity of ornithine aminotransferase (see Fig. 105.13). Approximately 30% of the reported cases are from Finland. Clinical manifestations may include hyperammonemia in the first months of life in some patients. Findings that define the phenotype of ornithine aminotransferase deficiency include night blindness, myopia, loss of peripheral vision, and posterior subcapsular cataracts. These eye changes start between 5 and 10 years of age and progress to complete blindness by the fourth decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence. Besides the characteristic 10- to 20-fold increase in plasma levels of ornithine (400-1,400 μmol/L), plasma levels of glutamate, glutamine, lysine, creatine, and creatinine can be moderately decreased. Some patients show partial improvement with high doses of pyridoxine. An arginine-restricted diet in conjunction with supplemental lysine, proline, and creatine has been successful in reducing plasma ornithine concentration and has produced some clinical improvement.

Hyperammonemia-Hyperornithinemia-Homocitrullinemia Syndrome

Biallelic pathogenic variants in *SLC25A15* result in an autosomal recessive disorder, HHH syndrome. This defect of the ornithine transport system leads to accumulation of ornithine in the cytosol and a depletion of this amino acid in mitochondria. The former causes hyperornithinemia, and the latter results in disruption of the urea cycle and hyperammonemia (see Fig. 105.13). Homocitrulline is presumably formed through condensation of mitochondrial carbamoyl phosphate with lysine. Clinical manifestations of hyperammonemia can develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. No ocular findings have been observed in these patients. Laboratory findings reveal marked increases in plasma levels of ornithine and homocitrulline in addition to hyperammonemia (see Fig. 105.14). Acute episodes of hyperammonemia should be treated promptly (see earlier). Restriction of protein intake improves hyperammonemia. Oral supplementation with arginine (or citrulline) has produced clinical improvement in some patients.

CONGENITAL GLUTAMINE DEFICIENCY

Glutamine is synthesized endogenously from glutamate and ammonia by a ubiquitously expressed enzyme, glutamine synthetase (see Fig. 105.11). Glutamine is known to be involved in several important functions, including detoxification of ammonia. Deficiency of this enzyme, resulting in glutamine deficiency, has been reported in three infants from three unrelated families. All affected infants manifested multiorgan involvement, including brain malformations (abnormal gyrations, hypomyelination), facial abnormalities (broad nasal root, low-set ears), hypotonia, and seizures at birth. Two of the patients died from multiorgan failure (respiratory and heart failure) in the neonatal period. One child was alive at 3 years of age with severe developmental delay. Glutamine was absent in plasma, urine, and CSF, but plasma levels of glutamic acid were normal. Congenital glutamine deficiency is an autosomal recessive condition caused by biallelic pathogenic variants in *GLUL*.

105.13 Histidine

Oleg A. Shchelochkov and Charles P. Venditti

Histidine is degraded through the urocanic acid pathway to glutamic acid. Several genetic biochemical aberrations involving the degradative pathway of histidine have been reported, but the clinical significance of elevated histidine levels has not been established.

Decarboxylation of histidine by histidine decarboxylase produces histamine. Deficiency of this enzyme has been implicated in the familial form of **Tourette syndrome** (see Chapter 105.11).

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

105.14 Lysine

Oleg A. Shchelochkov and Charles P. Venditti

Lysine is catabolized through two pathways. In the first pathway, lysine is condensed with α-ketoglutaric acid to form saccharopine. Saccharopine is then catabolized to α-aminoadipic semialdehyde and glutamic acid. These first two steps are catalyzed by α-aminoadipic semialdehyde synthase, which has two activities: lysine-ketoglutarate reductase and saccharopine dehydrogenase (Fig. 105.15). In the second pathway, lysine is first transaminated and then condensed to its cyclic forms: pipecolic acid and piperideine-6-carboxylic acid **(P6C)**. P6C and its linear form, α-aminoadipic semialdehyde, are oxidized to α-aminoadipic acid by the enzyme **antiquitin**. This is the major pathway for D-lysine in the body and for L-lysine in the brain.

Hyperlysinemia-saccharopinuria, α-aminoadipic, and α-ketoadipic acidemia are biochemical conditions caused by inborn errors of lysine degradation. Individuals with these conditions are usually asymptomatic.

PYRIDOXINE–DEPENDENT EPILEPSY (PDE)

Pyridoxal 5′-phosphate **(P5P)**, the active form of pyridoxine (vitamin B_6), is the cofactor for many enzymes, including those involved in the metabolism of neurotransmitters. Intracellular P5P deficiency in the brain may result in a seizure disorder that is refractory to common anticonvulsant agents but is responsive to high doses of pyridoxine. These pyridoxine-responsive phenotypes are seen in the following genetic metabolic conditions.

Antiquitin (α-Aminoadipic Semialdehyde Dehydrogenase) Deficiency

This is the most common cause of PDE. A deficiency of antiquitin (encoded by *ALDH7A1*) results in accumulation of P6C in brain tissue (see Fig. 105.15). P6C reacts with P5P and renders it inactive. Large doses of pyridoxine are therefore needed to overcome this inactivation. The condition is inherited as an autosomal recessive trait.

Pyridox(am)ine 5′-Phosphate Oxidase (PNPO) Deficiency

PNPO deficiency clinically overlaps with antiquitin deficiency. PNPO-deficient patients often present with neonatal-onset seizures, developmental delays, spastic tetraplegia, and nonspecific findings on brain imaging (delayed myelination, cerebral atrophy, and abnormal signals in the basal ganglia). Developmental regression, optic disc pallor, and retinopathy have been reported infrequently. Plasma and CSF amino acid analysis may reveal elevated glycine, prompting evaluation for NKH (see Chapter 105.7), leading to a delay in initiating treatment with P5P. A CSF neurotransmitter assay revealed inconsistent changes in the levels of 3-*O*-methyldopa, homovanillic acid, and 5-hydroxyindoleacetic acid. A normal CSF level of P5P was reported in one patient, suggesting that a therapeutic trial with P5P and molecular analysis may be a prudent strategy in some patients irrespective of the CSF studies. The lowest effective dose of P5P should be used to avoid toxicity. The disorder is caused by biallelic pathogenic variants in *PNPO*.

Sulfite Oxidase Deficiency and Molybdenum Cofactor Deficiency

In this rare condition (see Chapter 105.4), accumulation of sulfites causes inhibition of enzymatic activity of antiquitin and accumulation of P6C, which in turn causes inactivation of P5P and vitamin B_6 dependency.

Hyperprolinemia Type II

In this condition, accumulation of P5C in brain tissue can also cause inactivation of P5P, leading to pyridoxine dependency (see Chapter 105.9 and Fig. 105.9).

Hypophosphatasia

P5P is the main circulating form of pyridoxine. Alkaline phosphatase (ALP) is required for dephosphorylation of P5P to generate free pyridoxine, which is the only form of vitamin B_6 that can cross the BBB and enter the brain cells. Pyridoxine is rephosphorylated

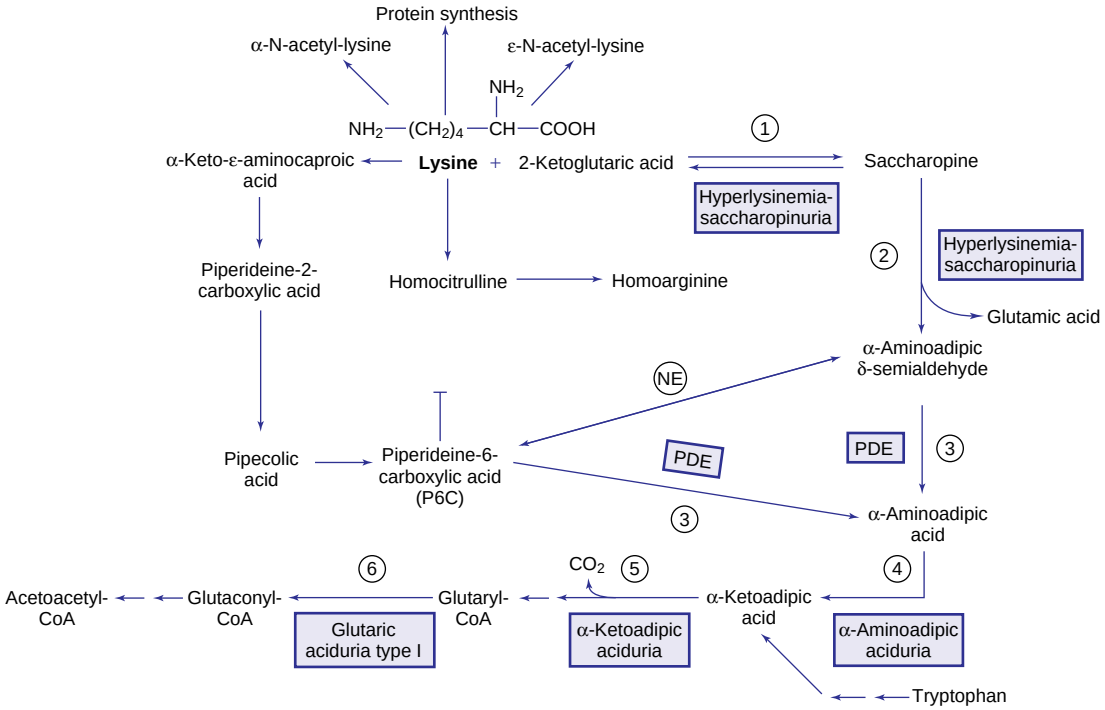

Fig. 105.15 Pathways in the metabolism of lysine. **Enzymes:** *(1)* Lysine ketoglutarate reductase, *(2)* saccharopine dehydrogenase, *(3)* α-aminoadipic semialdehyde/piperidine-6-carboxylic acid (P6C) dehydrogenase (antiquitin), *(4)* α-aminoadipic acid transferase, *(5)* α-ketoadipic acid dehydrogenase, *(6)* glutaryl-CoA-dehydrogenase. NE, Nonenzymatic; PDE, pyridoxine-dependent epilepsy.

intracellularly to form P5P. In the infantile form of hypophosphatasia, P5P cannot be dephosphorylated to free pyridoxine because of the marked deficiency of tissue-nonspecific ALP. This results in deficiency of pyridoxine in the brain and PDE (see Chapters 611 and 724).

The main **clinical manifestation** of PDE caused by antiquitin deficiency is generalized seizures, which usually occur in the first days of life and are unresponsive to conventional anticonvulsant therapies. Some mothers of affected fetuses report abnormal intrauterine fluttering movements. The seizures are usually tonic-clonic in nature but can be almost any type. Other manifestations such as dystonia, respiratory distress, and abdominal distention with vomiting, hepatomegaly, hypoglycemia, and hypothermia may be present. Learning problems and speech delay are common sequelae. Late-onset forms of the condition (as late as 5 years of age) have been reported. Consequently, a trial with vitamin B_6 is recommended in any infant with intractable convulsions (see Chapters 611.04 and 611.06).

Laboratory findings show increased concentrations of α-aminoadipic semialdehyde and pipecolic acid in the CSF, plasma, and urine. EEG abnormalities may normalize after treatment. Neuroimaging may be normal, but cerebellar and cerebral atrophy, periventricular hyperintensity, intracerebral hemorrhage, and hydrocephalus have been reported.

Treatment with vitamin B_6 (50-100 mg/day) usually results in a dramatic improvement of both seizures and the EEG abnormalities. High doses of pyridoxine can result in peripheral neuropathy, and doses >500 mg/day should be avoided. The pyridoxine dependency, and thus the therapy, are lifelong. The therapeutic benefit of a lysine-restricted, L-arginine-enriched diet is being evaluated.

Glutaric Aciduria Type 1 (Glutaryl-CoA Dehydrogenase Deficiency)

Glutaric acid is an intermediate in the degradation of lysine (see Fig. 105.15), hydroxylysine, and tryptophan. Glutaric aciduria type 1, a disorder caused by a deficiency of glutaryl-CoA dehydrogenase, should be differentiated from glutaric aciduria type 2, a distinct clinical and biochemical disorder caused by defects in the mitochondrial electron transport chain (see Chapter 106.1).

Glutaric aciduria type 1 is an autosomal recessive disorder caused by biallelic loss-of-function variants in *GCDH*. Its prevalence is estimated at 1 in 100,000 live births worldwide. The condition is more prevalent in some ethnic populations (e.g., Canadian Oji-Cree Indians, Irish Travelers, Black South Africans, Swedes, and the Old Order Amish population in the United States). A high prevalence of known pathogenic variants in specific ethnic populations can enable a cost-effective molecular evaluation and counseling. **Prenatal diagnosis** can be accomplished by demonstrating increased concentrations of glutaric acid in amniotic fluid, by assay of the enzyme activity in amniocytes or chorionic villus samples, or by identification of the known pathogenic variants in *GCDH*.

Clinical Manifestations

Macrocephaly is a common, but nonspecific, finding in patients with glutaric aciduria type 1. It develops in the first year of life but can also be present at birth and precede the onset of neurologic manifestations. Some affected infants may also show subtle neurologic symptoms, such as delayed onset of motor milestones, irritability, and feeding problems, during this seemingly asymptomatic period. The onset of the condition is usually heralded by **acute encephalopathic findings**, such as loss of normal developmental milestones (head control, rolling over, or sitting), seizures, generalized rigidity, opisthotonos, choreoathetosis, and dystonia caused by acute striatal injury. These symptoms may occur suddenly in an apparently normal infant after a minor infection. Brain imaging reveals increased extraaxial (particularly frontal) fluid with stretched bridging veins, striatal lesions, dilated lateral ventricles, cortical atrophy (mainly in the frontotemporal region), and fibrosis. Recovery from the first attack usually occurs slowly, and some residual neurologic abnormalities may persist, especially dystonia and choreoathetosis. Without treatment, additional acute attacks resembling the first can occur during subsequent episodes of intercurrent infections or catabolic states. In some patients, these signs and symptoms may develop gradually in the first few years of life. Hypotonia and choreoathetosis may gradually progress into rigidity and dystonia **(insidious form)**. Acute episodes of metabolic decompensation with vomiting, ketosis, seizures, and coma also occur in this form after infection or other catabolic states. Without treatment, death may occur in the first decade of life during one of these episodes. Affected infants are prone to development of subdural hematoma and retinal hemorrhage after minor falls and head traumas. This can be misdiagnosed as child abuse. The intellectual abilities usually remain relatively normal in most patients.

Laboratory Findings

During acute episodes, mild to moderate metabolic acidosis and ketosis may occur. Hypoglycemia, hyperammonemia, and elevations of serum transaminases are seen in some patients. High concentrations of glutaric acid are usually found in the urine, blood, and CSF. 3-Hydroxyglutaric acid may also be present in the body fluids. The acylcarnitine profile shows elevated glutarylcarnitine (C5DC) in blood and urine. Plasma concentrations of amino acids are usually within normal limits. Laboratory findings may be unremarkable between attacks. Glutaric aciduria type 1 can be identified on the newborn screen by measuring glutarylcarnitine (C5DC) levels in blood spots. The sensitivity of this screening method depends on the cutoff value used by a newborn screen program, and some patients may not be detected. For example, a subset of patients with glutaric aciduria type 1 can present with normal plasma and urinary levels of glutaric acid and variably elevated plasma glutarylcarnitine. This type of glutaric aciduria type 1, referred to as a "low-excretor" phenotype, carries the same risk of developing brain injury as in a "high-excretor" phenotype. In some low-excreting patients, glutaric acid is elevated only in the CSF. Urinary glutarylcarnitine appears to be a more sensitive screening method to identify affected low-excreting patients. Molecular analysis of *GCDH* can aid in identifying patients with a low-excretor phenotype associated with specific pathogenic variants (e.g., p.M405V, p.V400M, p.R227P). We recommend performing molecular analysis of *GCDH* or glutaryl-CoA dehydrogenase enzyme activity in any child presenting with unexplained progressive dystonia and dyskinesia.

Treatment

Patients require a lysine- and tryptophan-restricted diet while meeting physiologic requirements for protein, micronutrients, and vitamins. Increased dietary arginine may decrease cellular uptake of lysine and decrease the endogenous formation of glutaryl-CoA. Patients should be routinely evaluated for lysine and tryptophan deficiency by monitoring plasma amino acids and growth. L-Carnitine supplementation (50-100 mg/kg/day orally) is recommended in all cases. Emergency treatment during acute illness, including temporary cessation of protein intake for 24 hours, replacement of lost calories using carbohydrates or lipids, IV L-carnitine, IV dextrose, prompt treatment of infection, and control of fever is critical to decreasing the risk of striatal injury. All patients should be provided with an emergency letter describing the underlying diagnosis, recommended evaluation, and treatment. Early diagnosis through newborn screening with prevention and aggressive treatment of intercurrent catabolic states (infections) can help minimize striatal injury and ensure a more favorable prognosis. Patients with movement disorder and spasticity may require treatment with baclofen, diazepam, trihexyphenidyl, and injectable botulinum toxin A.

LYSINURIC PROTEIN INTOLERANCE (LPI)

This rare autosomal recessive disorder is caused by pathogenic variants in *SLC7A7* leading to impaired function of a protein transporting the cationic amino acids lysine, ornithine, and arginine in the intestine and kidneys. A deficiency of the transporter protein (Y+L amino acid transporter 1) in this condition causes multisystem manifestations, which often start with gastrointestinal symptoms. The transport defect in this condition resides in the basolateral (antiluminal) membrane of enterocytes and renal tubular epithelia. This explains the observation that cationic amino acids are unable to cross these cells even when administered as dipeptides. Lysine in the form of dipeptide crosses the luminal membrane of the enterocytes but hydrolyzes to free lysine in the cytoplasm. Free lysine, unable to cross the basolateral membrane of the cells, can diffuse back into the lumen leading to gastrointestinal symptoms.

Refusal to feed, nausea, aversion to protein, vomiting, and mild diarrhea, which may result in failure to thrive, wasting, and hypotonia, can be seen shortly after birth. Breastfed infants usually remain asymptomatic until soon after weaning, possibly because of the switch to a higher-protein solid foods. Episodes of hyperammonemia caused by the depletion of ornithine and arginine in the urea cycle may occur after ingestion of a high-protein meal. Mild to moderate hepatosplenomegaly, osteoporosis, sparse brittle hair, thin extremities with moderate centripetal adiposity, and growth retardation are common physical findings in patients whose condition has remained undiagnosed. Neurocognitive status is usually normal, but moderate intellectual disability has been observed in some patients.

Progressive interstitial pneumonitis with bouts of acute exacerbation often occurs and often progresses to severe alveolar proteinosis. Clinical manifestations include progressive exertional dyspnea, fatigue, cough, diminished breath sound, and inspiratory rales; cyanosis may develop in older patients. Some LPI patients have remained undiagnosed until the appearance of pulmonary manifestations. Radiographic evidence of pulmonary fibrosis has been observed in up to 65% of patients without clinical manifestations of pulmonary involvement.

Renal involvement is manifested initially by proteinuria, hematuria, and elevation of serum creatinine, which may progress to end-stage renal failure. Renal tubular involvement with laboratory findings of renal Fanconi syndrome may also be present. Renal biopsy reveals pathologic findings consistent with glomerulonephritis and tubulointerstitial nephritis. Hematologic findings of anemia, leukopenia, thrombocytopenia, and elevated ferritin may also be present.

Other organs are frequently involved. A condition resembling **hemophagocytic lymphohistiocytosis/macrophage activation syndrome** has been reported. Immunologic abnormalities (impaired lymphocyte function, abnormalities in immune globulins, hypocomplementemia) and acute pancreatitis are frequent features of LPI.

Pregnancies in affected mothers have been complicated by anemia, thrombocytopenia, toxemia, and bleeding, but offspring appear healthy at birth.

Laboratory findings may reveal hyperammonemia and an elevated concentration of urinary orotic acid, which develop after high-protein feeding. Plasma concentrations of lysine, arginine, and ornithine are usually mildly decreased, but urinary levels of these amino acids, especially lysine, are greatly increased. The pathogenesis of hyperammonemia is likely related to the depletion of urea cycle intermediates caused by poor absorption and the increased renal loss of ornithine and arginine. Plasma concentrations of alanine, glutamine, serine, glycine, and proline are usually increased. Anemia, increased serum levels of ferritin, LDH, thyroxine-binding globulin, hypercholesterolemia, and hypertriglyceridemia are common findings often leading to the workup for hemophagocytic lymphohistiocytosis. This condition should be differentiated from hyperammonemia caused by urea cycle defects (see Chapter 105.12), especially in heterozygous females with OTC deficiency, in whom increased urinary excretion of lysine, ornithine, and arginine is not seen.

Treatment with a low-protein diet providing the RDA of protein and supplemented with oral citrulline (50-100 mg/kg/day) can produce biochemical and clinical improvements. Episodes of hyperammonemia should be treated promptly (see Chapter 105.12). Supplementation with lysine (10-30 mg/kg/day) given in small and frequent doses helps improve plasma levels. The dose of lysine should be titrated down if patients develop abdominal pain and diarrhea. Treatment with high doses of prednisone has been effective in the management of acute pulmonary complications in some patients. **Bronchopulmonary lavage** is the treatment of choice for patients with alveolar proteinosis. The condition is more prevalent in Finland and Japan, where the prevalence is 1 in 60,000 and 1 in 57,000 live births, respectively.

105.15 *N*-Acetylaspartic Acid (Canavan Disease)

Reuben K. Matalon[†] and Dena R. Matalon

N-Acetylaspartic acid **(NAA)**, a derivative of aspartic acid, is synthesized in the brain and is found in a high concentration similar to glutamic acid. NAA has multiple functions, such as serving as an acetate reservoir for myelin synthesis, as well as being an organic osmolyte that helps regulate cerebral osmolality. However, the complete function of NAA is not yet fully understood. **Aspartoacylase** (ASPA) cleaves the *N*-acetyl group from NAA. A deficiency of aspartoacylase leads to **Canavan disease**, a severe **leukodystrophy** characterized by excessive excretion of NAA and spongy degeneration of the white matter of the brain. Canavan disease is an autosomal recessive disorder and is more prevalent in individuals of Ashkenazi Jewish descent than in other ethnic groups. The defective gene for Canavan disease *(ASPA)* can be tested in patients, family members, and at-risk populations.

ETIOLOGY AND PATHOLOGY

Deficiency of the enzyme aspartoacylase due to pathogenic variants in the *ASPA* gene leads to NAA accumulation in the brain, especially in the white matter, and massive urinary excretion. Excessive amounts of NAA are also present in the blood and CSF. Brain biopsies of patients with Canavan disease show spongy degeneration of the myelin fibers, astrocytic swelling, and elongated mitochondria. There is striking vacuolization and astrocytic swelling in the white matter. Electron microscopy reveals distorted mitochondria. As the disease progresses, the ventricles enlarge because of cerebral atrophy.

CLINICAL MANIFESTATIONS

The severity of Canavan disease covers a wide spectrum. Infants usually appear normal at birth and may not manifest symptoms of the disease until 3-6 months of age, when they develop **progressive macrocephaly**, severe hypotonia, persistent head lag, and delayed milestones. As the disease progresses, there is spasticity, joint stiffness, and contractures. Optic atrophy and seizures subsequently develop. Feeding difficulties, poor weight gain, and gastroesophageal reflux may occur in the first year of life followed by swallowing deterioration that may require nasogastric feeding or permanent gastrostomy. In the past, most individuals died in the first decade of life, but with the advances in medical technology and improved supportive care, survival now extends to the second or third decade.

[†]Deceased

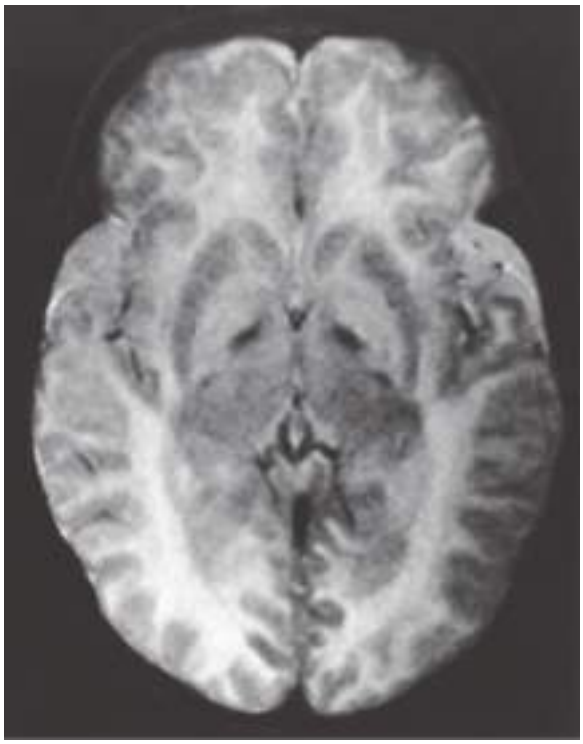

Fig. 105.16 Axial T2-weighted MRI of a 2-yr-old patient with Canavan disease. Extensive thickening of the white matter radiation is seen.

ATYPICAL CANAVAN DISEASE

Juvenile or **mild** Canavan disease is less common than **infantile** Canavan disease and is most prevalent in non-Ashkenazi Jews. Affected individuals with juvenile Canavan disease usually present with mild speech and motor delay and may have **retinitis pigmentosa**. The other typical features of Canavan disease are usually not present. These children have moderately increased urinary excretion of NAA to suggest Canavan disease. Brain MRI demonstrates increased signal intensity in the basal ganglia rather than global white matter disease, sometimes leading to confusion with mitochondrial disease.

DIAGNOSIS

In a typical individual with Canavan disease, brain MRI shows diffuse white matter degeneration, primarily in the cerebral hemispheres, with less involvement of the cerebellum and brainstem (Fig. 105.16). Repeated evaluations may be required. Magnetic resonance spectroscopy (MRS) can be done to show the high peak of NAA, which strongly suggests Canavan disease. The diagnosis can also be established by finding elevated amounts of NAA in the urine or blood. NAA is found in only trace amounts (24 ± 16 μmol/mmol creatinine) in the urine of unaffected individuals, whereas its concentration is in the range of 1,440 ± 873 μmol/mmol creatinine in individuals with Canavan disease. High levels of NAA can also be detected in plasma, CSF, and brain tissue. Aspartoacylase enzyme analysis from fibroblasts is often used to confirm the diagnosis but is not necessary. The activity of aspartoacylase in the fibroblasts of obligate carriers is half or less the activity found in normal individuals. Molecular analysis for variants in the *ASPA* gene is now recommended for all individuals in which Canavan disease is suspected.

The differential diagnosis of Canavan disease should include Alexander disease, another leukodystrophy associated with macrocephaly. Alexander disease is caused by a defect in the synthesis of glial fibrillary acidic protein, and the diagnosis can be ruled out by genetic testing of variants in the *GFAP* gene.

There are two predominant pathogenic variants leading to Canavan disease in the Ashkenazi Jewish population. The first is an amino acid substitution (p.Glu285Ala) in which glutamic acid is substituted for alanine. This pathogenic variant is the most frequent and encompasses 83% of mutant alleles in Ashkenazi Jewish individuals with Canavan disease. The second most common pathogenic variant is a change from tyrosine to a nonsense pathogenic variant, leading to a stop in the coding sequence (p.Tyr231*). This accounts for 13% of mutant Ashkenazi alleles. In the non-Jewish population, more diverse pathogenic variants have been observed, with the two variants common in the Ashkenazi Jewish population being rare. A different variant (p.Ala305Glu), the substitution of alanine for glutamic acid, accounts for 40% of mutant alleles in non-Jewish individuals. Over 70 pathogenic variants have been reported in the non-Jewish population. With Canavan disease, it is important to obtain a molecular diagnosis because this will lead to accurate counseling and prenatal guidance for the family. If the specific variants are not known, prenatal diagnosis relies on the NAA level in the amniotic fluid. In Ashkenazi Jewish individuals, the carrier frequency may be as high as 1:40, nearing that of Tay-Sachs disease. Carrier screening for Canavan disease is available. Genotype-phenotype studies and aspartoacylase expression and enzymatic activity help to prognosticate the severity of disease. Patients with juvenile or mild forms of Canavan disease have been compound heterozygotes with a mild pathogenic variant on one allele and a severe variant on the other allele. Mild variants include p.Tyr288Cys and p.Arg71His.

TREATMENT AND PREVENTION

Treatment for Canavan disease is supportive. After diagnosis, individuals should be monitored closely in terms of feeding and nutritional status, development, and risk for seizures. Medical intervention may be necessary such as antiepileptics, acetazolamide for increased intracranial pressures, and botulinum toxin injections for spasticity. Individuals benefit from early therapy interventions and special education programs to maximize developmental potential and communication. Genetic counseling, carrier testing, and prenatal diagnosis are the only current methods of prevention.

Studies of gene therapy using recombinant adeno-associated viruses (rAAVs) have shown some positive results in knockout mice models. Gene therapy attempts in children with Canavan disease have shown a lack of adverse events, some decrease in the brain elevation of *N*-acetylaspartic acid, improved seizure frequency, and slowing of the progression of brain atrophy. However, there was no improvement in long-term clinical status. Novel rAAV serotypes have been shown to better cross the **blood-brain barrier** and improved longevity of Canavan disease knockout mice, giving promise for further use of gene therapy in individuals with Canavan disease. **Enzyme-replacement therapy** with ASPA and pegylated ASPA is being studied in mice and has shown a decrease of NAA in the brain.

Chapter 106

Defects in Metabolism of Lipids

106.1 Disorders of Mitochondrial Fatty Acid β-Oxidation

Jerry Vockley

Mitochondrial β-oxidation of fatty acids is an essential energy-producing pathway. It is particularly important during prolonged periods of reduced caloric intake such as fasting or gastrointestinal illness or increased energy expenditure during physiologic stress such as febrile illness. Under these conditions, the body switches from using predominantly *carbohydrate* to predominantly *fat* as its major fuel. Fatty acids are also important fuels for exercising skeletal muscle and are the preferred substrate for normal cardiac metabolism. In these tissues, fatty acids are completely oxidized to carbon dioxide and water. The end products of hepatic fatty acid oxidation are the ketone bodies 3-*hydroxybutyrate* and *acetoacetate*. These compounds cannot be oxidized by the liver but are exported to serve as important fuels in peripheral tissues, particularly the brain, where ketone bodies can partially substitute for glucose during periods of fasting.

Genetic defects have been identified in almost all the known steps in the fatty acid oxidation pathway; all are recessively inherited (Table 106.1).

Clinical manifestations characteristically involve tissues with a high β-oxidation flux, including liver, skeletal, and cardiac muscle, and are age dependent. The most common early presentation is an acute episode of life-threatening coma, hepatic encephalopathy, and hypoglycemia with or without hyperammonemia induced by a period of fasting or illness in the first 2-4 years of life. After about age 6 years, muscle symptoms predominate in the disorders of long-chain fatty acid oxidation, including myopathy, fatiguability, and recurrent rhabdomyolysis. The latter is often brought on by excess activity or exercise. Cardiomyopathy can occur at any age in individuals with long-chain defects and may be exacerbated with acute episodes of illness. Patients with fatty acid oxidation defects are often asymptomatic when well. Acutely presenting disease may be misdiagnosed as **Reye syndrome** or, if fatal, as **sudden unexpected infant death**. In some circumstances, clinical manifestations appear to arise from toxic effects of fatty acid metabolites rather than inadequate energy production. These circumstances include certain long chain fatty acid oxidation disorders (deficiencies of long chain 3-hydroxyacyl dehydrogenase **[LCHAD]**, carnitine palmitoyltransferase-IA **[CPT-IA]**, or mitochondrial trifunctional protein [**MTP**; also known as *TFP*]) in which the presence of a homozygous affected fetus increases the risk of a life-threatening illness in the heterozygote mother, resulting in **acute fatty liver of pregnancy** (AFLP) or **preeclampsia with HELLP** (hemolysis, elevated liver enzymes, low platelets) syndrome. The mechanism of these obstetric complications is likely accumulation of toxic intermediates. Malformations of the brain and kidneys have been described in severe deficiencies of electron transfer flavoprotein **(ETF)**, ETF dehydrogenase **(ETF-DH)**, and carnitine palmitoyltransferase-II **(CPT-II)**, which might reflect in utero toxicity of fatty acid metabolites or a developmental role for these enzymes. Progressive retinal degeneration, peripheral neuropathy, and chronic progressive liver disease have been identified in LCHAD and MTP deficiency.

Fatty acid oxidation disorders are easily overlooked because the only specific clue to the diagnosis may be the finding of inappropriately *low* concentrations of plasma or urinary ketones in an infant who has hypoglycemia unless specialized metabolic testing is performed. Genetic defects in ketone body utilization may also be overlooked because ketonemia is an expected finding with fasting hypoglycemia. Newborn screening programs using tandem mass spectrometry detect characteristic plasma acylcarnitine profiles in most of these disorders, allowing early and presymptomatic diagnosis. Screening programs have demonstrated that all the fatty acid oxidation disorders combined are among the most common inborn errors of metabolism, at least in predominantly White populations.

Figures 106.1 and 106.2 outline the steps involved in the oxidation of a typical long chain fatty acid. In the *carnitine cycle,* long chain fatty acids are transported across the barrier of the inner mitochondrial membrane as acylcarnitine esters. Medium-chain fatty acids, which are commonly provided as medium-chain triglyceride supplementation in infants who are failing to thrive, can bypass the carnitine cycle and enter the mitochondrial β-oxidation cycle directly. Within the mitochondria, successive rounds of the four-step *β-oxidation cycle* convert the **coenzyme A (CoA)**–activated fatty acids to acetyl-CoA units. Two or three different chain-length-specific isoenzymes are needed for each of these β-oxidation steps to accommodate the different chain-length fatty acyl-CoA species. The electrons generated in the first β-oxidation step (acyl-CoA dehydrogenase) are carried by the *electron transfer pathway* to the *electron transport chain* at the level of coenzyme Q for adenosine triphosphate production, whereas electrons generated from the third step (3-hydroxyacyl-CoA dehydrogenase) enter the *electron transport chain* at the level of complex 1. Most of the acetyl-CoA generated from fatty acid β-oxidation in the liver flows through the *pathway of ketogenesis* to form 3-hydroxybutyrate and acetoacetate, whereas in muscle and heart, the fatty acids are completely oxidized to CO_2 and water through oxidative phosphorylation. It has been demonstrated that the enzymes of fatty acid oxidation physically and functionally interact with each other and those of the mitochondrial electron transport chain.

DEFECTS IN THE β-OXIDATION CYCLE

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase **(MCAD)** deficiency is the most common fatty acid oxidation disorder. The disorder shows a strong founder effect; most patients have a northwestern European ancestry, and the majority of these patients have at least one copy of a common MCAD missense pathogenic variant, an A-G transition at cDNA position 985 (c.985A>G) that changes a lysine to glutamic acid at residue 329 (p.Lys329Glu).

Clinical Manifestations

Previously undiagnosed affected patients usually present in the first 3 months to 5 years of life with episodes of acute illness triggered by prolonged fasting (>12-16 hours). Signs and symptoms include vomiting and lethargy, which rapidly progress to coma or seizures and cardiorespiratory collapse. Sudden unexpected infant death may occur. The liver may be slightly enlarged with fat deposition. Episodes are rare until the infant is beyond the first few months of life, presumably because of more frequent feedings at a younger age. Affected older infants are at higher risk of symptoms as they begin to fast through the night or are exposed to fasting stress during an intercurrent childhood illness. Presentation in the first days of life with neonatal hypoglycemia has been reported in newborns who were fasted inadvertently or were being breastfed exclusively and thus are at higher risk because of early reduced caloric intake. A diagnosis of MCAD has occasionally been documented in previously healthy teenage and adult individuals, indicating that even patients who have been asymptomatic in infancy are still at risk for metabolic decompensation if exposed to sufficient periods of fasting. An unknown number of patients may remain asymptomatic. Prior to routine newborn screening testing, as many as 25% of MCAD-deficient patients died or suffered severe brain injury from their first episode. Most patients are diagnosed in the newborn period by **blood spot acylcarnitine screening** (part of newborn screening), allowing the initiation of early intervention and prevention of most signs and symptoms.

Laboratory Findings

During acute episodes, hypoglycemia is usually present. Plasma and urinary ketone concentrations are inappropriately low **(hypoketotic**

Table 106.1 Mitochondrial Fatty Acid Oxidation Disorders: Clinical and Biochemical Features

ENZYME DEFICIENCY	GENE	CLINICAL PHENOTYPE	LABORATORY FINDINGS
Carnitine transporter	*SLC22A5*	Cardiomyopathy, skeletal myopathy, liver disease, sudden death, endocardial fibroelastosis, cardiac arrhythmia	↓ Total and free carnitine; normal acylcarnitines, acylglycine, and organic acids; prenatal and newborn possible diagnosis reported
Long chain fatty acid transporter	*FATP1-6*	Rare, acute liver failure in childhood requiring liver transplantation	↓ Intracellular C_{14}-C_{18} fatty acids; ↓ fatty acid oxidation; disease-causing pathogenic variants have not been identified in patients
Carnitine palmitoyl transferase-IA	*CPTIA*	Liver failure, renal tubulopathy, and sudden death reported; maternal preeclampsia; HELLP syndrome association described in a few patients	Normal or ↑ free carnitine; normal acylcarnitines, acylglycine, and organic acids; newborn screening diagnosis reported
Carnitine acylcarnitine translocase	*SLC25A20*	Chronic progressive liver failure, persistent ↑ NH_3, hypertrophic cardiomyopathy	Normal or ↓ free carnitine, abnormal acylcarnitine profile; newborn screening diagnosis reported
Carnitine palmitoyl transferase-II	*CPT2*	Early and late onset types; liver failure, encephalopathy, skeletal myopathy, cardiomyopathy, renal cystic changes; adult form with acute rhabdomyolysis, myoglobinuria	Normal or ↓ free carnitine; abnormal acylcarnitine profile; newborn screening diagnosis possible
Short chain acyl-CoA dehydrogenase	*ACADS*	Biochemical phenotype only; no consistent clinical phenotype	Normal or ↓ free carnitine; elevated urine ethylmalonic acid; inconsistently abnormal acylcarnitine profile
Medium-chain acyl-CoA dehydrogenase	*ACADM*	Hypoglycemia, hepatic encephalopathy, sudden death; maternal preeclampsia, HELLP syndrome association described rarely, possible long QT interval	Normal or ↓ free carnitine, ↑ urine acylglycine, plasma C_6-C_{10} free fatty acids, ↑ C_8-C_{10} acyl-carnitine; newborn screening diagnosis possible
Very long chain acyl-CoA dehydrogenase (VLCAD)	*ACADVL*	Dilated cardiomyopathy, arrhythmias, hypoglycemia, and hepatic steatosis; late-onset, stress-induced rhabdomyolysis, episodic myopathy	Normal or ↓ free carnitine; ↑ plasma $C_{14:1}$, C_{14} acylcarnitine; ↑ plasma C_{10}-C_{16} free fatty acids; prenatal and newborn screening diagnosis possible
ETF dehydrogenase*	*ETFDH*	Nonketotic fasting hypoglycemia, congenital anomalies, milder forms of liver disease, cardiomyopathy, and skeletal myopathy	Normal or ↓ free carnitine; increased ratio of acyl:free carnitine, ↑ blood acylcarnitines; characteristic urine organic acids and acylglycines; newborn screening diagnosis possible
ETF-α*	*ETFA*	Nonketotic fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy; skeletal myopathy also described	Normal or ↓ free carnitine; increased ratio of acyl:free carnitine; ↑ acylcarnitines; urine organic acid and acylglycines; newborn screening diagnosis possible
ETF-β*	*ETFB*	Fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy; skeletal myopathy also described	Normal or ↓ free carnitine; increased ratio of acyl:free carnitine, ↑ blood acylcarnitines; urine organic acid and acylglycines; newborn screening diagnosis possible
Short chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD)	*HAD1*	Hyperinsulinemic hypoglycemia, cardiomyopathy, myopathy	Normal or ↓ free carnitine, elevated free fatty acids, inconsistently abnormal urine organic acid, ↑ 3-OH glutarate, ↑ plasma C_4-OH acylcarnitine; newborn screening diagnosis possible
Long chain L-3-hydroxyacyl-CoA dehydrogenase (LCHAD)	*HADHA*	Maternal preeclampsia, HELLP syndrome, and AFLP association described frequently; see MTP later for clinical manifestations	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines; newborn screening diagnosis possible
MTP	*HADHA, HADHB*	Severe cardiac and skeletal myopathy, hypoglycemia, acidosis, hyper NH_3, sudden death, elevated liver enzymes, retinopathy; maternal preeclampsia, HELLP syndrome, and AFLP association described frequently	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines; newborn screening diagnosis possible
Long chain 3-ketoacyl-CoA thiolase	*HADHB*	Severe neonatal presentation, hypoglycemia, acidosis, ↑ creatine kinase, cardiomyopathy, neuropathy, and early death	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ 2-*trans*, 4-*cis*-decadienoylcarnitine; newborn screening diagnosis possible
Short chain 2,3-enoyl-CoA hydratase	*ECHS1*	Leigh disease, lactic acidosis, seizures, cystic degeneration of white matter, microcephaly, metabolic acidosis, extrapyramidal dystonia, dilated cardiomyopathy	Abnormal organic acids, 2-methacrylglycine, 2-methyl-2,3 dihydroxybutyrate, also S-(2-carboxypropyl)cysteine, S-(2-carboxyethyl) cysteamine; acylcarnitine shows ↑ C4OH (inconsistently)

Table 106.1 Mitochondrial Fatty Acid Oxidation Disorders: Clinical and Biochemical Features—cont'd

ENZYME DEFICIENCY	GENE	CLINICAL PHENOTYPE	LABORATORY FINDINGS
2,4-Dienoyl-CoA reductase	*DECR1*	Only one patient described, hypotonia in the newborn, mainly severe skeletal myopathy and respiratory failure; hypoglycemia is rare	Normal or ↓ free carnitine, ↑ acyl:free carnitine ratio, normal urine organic acids and acylglycines
HMG CoA synthetase	*HMGCS2*	Hypoketosis and hypoglycemia, rarely myopathy	↑ Total plasma fatty acids; enzyme studies in biopsied liver may be diagnostic; genetic testing preferred
HMG CoA lyase	*HMGCL*	Hypoketosis and hypoglycemia, rarely myopathy	Normal free carnitine, ↑ C_5-OH, and methylglutaryl-carnitine; enzymes studies in fibroblasts may be diagnostic
Monocarboxylate transporter 1 (MCT1)	*SLC16A1*	Severe fasting-induced ketoacidosis, rarely hypoglycemia	Profound ketoacidosis; no specific biomarkers yet identified

*Also known as glutaric acidemia type II or multiple acyl-CoA dehydrogenase defect (MADD).
AFLP, Acute fatty liver of pregnancy; CoA, coenzyme A; ETF, electron transport flavoprotein; HELLP, hemolysis, elevated liver enzymes, low platelets; MTP, mitochondrial trifunctional protein; NH_3, ammonia.
From Shekhawat PS, Matern D, Strauss AW. Fetal fatty oxidation disorders, their effect on maternal health and neonatal outcome: impact of expanded newborn screening on their diagnosis and management. *Pediatr Res.* 2005;57:78R–84R.

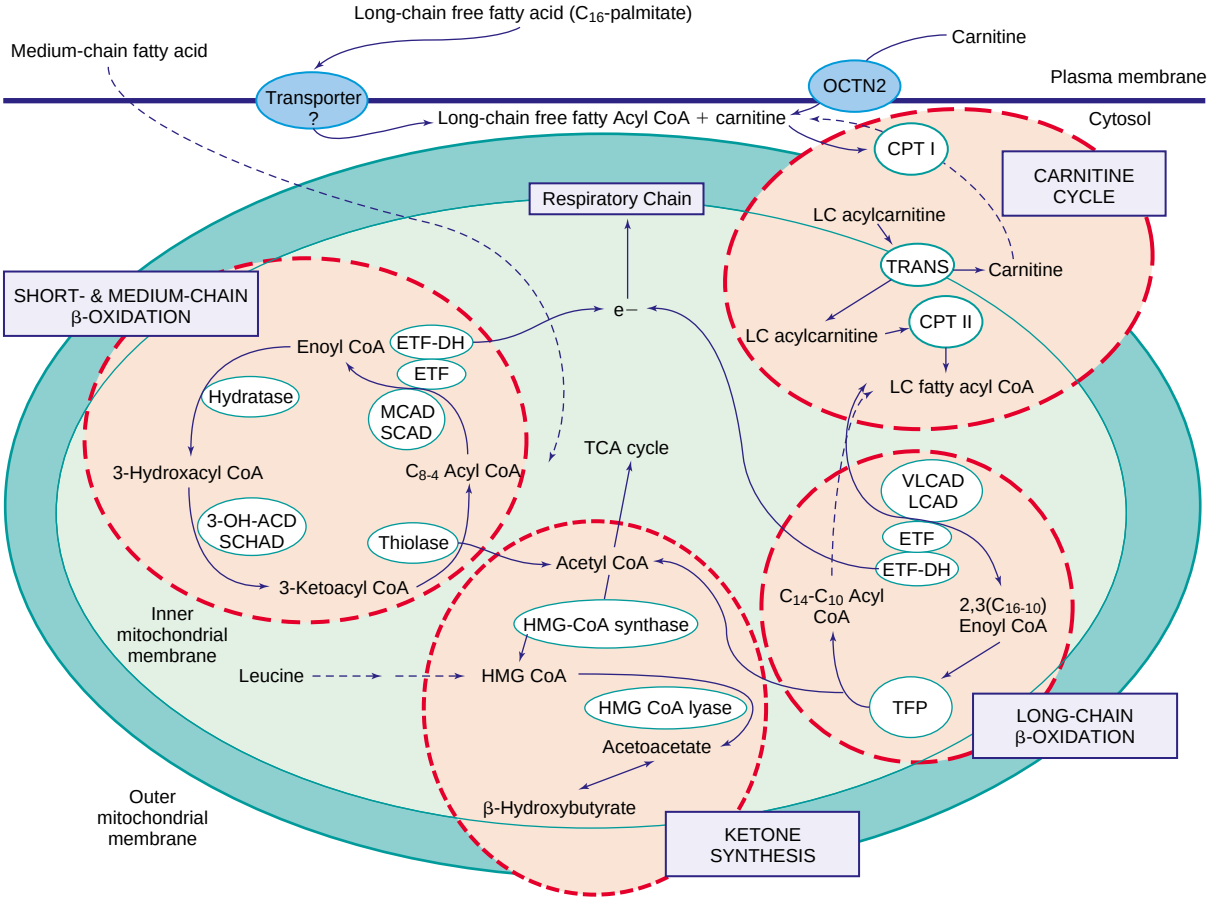

Fig. 106.1 Mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long chain (LC) fatty acid, is transported across the plasma membrane and can be activated to form an LC fatty acyl coenzyme A (CoA). It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into an LC fatty acyl-CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo β-oxidation. Very LC acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of (C_{16}-C_{10}) 2,3-enoyl CoA. Mitochondrial trifunctional protein (MTP) contains the activities of enoyl CoA hydratase (hydratase), 3-OH-hydroxyacyl-CoA dehydrogenase (3-OH-ACD), and β-ketothiolase (thiolase). Acetyl-CoA, a reduced form of flavin adenine dinucleotide (FADH), and a reduced form of nicotinamide adenine dinucleotide (NADH) are produced. Medium- and short chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short chain acyl-CoA dehydrogenase (SCAD), and short chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron transfer flavoprotein (ETF) and the electron transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. In the liver, acetyl-CoA can be converted into hydroxymethylglutaryl (HMG) CoA by β-hydroxy-β-methylglutaryl-CoA synthase (HMG CoA synthase) and then the ketone body acetoacetate by the action of β-hydroxy-β-methylglutaryl-CoA lyase (HMG-CoA lyase).

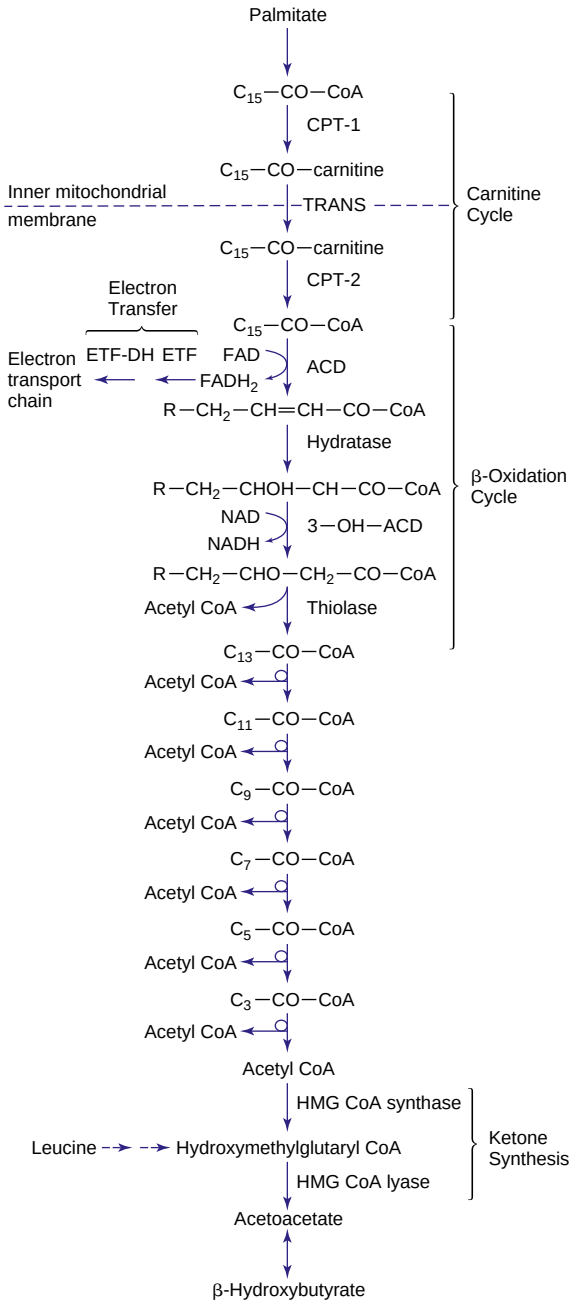

Fig. 106.2 Pathway of mitochondrial oxidation of palmitate, a typical 16-carbon long chain fatty acid. Enzyme steps include carnitine palmitoyltransferase (CPT) 1 and 2, carnitine/acylcarnitine translocase (TRANS), electron transfer flavoprotein (ETF), ETF dehydrogenase (ETF-DH), acyl-CoA dehydrogenase (ACD), enoyl CoA hydratase (hydratase), 3-hydroxy-acyl-CoA dehydrogenase (3-OH-ACD), β-ketothiolase (thiolase), β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase, and lyase.

hypoglycemia). Because of the hypoketonemia, there is little or no metabolic acidosis, which is typically present in children with hypoglycemia not caused by fatty acid oxidation disorders. Liver function tests (LFTs) are abnormal, with elevations of liver enzymes (alanine transaminase, aspartate transaminase), elevated blood ammonia, and prolonged prothrombin and partial thromboplastin times. Liver biopsy at times of acute illness shows microvesicular or macrovesicular steatosis from triglyceride accumulation. During fasting stress or acute illness, urinary organic acid profiles by gas chromatography/mass spectrometry show inappropriately low concentrations of ketones and elevated levels of medium-chain dicarboxylic acids (adipic, suberic, and sebacic acids) that derive from microsomal and peroxisomal omega oxidation of accumulated medium-chain fatty acids. Plasma and tissue concentrations of total carnitine are reduced to 25–50% of normal, and the fraction of total esterified carnitine is increased. This pattern of **secondary carnitine deficiency** is seen in most fatty acid oxidation defects and reflects competition between increased acylcarnitine levels and free carnitine for transport at the renal tubular plasma membrane. Significant exceptions to this rule are the plasma membrane carnitine transporter, CPT-IA, and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase deficiencies, which do not manifest secondary carnitine deficiency.

Diagnostic metabolite patterns for MCAD deficiency include increased plasma $C_{6:0}$, $C_{8:0}$, $C_{10:0}$, and $C_{10:1}$ acylcarnitine species and increased urinary acylglycines, including hexanoylglycine, suberylglycine, and 3-phenylpropionylglycine. Newborn screening, performed in all states in the United States and in many other countries, can detect presymptomatic MCAD deficiency based on these abnormal acylcarnitines in filter paper blood spots. The diagnosis can be confirmed by demonstrating the common Ala985Gly pathogenic variant or sequencing the MCAD gene. A second common variant, Thr199Cys, has been detected in infants identified by newborn screening. Interestingly, this allele has not been seen to date in symptomatic MCAD patients, likely because of the significant residual activity of this milder pathogenic variant.

Treatment

Acute illnesses should be promptly treated with intravenous (IV) fluids containing 10% dextrose to correct or prevent hypoglycemia and to suppress lipolysis as rapidly as possible (see Chapter 113). Chronic therapy consists of avoiding fasting. This usually requires simply adjusting the diet to ensure that overnight fasting periods are limited to <6 hours in infants under 6 months of age, <8 hours for infants 6-24 months of age, and <12 hours for older children. Restricting dietary fat or treatment with carnitine is unnecessary. There is likely no need for active therapeutic intervention for individuals with the Thr199Cys variant.

Prognosis

Up to 25% of previously undiagnosed patients may die during their first attack of illness. There is often a history of a previous sibling death that is presumed to be from an unrecognized MCAD deficiency. Some patients may sustain permanent brain injury during an attack of profound hypoglycemia. For survivors without brain damage and essentially all babies identified by newborn screening, the prognosis is excellent because progressive cognitive impairment or cardiomyopathy does not occur in MCAD deficiency. Fasting tolerance improves with age, and the risk of decompensation decreases. Because as many as 35% of affected patients have never had an episode, testing of siblings of affected patients is important to detect asymptomatic family members who did not receive newborn screening.

Very Long Chain Acyl-CoA Dehydrogenase Deficiency

Very long chain acyl-CoA dehydrogenase **(VLCAD)** deficiency is the second most common diagnosed disorder of fatty acid oxidation. It was originally termed "long chain acyl-CoA dehydrogenase deficiency" before the existence of the inner mitochondrial membrane-bound VLCAD was known. *All patients previously diagnosed as having long chain acyl-CoA dehydrogenase deficiency have* VLCAD *gene defects.* Patients with VLCAD deficiency have no ability to oxidize physiologic long chain fatty acids and are usually more severely affected than those with MCAD deficiency, who have a milder oxidative defect. VLCAD deficiency presents earlier in infancy and has more chronic problems with muscle weakness or episodes of muscle pain and rhabdomyolysis. Cardiomyopathy may be present during acute attacks provoked by fasting. The left ventricle may be hypertrophic or dilated and may show poor contractility on echocardiography. Sudden unexpected death has occurred in several patients, but most who survive the initial episode show improvement, including normalization of cardiac function.

Other physical and routine laboratory features are similar to those of MCAD deficiency, including secondary carnitine deficiency. The urinary organic acid profile shows a nonketotic dicarboxylic aciduria with increased levels of $C_{6\text{-}12}$ dicarboxylic acids. Diagnosis may be suggested by an abnormal acylcarnitine profile with plasma or blood spot $C_{14:0,\ 14:1,\ 14:2}$ acylcarnitine species. However, the specific diagnosis requires pathogenic variant analysis of the *VLCAD* gene. Newborn screening by tandem mass spectrometry of dried blood spots is effective in identifying early/severe disease, though it can miss milder, later-onset cases. A common mild variant is identified by a newborn screen that typically predicts later-onset disease. Treatment has traditionally been based primarily on avoidance of fasting for >8-12 hours depending on age, along with supplementation with medium-chain triglycerides. Triheptanoin (Dojolvi) has been approved as a treatment for VLCAD deficiency and for all other disorders of long-chain fatty acid oxidation. The odd-chain fat heptanoate (C7) released from this triglycerol provides acetyl-CoA for the tricarboxylic acid cycle *and* propionyl-CoA, which is metabolized through methylmalonyl-CoA to succinyl-CoA and succinate. This anaplerotic effect essentially eliminates hypoglycemia in long-chain fatty acid oxidation disorder patients and significantly improves heart function in patients with cardiomyopathy. However, although heptanoin does reduce the incidence, rhabdomyolysis remains a major problem in treated patients. This finding led to the recognition of previously unrecognized inflammation as a component of these disorders, likely caused by the accumulation of a high level of proinflammatory long-chain complex lipids. Patients can develop a secondary carnitine deficiency; however, the need for replacement therapy remains unclear. If the free carnitine level in blood is <10 μM, supplementation with 25-50 mg/kg of oral carnitine (with a maximum of 1,000 mg/day) may be helpful, especially in the face of cardiomyopathy or significant muscular symptoms.

Short Chain Acyl-CoA Dehydrogenase Deficiency

A small number of patients with two null pathogenic variants in the short chain acyl-CoA dehydrogenase (SCAD) gene have been described with a variable phenotype. Most individuals classified as being SCAD deficient actually have polymorphic DNA changes in the *SCAD* gene; two common polymorphisms are Gly185Ser and Arg-147Trp, present in biallelic fashion in 7% of the population. Although SCAD deficiency was originally reported with a wide range of symptoms, it was likely a result of the frequency of the common polymorphisms in unrelated disease rather than a true causal relationship. Long-term follow-up of infants identified by newborn screening has failed to demonstrate a convincing, consistent phenotype, and thus SCAD deficiency is best described as a biochemical phenotype rather than a disease. The diagnosis is indicated by elevated levels of butyrylcarnitine (C4-carnitine) on newborn blood spots or plasma and increased excretion of urinary ethylmalonic acid and butyrylglycine. These metabolic abnormalities are most pronounced in patients with null pathogenic variants and are variably present in patients who are homozygous for the common polymorphisms. In the context of metabolic abnormalities consistent with SCAD deficiency in patients with significant clinical problems, a thorough evaluation for *another* unrelated diagnosis is indicated. There is no need for treatment of individuals with SCAD deficiency.

Long Chain 3-Hydroxyacyl-CoA Dehydrogenase/ Mitochondrial Trifunctional Protein Deficiency

The LCHAD enzyme is part of the MTP, which also contains two other steps in β-oxidation: long chain 2,3-enoyl CoA hydratase and long chain β-ketothiolase. MTP is a heterotetrameric protein composed of two α and two β chains derived from distinct contiguous genes, *HADHA* and *HADHB,* that share a common promoter. In some patients, only the LCHAD activity of the MTP is affected **(LCHAD deficiency)**, whereas others have deficiencies of all three activities **(MTP deficiency)**.

Clinical manifestations include attacks of acute hypoketotic hypoglycemia similar to VLCAD deficiency; however, patients often show evidence of more severe disease, including cardiomyopathy, muscle cramps and weakness, and abnormal liver function (cholestasis). Pigmented retinopathy leading to blindness, progressive liver failure, peripheral neuropathy, and rhabdomyolysis are also present, with retinopathy being more severe in isolated LCHAD deficiency and neuropathy worse in combined MTP defects. Life-threatening obstetric complications (AFLP, HELLP syndrome) have been observed in heterozygous mothers carrying homozygous fetuses affected with LCHAD/MTP deficiency. Sudden unexpected infant death may occur, especially in populations where tandem mass spectrometry newborn screening is not routine. The **diagnosis** is indicated by elevated levels of blood spot or plasma 3-hydroxy acylcarnitines of chain lengths C_{16}-C_{18}. The urinary organic acid profile in patients may show increased levels of 3-hydroxydicarboxylic acids of chain lengths C_6-C_{14}. Secondary carnitine deficiency is common. A common pathogenic variant in the α subunit, E474Q, is seen in more than 60% of isolated LCHAD-deficient patients. This pathogenic variant in the fetus is especially associated with the obstetric complications, but other pathogenic variants in either subunit may also be linked to maternal illness.

Treatment is similar to that for VLCAD deficiency; that is, avoiding fasting stress, triheptanoin, and potentially carnitine. Docosahexaenoic acid may slow the retinal changes but does not prevent them. None of these therapeutic measures likely affect the development or progression of peripheral neuropathy. Liver transplantation has been attempted in patients with severe liver failure but does not ameliorate the metabolic abnormalities or prevent the myopathic or retinal complications.

Short Chain 3-Hydroxyacyl-CoA Dehydrogenase Deficiency

Very few patients with proven pathogenic variants of short chain 3-hydroxyacyl-CoA dehydrogenase **(SCHAD)** have been reported. Most cases with recessive pathogenic variants of the SCHAD gene have presented with episodes of hypoketotic hypoglycemia that was caused by *hyperinsulinism*. In contrast to those with other forms of fatty acid oxidation disorders, these patients required specific therapy with diazoxide for hyperinsulinism to avoid recurrent hypoglycemia. A single patient with compound heterozygous pathogenic variants presented with fulminant hepatic failure at age 10 months. The SCHAD protein has a nonenzymatic function in which it directly interacts with glutamate dehydrogenase (GDH) to inhibit its activity. In the absence of SCHAD protein, this inhibition is removed, leading to upregulation of GDH enzyme activity, a recognized cause of *hyperinsulinism,* usually from activating pathogenic variants of the *GDH* gene. Severe deficiency of SCHAD protein often presents predominantly as **protein-sensitive hypoglycemia** rather than as fasting hypoglycemia. It appears that if SCHAD protein is present, inhibition of GDH is maintained even when there is no SCHAD enzyme activity; these patients may present with a more traditional fatty acid oxidation defect. Specific metabolic markers for SCHAD deficiency include elevated plasma C4-hydroxy acylcarnitine and urine 3-hydroxyglutaric acid. Successful newborn screening for SCHAD deficiency has been recorded, but the sensitivity of the process has not yet been established.

Treatment of SCHAD-deficient patients with hyperinsulinism is with diazoxide. There is insufficient experience with the non-hyperinsulinemic form of SCHAD deficiency at present to recommend treatment modalities, but prevention of fasting seems advisable.

Short Chain 2,3-Enoyl-CoA Hydratase Deficiency

This rare disorder, resulting from pathogenic variants in the *ECHS1* gene, was identified through exome sequencing. The disorder affects a shared pathway of short chain fatty acid and valine metabolism. The clinical phenotypes are more characteristic of mitochondrial disorders of pyruvate metabolism with predominantly a **Leigh-like disease** (see Chapters 108 and 638.2) with profound and often-fatal lactic acidosis. No treatment modalities or specific biomarkers have been established. Several patients were found to excrete increased levels of methacrylylglycine, a highly reactive and potentially toxic intermediate; 2-methyl-2.3 dihydroxybutyrate; *S*-(2-carboxypropyl) cysteine; and *S*-(2-carboxpropyl) cysteamine.

DEFECTS IN THE CARNITINE CYCLE

Plasma Membrane Carnitine Transport Defect (Primary Carnitine Deficiency)

Primary carnitine deficiency is the only genetic defect in which carnitine deficiency is the *cause,* rather than the consequence, of impaired fatty acid oxidation. The most common presentation is progressive **cardiomyopathy** with or without **skeletal muscle weakness** beginning at age 1-4 years. A smaller number of patients may present with fasting hypoketotic hypoglycemia in the first year of life, before the cardiomyopathy becomes evident. Cardiac arrythmias are often seen. A common pathogenic variant causes late-onset disease in the Faroe Islands with sudden death caused by cardiomyopathy and/or arrhythmia. The underlying defect involves the high-affinity plasma membrane sodium gradient–dependent carnitine transporter encoded by the *SLC22A5* gene that is expressed at high levels in heart, muscle, and kidney. This transporter is responsible both for maintaining intracellular carnitine concentrations 20- to 50-fold higher than plasma concentrations and for renal conservation of carnitine.

Diagnosis of the carnitine transporter defect is aided by patients having extremely reduced carnitine levels in plasma and muscle (1–2% of normal). Heterozygote parents have plasma carnitine levels approximately 50% of normal. Fasting ketogenesis may be normal because liver carnitine transport is normal, but it may become impaired if dietary carnitine intake is interrupted. The fasting urinary organic acid profile may show a hypoketotic dicarboxylic aciduria pattern if hepatic fatty acid oxidation is impaired but is otherwise unremarkable. The defect in carnitine transport can be demonstrated clinically by the severe reduction in renal carnitine threshold or by in vitro assay of carnitine uptake using cultured fibroblasts or lymphoblasts. *SLC22A5* sequencing is the most common method to confirm the diagnosis. A common relatively severe pathogenic variant has been described in the Chinese population in Taiwan. **Treatment** with pharmacologic doses of oral carnitine (100-300 mg/kg/day) is highly effective in correcting the cardiomyopathy and muscle weakness, as well as any impairment in fasting ketogenesis. Muscle total carnitine concentrations remain <5% of normal on treatment.

Carnitine Palmitoyltransferase-IA Deficiency

Several dozen infants and children have been described with a deficiency of the liver and kidney CPT-I isozyme (CPT-IA). **Clinical manifestations** include fasting-induced hypoketotic hypoglycemia, occasionally with extremely abnormal LFTs and, rarely, with renal tubular acidosis. The heart and skeletal muscles are not involved because the muscle isozyme is unaffected. Fasting urinary organic acid profiles sometimes show a hypoketotic C_6-C_{12} dicarboxylic aciduria but may be normal. Plasma acylcarnitine analysis demonstrates mostly free carnitine with very little acylated carnitine. This observation has been used to identify CPT-IA deficiency on newborn screening by tandem mass spectrometry. CPT-IA deficiency is the only fatty acid oxidation disorder in which plasma total carnitine levels may be elevated, often to 150–200% of normal. This phenomenon is explained by the absence of inhibitory effects of long chain acylcarnitines on the renal tubular carnitine transporter in CPT-IA deficiency. The enzyme defect can be demonstrated in cultured fibroblasts or lymphoblasts. CPT-IA deficiency in the fetus has been associated in a single case report with AFLP in the mother. A common variant in the *CPTIA* gene (c.1436C>t, p.Pro479Leu) has been identified in individuals of Inuit background in the United States, Canada, and Greenland. This variant is associated with an increased risk for sudden infant death syndrome (SIDS) in the Inuit population. The variant can be detected by newborn screening; enzyme activity is reduced by 80%, and regulation by malonyl-CoA is lost. It has not been established whether this variant is a pathologic enzyme variant or an adaptation to ancient Inuit high-fat diets. Another pathogenic variant is common in the Ashkenazi Jewish population and leads to infantile symptoms. **Treatment** for the severe form of CPT-IA deficiency that is found in non-Inuit populations is similar to that for VLCAD deficiency, with avoidance of situations where fasting ketogenesis is necessary and use of triheptanoin to provide an anaplerotic fuel source. The need for treatment of the Inuit variant has not yet been determined.

Carnitine:Acylcarnitine Translocase Deficiency

This defect of the inner mitochondrial membrane carrier protein for long chain acylcarnitines blocks the entry of long chain fatty acids into the mitochondria for oxidation. The clinical phenotype of this disorder is driven by a typically severe and generalized impairment of fatty acid oxidation. Most newborn patients present with attacks of fasting-induced hypoglycemia, hyperammonemia, and cardiorespiratory collapse. All symptomatic newborns have had evidence of cardiomyopathy and muscle weakness. Several patients with a partial translocase deficiency and milder disease without cardiac involvement have also been identified. No distinctive urinary or plasma organic acids are noted, although increased levels of plasma long chain acylcarnitines of chain lengths C_{16}-C_{18} are reported, not distinguishable from the pattern seen in CPT-II deficiency (see later). **Diagnosis** can be confirmed using genetic analysis. Functional carnitine:acylcarnitine translocase activity can be measured in cultured fibroblasts or lymphoblasts. **Treatment** is similar to that of VLCAD deficiency and is particularly effective in reducing the hyperammonemia that is often otherwise persistent in severe patients.

Carnitine Palmitoyltransferase-II Deficiency

Three forms of CPT-II deficiency have been described. A **severe neonatal lethal** presentation associated with a profound enzyme deficiency, and early death has been reported in newborns with hypoglycemia and hyperammonemia in association with dysplastic kidneys, cerebral malformations, and mild facial anomalies. A milder defect is associated with an **adult presentation** of episodic rhabdomyolysis. The first episode usually does not occur until late childhood or early adulthood. Attacks are frequently precipitated by prolonged exercise. There is aching muscle pain and myoglobinuria that may be severe enough to cause renal failure. Hypoglycemia has not been described, but fasting may contribute to attacks of myoglobinuria. Muscle biopsy shows increased deposition of neutral fat. This adult myopathic presentation of CPT-II deficiency is associated with a common *CPT2* pathogenic variant, c.338C>T, p.Ser113Leu, seen as a recurrent pathogenic variant in the Ashkenazi Jewish population. This pathogenic variant produces a heat-labile protein that is unstable to increased muscle temperature during exercise that may contribute to the myopathic presentation. A third **intermediate form** of CPT-II deficiency presents in infancy or early childhood with fasting-induced hepatic failure, cardiomyopathy, and skeletal myopathy with hypoketotic hypoglycemia but is not associated with the severe developmental changes seen in the neonatal lethal presentation. This pattern of illness is similar to VLCAD deficiency, and management is identical. It is often caused by the presence of one severe pathogenic variant in combination with the mild c.338C>T variant.

Diagnosis of all forms of CPT-II deficiency can be made by a combination of molecular genetic analysis and demonstrating deficient enzyme activity in muscle or other tissues and in cultured fibroblasts. Severe and intermediate disease can be identified through newborn screening, but patients homozygous for the common mild variant typically have normal newborn screens.

DEFECTS IN THE ELECTRON TRANSFER PATHWAY

Electron Transfer Flavoprotein and Electron Transfer Flavoprotein Dehydrogenase Deficiencies (Glutaric Acidemia Type 2, Multiple Acyl-CoA Dehydrogenation Defects)

Electron transfer flavoprotein (ETF) and electron transfer flavoprotein dehydrogenase (ETF-DH) function to transfer electrons into the mitochondrial electron transport chain from dehydrogenation reactions catalyzed by VLCAD, MCAD, SCAD, and glutaryl-CoA dehydrogenase, four enzymes involved in branched-chain amino acid (BCAA) oxidation and sarcosine and dimethylglycine dehydrogenases. Deficiencies of ETF or ETF-DH produce illness that combines the features of impaired fatty acid oxidation and impaired oxidation of several amino acids. Complete deficiencies of either protein are associated with severe illness in the newborn period, characterized by acidosis, hypoketotic hypoglycemia, coma, hypotonia, cardiomyopathy, and

an unusual odor of sweaty feet caused by isovaleryl-CoA dehydrogenase inhibition. Some affected neonates have had congenital facial dysmorphism and polycystic kidneys similar to those in severe CPT-II deficiency, which suggests that toxic effects of accumulated metabolites may occur in utero. Most severely affected infants do not survive the neonatal period. Disorders of cellular or mitochondrial riboflavin transport or flavin adenine dinucleotide (FAD, an essential cofactor for the acyl-CoA dehydrogenases) have been identified with similar biochemical profiles to ETF and ETF-DH deficiency but with more variable features.

Diagnosis can be made from the newborn blood spot acylcarnitine profile and urinary organic acids; both tests show abnormalities corresponding to disruptions in the oxidation of fatty acids (ethylmalonate and C_6-C_{10} dicarboxylic acids), lysine (glutarate), and BCAAs (isovaleryl-, isobutyryl-, and 2-methylbutyrylglycine). The diagnosis can be confirmed by genetic testing of *ETFA, ETFB,* and *ETFDH*. If no pathogenic variants in these genes are identified, additional testing for the riboflavin transport and FAD synthesis genes should be pursued.

Partial deficiencies of ETF and ETF-DH produce a disorder that may mimic MCAD deficiency or other milder long-chain fatty acid oxidation defects with attacks of fasting hypoketotic coma. The urinary organic acid profile reveals primarily elevations of dicarboxylic acids and ethylmalonate, derived from short chain fatty acid intermediates. Secondary carnitine deficiency is present. Some patients with mild forms of ETF/ETF-DH deficiency may benefit from treatment with high doses of *riboflavin,* a precursor of the various flavoproteins involved in electron transfer.

DEFECTS IN THE KETONE SYNTHESIS PATHWAY

The final steps in production of ketones from mitochondrial fatty acid β-oxidation convert acetyl-CoA to acetoacetate through two enzymes of the HMG-CoA pathway (see Fig. 106.2).

β-Hydroxy-β-Methylglutaryl-CoA (HMG-CoA) Synthase Deficiency

See Chapter 103.6.

HMG-CoA synthase is the rate-limiting step in the conversion of acetyl-CoA derived from fatty acid β-oxidation in the liver to ketones. The presentation of deficiency is one of fasting hypoketotic hypoglycemia without evidence of impaired cardiac or skeletal muscle function. The urinary organic acid profile shows only a nonspecific hypoketotic dicarboxylic aciduria. Plasma and tissue carnitine levels are normal, in contrast to all the other disorders of fatty acid oxidation. A separate synthase enzyme, present in cytosol for cholesterol biosynthesis, is not affected. The HMG-CoA synthase defect is expressed only in the liver and kidney and cannot be demonstrated in cultured fibroblasts. The **diagnosis** can be made by genetic testing. *Avoiding fasting is usually a successful treatment.*

β-Hydroxy-β-Methylglutaryl-CoA Lyase Deficiency (3 Hydroxy-3-Methylgutaric Aciduria)

See Chapter 105.6.

DEFECTS IN KETONE BODY UTILIZATION

The ketone bodies β-hydroxybutyrate and acetoacetate are the end products of hepatic fatty acid oxidation and are important metabolic fuels for the brain during fasting. Three defects in utilization of ketones in brain and other peripheral tissues present as episodes of **hyperketotic coma**, with or without hypoglycemia.

Monocarboxylate Transporter-1 Deficiency

About 10 patients have been described with recurrent episodes of potentially lethal ketoacidosis, with or without hypoglycemia, caused by a deficiency of monocarboxylate transporter 1 (MCT1), a plasma membrane carrier encoded by *SLC16A1* that is required to transport ketones into tissues from plasma. Although the first cases identified were homozygous for inactivating pathogenic variants of *SLC16A1,* heterozygous carriers can also be affected. Affected patients develop severe ketoacidosis provoked by fasting or infections in their first years of life; hypoglycemia is not always present. The differential includes ketotic hypoglycemia associated with milder forms of glycogen storage disease, such as phosphorylase or phosphorylase kinase deficiency (see Chapter 107). **Treatment** for acute episodes includes IV dextrose to suppress lipolysis and inhibit ongoing ketogenesis. Long-term treatment includes avoidance of prolonged fasting stress. The **diagnosis** should be suspected by unusually severe ketosis and delayed suppression of ketones after starting treatment with dextrose. There are no specific metabolic markers or newborn screening methods. The diagnosis can be established by genetic sequencing of *SLC16A1*.

Succinyl-CoA:3-Ketoacid-CoA Transferase Deficiency

See Chapter 103.6.

The characteristic presentation of succinyl-CoA:3-ketoacid-CoA transferase **(SCOT)** deficiency is an infant with recurrent episodes of severe ketoacidosis induced by fasting. Plasma acylcarnitine and urine organic acid abnormalities do not distinguish SCOT deficiency from other causes of ketoacidosis. **Treatment** of episodes requires infusion of glucose and large amounts of bicarbonate until metabolic stability is reestablished. Patients usually exhibit inappropriate, persistent hyperketonemia even between episodes of illness. SCOT is responsible for activating acetoacetate in peripheral tissues, using succinyl CoA as a donor to form acetoacetyl-CoA. Deficient enzyme activity can be demonstrated in the brain, muscle, and fibroblasts from affected patients. The gene has been cloned, and numerous pathogenic variants have been characterized. The diagnosis is usually established by sequencing analysis of the *OXCT1* gene that encodes the SCOT enzyme.

β-Ketothiolase Deficiency

106.2 Disorders of Very Long Chain Fatty Acids and Other Peroxisomal Functions

Michael F. Wangler

PEROXISOMAL DISORDERS

Disorders of very long chain fatty acids (VLCFAs) fall within the broader group of peroxisomal diseases. The peroxisomal diseases are genetically determined disorders caused either by the failure to form or maintain the peroxisome or by a defect in the function of a single protein that is localized to the peroxisome. These disorders cause serious disability in childhood and occur more frequently and present a wider range of phenotypes than recognized in the past. Many, but not all, peroxisomal disorders are associated with elevations of VLCFAs.

Etiology

Peroxisomal disorders are subdivided into two major categories (Table 106.2). In the **peroxisomal biogenesis disorders (PBDs)**, the basic defect is the failure to import one or more proteins into the organelle. In the other group, defects affect a single peroxisomal protein (**single-enzyme defects**). The *peroxisome* is present in all cells except mature erythrocytes and is a subcellular organelle surrounded by a single membrane; there are >50 peroxisomal enzymes. Some enzymes are involved in the production and decomposition of hydrogen peroxide and others in lipid and amino acid metabolism. Peroxisomal enzymes have a unique system to ship them to the peroxisome that uses specific **peroxisome targeting sequences** (PTSs). These enzymes are first synthesized in their mature form on free polyribosomes and float free in the cytoplasm until their specific PTS is recognized. Most peroxisomal matrix proteins contain a **PTS1**, a short amino acid sequence at the carboxyl terminus. In addition, the amino-terminal–located **PTS2** is critical for the import of enzymes involved in plasmalogen

Table 106.2 Peroxisomal Disorder Classification, Disorders, and Genes

PEROXISOMAL BIOGENESIS DISORDERS	GENES
Peroxisome biogenesis disorder–Zellweger spectrum disorders (PBD-ZSD) Zellweger syndrome (severe PBD-ZSD) Neonatal adrenoleukodystrophy (intermediate PBD-ZSD) Infantile Refsum disease (mild PBD-ZSD)	*PEX1, PEX2, PEX3, PEX5, PEX6, PEX10, PEX11B, PEX12, PEX13, PEX14, PEX16, PEX19, PEX26*
Rhizomelic chondrodysplasia punctata, types 1 and 5 (RCDP1 and RCDP5)	*PEX7* and *PEX5*, respectively
SINGLE-ENZYME DEFECTS	
X-linked adrenoleukodystrophy	*ABCD1*
Acyl-CoA oxidase deficiency	*ACOX1*
D-Bifunctional protein deficiency	*HSD17B4*
2-Methylacyl-CoA racemase deficiency	*AMACR*
Rhizomelic chondrodysplasia punctata, types 2 and 3 (RCDP2 and RCDP3)	*AGPS, GNPAT*
Adult Refsum disease	*PHYH*

Table 106.3 Abnormal Laboratory Findings Common to Zellweger Spectrum Disorders

Defective oxidation and abnormal accumulation of very long chain fatty acids
Peroxisomes absent to reduced in number
Catalase in cytosol
Deficient synthesis and reduced tissue levels of plasmalogens
Deficient oxidation and age-dependent accumulation of phytanic acid
Defects in certain steps of bile acid formation and accumulation of bile acid intermediates
Defects in oxidation and accumulation of L-pipecolic acid
Increased urinary excretion of dicarboxylic acids

and branched-chain fatty acid metabolism. The peroxisome biogenesis machinery then recognizes, binds, and targets PTS-containing proteins to the peroxisome. This process involves a complex series of reactions mediated by at least 23 distinct proteins. These proteins, referred to as *peroxins,* are encoded by the *PEX* genes. Pathogenic genetic variants in these genes are the cause of PBDs.

Epidemiology

Except for X-linked adrenoleukodystrophy (ALD), all the peroxisomal disorders listed in Table 106.2 are inherited as *autosomal recessive diseases*. ALD is the most common peroxisomal disorder, with an estimated incidence of 1 in 17,000 live births. The combined incidence of the other peroxisomal disorders is estimated to be 1 in 50,000 live births, although with broader newborn screening, it is expected that the actual incidences of all the disorders of VLCFAs will be more accurately established.

Pathology

Absence or reduction in the number of peroxisomes is pathognomonic for disorders of peroxisome biogenesis. In most cases, a close examination of cells in these patients reveals membranous sacs that lack the normal complement of matrix proteins; these are peroxisome "ghosts," and they indicate the inability of the cell to properly localize peroxisomal proteins. Pathologic changes are observed in most organs and include profound and characteristic defects in neuronal migration, micronodular cirrhosis of the liver, renal cysts, chondrodysplasia punctata, sensorineural hearing loss, retinopathy, congenital heart disease, and dysmorphic features.

Pathogenesis

Clinical pathologic changes of the PBDs are secondary to the underlying peroxisome biogenesis defect. As a result, multiple peroxisomal enzymes fail to function in the PBDs (Table 106.3). PBDs include the Zellweger spectrum disorders **(PBD-ZSD)** and one form of rhizomelic chondrodysplasia punctata **(PBD-RCDP)**, which are distinguished by clinical phenotype and differences in the extent of biogenesis abnormality. In PBDs, enzymes that are synthesized cannot be properly located to the peroxisome and are thus degraded abnormally quickly because they are unprotected outside the peroxisome. However, it has yet to be clarified as to how specific peroxisome defects lead to each of the pathologic manifestations.

Pathogenic variants in 14 different *PEX* genes have been identified in PBDs. For PBD-RCDP, *PEX7* pathogenic variants are the most common, but rarer *PEX5* pathogenic variants are seen. The pattern and severity of pathologic features vary with the nature of the import defects and the degree of import impairment leading to the severity spectrum of PBD-ZSD. These gene defects lead to disorders named prior to recognizing their relationship to the peroxisome, namely, Zellweger syndrome, neonatal ALD, infantile Refsum disease, and RCDP. The first three disorders are considered to be a form of *clinical continuum,* with Zellweger syndrome the most severe **(severe PBD-ZSD)**, infantile Refsum disease the least severe **(mild PBD-ZSD)**, and neonatal ALD being intermediate **(intermediate PBD-ZSD)**. For PBD-ZSD, 13 genes can be affected to result in autosomal recessive disease *(PEX1, PEX2, PEX3, PEX5, PEX6, PEX10, PEX11B, PEX12, PEX13, PEX14, PEX16, PEX19, PEX26)*. Specific gene defects cannot be distinguished by clinical features. Clinical severity varies with the degree to which protein import is impaired. Pathogenic variants that completely abolish import are often associated with the severe PBD-ZSD or Zellweger phenotype, whereas a missense variant, in which some degree of import function is retained, leads to the somewhat milder presentations. A defect in *PEX7* or, very rarely, *PEX5*, which depend on peroxisomal import that use PTS2, is associated with RCDP. *PEX7* defects that leave the import partially intact are associated with milder phenotypes, some of which resemble classic (adult) Refsum disease.

The genetic disorders that involve single peroxisomal enzymes usually have clinical manifestations that are more restricted and relate to the single biochemical defect. The primary adrenal insufficiency of ALD is caused by an accumulation of VLCFAs in the adrenal cortex, and the peripheral neuropathy in adult Refsum disease is caused by the accumulation of phytanic acid in Schwann cells and myelin.

PBD-ZSD

Newborn infants with *severe* PBD-ZSD, previously described as **Zellweger syndrome**, show striking and consistent recognizable abnormalities. Of central diagnostic importance are the typical facial appearance (large anterior fontanelle, wide sutures, high forehead, hypoplastic supraorbital ridges, flat face, and broad nasal bridge; Fig. 106.3), severe weakness and hypotonia, neonatal seizures, and eye abnormalities. Because of the hypotonia and craniofacial appearance, Down syndrome may be suspected in neonates. Infants with severe PBD-ZSD rarely live more than a few months. More than 90% show postnatal growth failure. Table 106.4 lists the main clinical abnormalities.

Patients with *intermediate* PBD-ZSD, previously described as **neonatal ALD**, show fewer, less prominent craniofacial features. Neonatal seizures occur frequently. Psychomotor developmental delay is present; function remains in the range of severe intellectual disability, and development may regress after 3-5 years of age, likely from progressive leukodystrophy. Hepatomegaly, impaired liver function, pigmentary degeneration of the retina, and severely impaired hearing are invariably present. Adrenocortical function is usually impaired and may require adrenal hormone replacement. Chondrodysplasia punctata and renal cysts are absent.

Patients with *mild* PBD-ZSD, previously described as **infantile Refsum disease**, have survived to adulthood. They can walk, although gait may be ataxic and broad based. Cognitive function is generally

Fig. 106.3 Zellweger syndrome. Three affected neonates. Note the hypotonia, high forehead with shallow supraorbital ridges, anteverted nares, and mild micrognathia, as well as the talipes equinovarus and contractures at the knees. *(From Shaheen R, Al-Dirbashi OY, Al-Hassnan ZN, et al. Clinical, biochemical and molecular characterization of peroxisomal diseases in Arabs. Clin Genet. 2011;79[1]:60–70.)*

Table 106.4 Main Clinical Abnormalities in Zellweger Syndrome

	PATIENTS IN WHOM THE FEATURE WAS PRESENT	
ABNORMAL FEATURE	**NUMBER**	**%**
High forehead	58	97
Flat occiput	13	81
Large fontanelle(s), wide sutures	55	96
Shallow orbital ridges	33	100
Low/broad nasal bridge	23	100
Epicanthus	33	92
High-arched palate	35	95
External ear deformity	39	97
Micrognathia	18	100
Redundant skin fold of neck	13	100
Brushfield spots	5	83
Cataract/cloudy cornea	30	86
Glaucoma	7	58
Abnormal retinal pigmentation	6	40
Optic disc pallor	17	74
Severe hypotonia	94	99
Abnormal Moro response	26	100
Hyporeflexia or areflexia	56	98
Poor sucking	74	96
Gavage feeding	26	100
Epileptic seizures	56	92
Intellectual disability	45	100
Impaired hearing	9	40
Nystagmus	30	81

From Heymans HAS. Cerebro-hepato-renal (Zellweger) syndrome: Clinical and biochemical consequences of peroxisomal dysfunctions. Thesis, University of Amsterdam, 1984.

impaired, but accurate assessment is limited, usually by the presence of both vision and hearing impairment. Almost all have some degree of sensorineural hearing loss and pigmentary degeneration of the retina. They have moderately dysmorphic features that may include epicanthal folds, a flat nose bridge, and low-set ears. Early hypotonia and hepatomegaly with impaired function are common. Levels of plasma cholesterol and high-density and low-density lipoprotein are often moderately reduced. Chondrodysplasia punctata and renal cortical cysts are absent. Postmortem study in these mild PBD-ZSD cases reveals micronodular liver cirrhosis and small, hypoplastic adrenals. The brain shows no malformations, except for severe hypoplasia of the cerebellar granule layer and ectopic locations of the Purkinje cells in the molecular layer.

Some patients with PBD-ZSD have milder and atypical phenotypes. They may present with peripheral neuropathy or with retinopathy, impaired vision, or cataracts in childhood, adolescence, or adulthood and have been considered to have Charcot-Marie-Tooth disease or Usher syndrome. Some patients with *PEX16* variants present with cerebellar ataxia. Some patients have survived to the fifth decade.

Rhizomelic Chondrodysplasia Punctata

RCDP is characterized by the presence of stippled foci of calcification within the hyaline cartilage and is associated with short stature, cataracts (72%), and multiple malformations caused by contractures. Vertebral bodies have coronal clefting filled by cartilage that results from an embryonic arrest. Disproportionate short stature affects the proximal parts of the extremities (rhizomelia; Fig. 106.4A). Radiologic abnormalities consist of shortening of the proximal limb bones, metaphyseal cupping, and disturbed punctate ossification (Fig. 106.4B). Height, weight, and head circumference are less than the third percentile, and these children have a severe intellectual disability. Skin changes such as those observed in ichthyosiform erythroderma are present in approximately 25% of patients. RCDP can be caused by pathogenic variants in one of four genes *(PEX5, PEX7, AGPS, GNPAT)*. Defects in *PEX7*, which most frequently lead to the RCDP phenotype, may also lead to a milder phenotype with clinical manifestations similar to those of adult Refsum disease, a later-onset disorder described later.

Isolated Defects of Peroxisomal Fatty Acid Oxidation

In the group of single-enzyme defects, acyl-CoA oxidase and bifunctional enzyme deficiency involve a single enzymatic step in peroxisomal fatty acid oxidation. **Defects of bifunctional enzyme** are found in approximately 15% of patients who are initially suspected of having PBD-ZSD. Patients with isolated **acyl-CoA oxidase deficiency** have a somewhat milder phenotype that resembles mild or intermediate PBD-ZSD or Usher syndrome and typically comes to attention because of the development of an early childhood leukodystrophy.

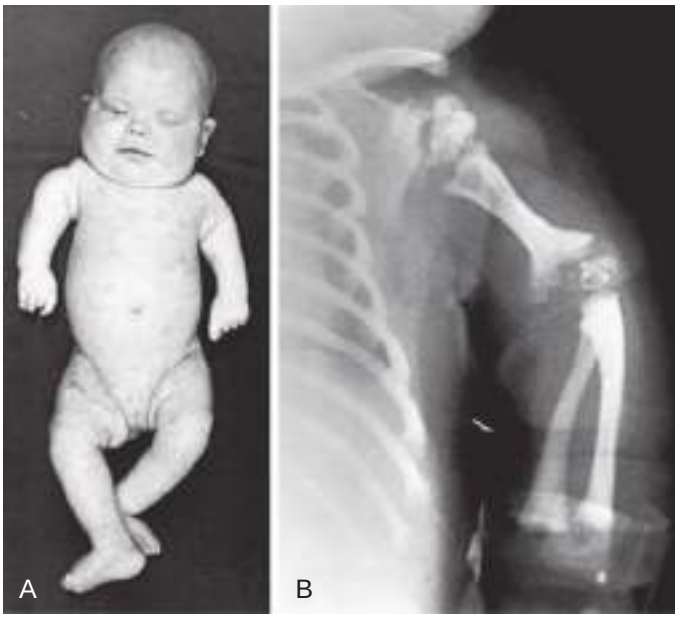

Fig. 106.4 A, Newborn infant with rhizomelic chondrodysplasia punctata. Note the severe shortening of the proximal limbs, the depressed bridge of the nose, hypertelorism, and widespread scaling skin lesions. B, Note the marked shortening of the humerus and epiphyseal stippling at the shoulder and elbow joints. *(Courtesy John P. Dorst, MD.)*

Isolated Defects of Plasmalogen Synthesis

Plasmalogens are lipids in which the first of three glycerol carbons is linked to an alcohol rather than a fatty acid. They are synthesized through a complex series of reactions, the first two steps of which are catalyzed by the peroxisomal enzymes dihydroxyacetone phosphate alkyl transferase (DHAPT, encoded by the gene *GNPAT*) and synthase (AGPS, encoded by the gene *AGPS*). Deficiency of either of these enzymes leads to RCDP types 2 and 3, respectively, phenotypes that are clinically indistinguishable from each other and from the peroxisomal import disorder RCDP1. This latter disorder is caused by a defect in *PEX7,* the receptor for PTS2 upon which DHAPT and AGPS are dependent for peroxisomal import. RCDP1 shares the severe deficiency of plasmalogens with these single-enzyme disorders but also has defects of phytanic oxidation. The fact that these single genetic disorders are associated with the full phenotype of RCDP suggests that a deficiency of plasmalogens is sufficient to produce it.

Adult (Classic) Refsum Disease

The defective enzyme (phytanoyl-CoA hydroxylase, encoded by the *PHYH* gene) is localized to the peroxisome. The manifestation of Refsum disease includes impaired vision from retinitis pigmentosa, anosmia, ichthyosis, peripheral neuropathy, ataxia, and occasionally cardiac arrhythmias. In contrast to infantile Refsum disease, cognitive function is normal, and there are no congenital malformations. Refsum disease often does not manifest until young adulthood, but visual disturbances such as night blindness, ichthyosis, and peripheral neuropathy may already be present in childhood and adolescence. Early diagnosis is important because institution of a phytanic acid–restricted diet can reverse the peripheral neuropathy and prevent the progression of the visual and central nervous system (CNS) manifestations. Adult Refsum disease may also be caused by defects in *PEX7*.

2-Methylacyl-CoA Racemase Deficiency (AMACR)

This disorder is caused by an enzyme defect that leads to the accumulation of the branched-chain fatty acids (phytanic and pristanic acid) and bile acids. Individuals present with typically an adult-onset peripheral neuropathy and may also have pigmentary degeneration of the retina.

Atypical Autosomal Dominant Disorders

Peroxisomal disorders are classically autosomal recessive in family pedigrees. X-linked adrenoleukodystrophy is a key exception. Several other exceptions of rare dominant inheritance of peroxisomal disease manifesting as neurologic disease have emerged for a few peroxisomal genes, including *ACOX1, PEX6*, and *DNM1L*.

Laboratory Findings

Clinical suspicion would be followed by specific biochemical determination of an abnormality and then confirmation through genetic testing targeted to specific genes. However, an extended gene panel and exome and genome testing have been used to identify pathogenic variants or variants of uncertain significance (VUS) in peroxisomal genes. *These patients still require biochemical testing for confirmation.* In addition, newborn screening for X-linked ALD using dried blood spots on filter paper in states across the United States and many parts of Europe also identifies other forms of peroxisomal deficiency. Early recognition of peroxisomal disorders in newborns will be a clinical reality.

Whether based on clinical suspicion, an abnormal newborn screen, or reported genetic variants, the biochemical characterization of peroxisomal disorders is a necessary step and uses the generally available testing strategy listed in Table 106.5. Measurement of plasma VLCFA levels is the most common assay. It must be emphasized that although plasma VLCFA levels are elevated in many patients with peroxisomal disorders and the same defect is the indirect basis for the newborn screen assay, this is not always the case. The most important exception is RCDP, in which VLCFA levels are normal but plasma phytanic acid levels are increased and red blood cell (RBC) plasmalogen levels are reduced. In other peroxisomal disorders, the biochemical abnormalities are still more restricted. Therefore a panel of tests is recommended and includes plasma levels of VLCFAs and phytanic, pristanic, and pipecolic acids and RBC levels of plasmalogens. Tandem mass spectrometry techniques also permit convenient quantitation of bile acids in plasma and urine. This panel of tests can be performed on very small amounts of venous blood and permits detection of most peroxisomal disorders.

Definition of the molecular defect either through gene panel testing or exome sequencing in the *proband* is essential for carrier detection and speeds prenatal diagnosis. Characterization of the pathogenic variant may be of prognostic value in patients with *PEX1* defects. This defect is present in approximately 60% of PBD patients, and about half the *PEX1* defects have the G843D allele, which is associated with a significantly milder phenotype than found in other pathogenic variants.

Diagnosis

Several noninvasive laboratory tests permit precise and early diagnosis of peroxisomal disorders (see Table 106.5). The challenge in PBDs is to differentiate them from the large variety of other conditions that can cause hypotonia, seizures, failure to thrive, or dysmorphic features. Experienced clinicians readily recognize classic Zellweger syndrome by its clinical manifestations. However, more mildly affected PBD-ZSD patients often do not show the full clinical spectrum of disease and may be identifiable only by laboratory assays. Clinical features that warrant diagnostic assessment include intellectual disability; weakness and hypotonia; dysmorphic features; neonatal seizures; retinopathy, glaucoma, or cataracts; hearing deficits; enlarged liver and impaired liver function; and chondrodysplasia punctata. The presence of one or more of these abnormalities increases the likelihood of this diagnosis. Atypical milder forms presenting as peripheral neuropathy have also been described.

Some patients with the isolated defects of peroxisomal fatty acid oxidation resemble those with ZSD and can be detected by the demonstration of abnormally high levels of VLCFAs.

Patients with RCDP must be distinguished from patients with *other* causes of chondrodysplasia punctata. RCDP is suspected clinically because of the shortness of limbs, developmental delays, and ichthyosis. The most decisive laboratory test is the demonstration of abnormally low plasmalogen levels in RBCs and an alteration in *PEX7*.

Table 106.5 Diagnostic Biochemical Abnormalities in Peroxisomal Disorders

DISORDER	VLCFA	PHYTANIC ACID	PRISTANIC ACID	PLASMALOGENS
PBD-ZSD	↑↑	↑*	↑*	↓
RCDP	Nl	↑	Nl	↓↓
ALD	↑	Nl	Nl	Nl
ACoX	↑	Nl	Nl	Nl
Bifunctional enzyme deficiency	↑	↑	↑	Nl
AMACR	Nl	↑	↑	Nl
Refsum disease	Nl	↑	↑	Nl

*Phytanic acid and pristanic acid accumulation is age dependent, and normal (Nl) levels may be seen in infants and young children.
VLCFA, Very long chain fatty acids; ZSD, Zellweger spectrum disorder; RCDP, rhizomelic chondroplasia punctata; ALD, adrenoleukodystrophy; ACoX, acyl-CoA oxidase deficiency; AMACR, 2-methylacyl-CoA racemase deficiency.

Complications
Patients with severe PBD-ZSD have multiple disabilities involving muscle tone, swallowing, cardiac abnormalities, liver disease, and seizures. These conditions are treated symptomatically, but the prognosis is poor, and most patients succumb in the first years of life. Similarly, individuals with RCDP have multiple systemic and neurologic issues. In addition, they may develop spinal cord compression at any level of the spine.

Treatment
The most effective therapy is the dietary treatment of adult Refsum disease with a phytanic acid–restricted diet. However, this only applies to this specific condition.

For patients with the somewhat milder variants of the peroxisome import disorders, success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids or cochlear implants, augmentative and alternative communication, nutrition, and support for the families. Although most patients continue to function in the impaired range, some make significant gains in self-help skills, and several are in stable condition in their teens or even early 20s.

Attempts to mitigate some of the secondary biochemical abnormalities include the oral administration of docosahexaenoic acid (DHA). The DHA level is greatly reduced in patients with disorders of peroxisome biogenesis, and this therapy normalizes DHA plasma levels. Although there were anecdotal reports of clinical improvement with DHA therapy, a randomized placebo-controlled study failed to find benefit.

Genetic Counseling
Most of these disorders can be diagnosed prenatally. Prenatal testing using chorionic villus sampling or amniocentesis enables genetic testing when the alteration is known, but biochemical measurements may be made using the same tests as described for postnatal diagnosis (see Table 106.5). Because of the 25% recurrence risk with autosomal recessive inheritance, couples with an affected child should be advised about the availability of prenatal and preconception diagnosis.

ADRENOLEUKODYSTROPHY
ALD is an X-linked disorder associated with the accumulation of saturated VLCFAs and a progressive dysfunction of the adrenal cortex and nervous system. It is the most common peroxisomal disorder.

Etiology
The key biochemical abnormality in ALD is the tissue accumulation of saturated VLCFAs, with a carbon chain length of 24 or more. Excess hexacosanoic acid ($C_{26:0}$) is the most striking and characteristic feature. This accumulation of fatty acids is caused by genetically deficient peroxisomal degradation of fatty acid. The defective gene *(ABCD1)* codes for a peroxisomal membrane protein (ALDP, the ALD protein). Many alterations in *ABCD1* have been determined to be pathogenic, with over half these being private or unique to the family. There is no genotype-phenotype correlation, as wide ranges of clinical severity can occur within a family across multiple individuals with the same pathogenic variant. A curated database of pathogenic variants is maintained (www.x-ald.nl). The mechanism by which the ALDP defect leads to VLCFA accumulation appears to be a disruption of transport of saturated fatty acids into the peroxisome, with resultant continued progressive elongation of fatty acids.

Epidemiology
The incidence of ALD in males is 1 in 21,000, and the combined incidence of ALD males and heterozygous females in the general population is estimated to be 1 in 17,000. All ethnicities are affected. The various phenotypes often occur in members of the same kindred.

Pathology
Characteristic lamellar cytoplasmic inclusions can be demonstrated on electron microscopy in adrenocortical cells, testicular Leydig cells, and nervous system macrophages. These inclusions probably consist of cholesterol esterified with VLCFA. They are most prominent in cells of the zona fasciculata of the adrenal cortex, which at first are distended with lipids and subsequently atrophy.

The nervous system displays two types of ALD lesions. In the severe cerebral form, demyelination is associated with an inflammatory response manifested by the accumulation of perivascular lymphocytes that is most intense in the involved region. In the slowly progressive adult form, **adrenomyeloneuropathy** (AMN), the main finding is a distal axonopathy that affects the long tracts in the spinal cord. In this form the inflammatory response is mild or absent.

Pathogenesis
The adrenal dysfunction is probably a direct consequence of the accumulation of VLCFAs. The cells in the adrenal zona fasciculata are distended with abnormal lipids. Cholesterol esterified to VLCFA is relatively resistant to adrenocorticotropic hormone (ACTH)–stimulated cholesterol ester hydrolases, and this limits the capacity to convert cholesterol to active steroids. In addition, $C_{26:0}$ excess increases the viscosity of the plasma membrane, which may interfere with receptor and other cellular functions.

There is no defined correlation between the neurologic phenotype and the nature of the pathogenic variant or the severity of the biochemical defect as assessed by plasma VLCFA levels or between the degree of adrenal involvement and nervous system involvement. The severity of the illness and rate of progression correlate with the intensity of the inflammatory response. The inflammatory response may be partially cytokine mediated and may involve an autoimmune response triggered in an unknown way by the excess of VLCFAs. Mitochondrial damage and oxidative stress also appear to contribute. Approximately half the patients do not experience the inflammatory response, although the basis of this difference is not understood.

Clinical Manifestations

There are five relatively distinct ALD phenotypes, three of which present in childhood with symptoms and signs. In all the phenotypes, development is usually normal in the first 3-4 years of life.

In the **childhood cerebral form** of ALD, symptoms most often are first noted between ages 4 and 8 years. The most common initial manifestations are hyperactivity, inattention, and worsening school performance in a child who had previously been a good student. *Auditory discrimination* is often impaired, although tone perception is preserved. This may be evidenced by difficulty in using the telephone and greatly impaired performance on intelligence tests in items that are presented verbally. Spatial orientation is often impaired. Other initial symptoms are disturbances of vision, ataxia, poor handwriting, seizures, and strabismus. Visual disturbances are often caused by involvement of the parietooccipital cortex rather than eye or optic tract abnormalities, which leads to variable and seemingly inconsistent visual capacity. Seizures occur in most patients and may represent the first manifestation of the disease. Some patients present with increased intracranial pressure. Impaired cortisol response to ACTH stimulation is present in 85% of patients, and mild hyperpigmentation is noted. In most patients with this phenotype, adrenal dysfunction is recognized only after the condition is diagnosed because of the cerebral symptoms. Cerebral childhood ALD tends to progress rapidly with increasing spasticity and paralysis, visual and hearing loss, and loss of ability to speak or swallow. The mean interval between the first neurologic symptom and an apparently unresponsive wakeful state is 1.9 years. Patients may continue in this apparently unresponsive wakeful state for ≥10 years.

Adolescent ALD designates patients who experience neurologic symptoms between ages 10 and 21 years. The manifestations resemble those of childhood cerebral ALD except that progression is slower. Approximately 10% of patients present acutely with status epilepticus, adrenal crisis, acute encephalopathy, or coma.

AMN first manifests in late adolescence or adulthood as a progressive paraparesis caused by long tract degeneration in the spinal cord. Approximately half the affected males also have involvement of the cerebral white matter.

The **Addison-only** phenotype is an important condition. Of male patients with Addison disease, 25% may have the biochemical defect of ALD. Many of these patients have intact neurologic systems, whereas others have subtle neurologic signs. Many acquire AMN in adulthood.

The term **asymptomatic ALD** is applied to persons who have the biochemical defect of ALD but are free of neurologic or endocrinal disturbances. Almost all persons with the gene defect eventually become neurologically symptomatic.

Approximately 50% of female heterozygotes acquire a syndrome that resembles AMN but is milder and of later onset. Adrenal insufficiency and cerebral disease are rare.

Cases of typical ALD have occurred in relatives of those with AMN. One of the most difficult problems in the management of ALD is the common observation that affected individuals in the same family may have quite different clinical courses. For example, in one family, an affected male may have severe classic ALD culminating in death by age 10 years, and another brother will have the later-onset AMN.

Laboratory and Radiographic Findings

The most specific and important laboratory finding is the demonstration of abnormally high levels of VLCFAs in plasma, RBCs, or cultured skin fibroblasts. Positive results are obtained in all male patients with ALD and in approximately 85% of female carriers of ALD. Pathogenic variant analysis is the most reliable method for the identification of carriers. Simply finding a variation in ABCD1 is not adequate for making the diagnosis of ALD. It must be shown to segregate with elevated VLCFA levels.

Neuroimaging

Patients with childhood cerebral or adolescent ALD have characteristic white matter lesions on MRI. In 80% of patients, the lesions are symmetric and involve the splenium of the corpus callosum and periventricular white matter in the posterior parietal and occipital lobes. Many will show a garland of contrast enhancement adjacent and anterior to the posterior hypodense lesions (Fig. 106.5). This zone corresponds to the zones of intense perivascular lymphocytic infiltration where the blood-brain barrier breaks down. In 10–15% of patients, the initial lesions are frontal. Unilateral lesions that produce a mass effect suggestive of a brain tumor may occur rarely. MRI provides a clearer delineation of normal and abnormal white matter than does CT and is the preferred imaging modality.

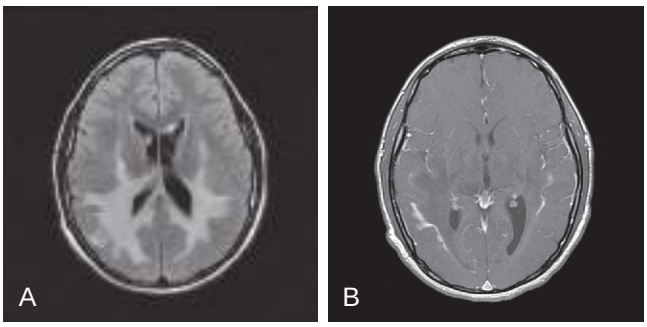

Fig. 106.5 Characteristic MRI findings in cerebral adrenoleukodystrophy. **A,** Symmetric T2-weighted MRI abnormalities involve the posterior white matter, including the corpus callosum. **B,** Contrast administration reveals a garland of enhancement.

Impaired Adrenal Function

More than 85% of patients with the childhood form of ALD have elevated levels of ACTH in plasma and a subnormal rise of cortisol levels in plasma after IV injection of ACTH.

Newborn Screening and Diagnosis

Diagnosis of asymptomatic males is available by newborn screening, which allows for early diagnosis of ALD years before the manifestations of disease. Males then enter a program of surveillance for adrenal insufficiency and early detection of potential cerebral disease. Females identified through these programs should also have confirmatory testing, genetic counseling for the family, and screening of other at-risk males. Females do not generally require any other monitoring in childhood. This early screening paradigm allows for early surveillance of ALD neurologic symptoms, which are difficult to distinguish from the more common attention-deficit disorders or learning disabilities of school-age children. Early diagnosis could lead to early cortisol treatment for adrenal problems, which could be life-threatening. Early bone marrow transplant is likely to result as a benefit of screening. For positive newborn screens or for individuals with clinical suspicion of ALD, confirmatory VLCFA testing and genetic counseling should be provided.

The Earliest Manifestations of Childhood Cerebral ALD

Rapid progression, signs of dementia, or difficulty in auditory discrimination suggest ALD. Even in early stages, neuroimaging shows abnormal changes. Other leukodystrophies or multiple sclerosis may sometimes mimic these radiographic findings, although early ALD has more of a predilection for the posterior brain than its mimics. Definitive diagnosis depends on demonstration of VLCFA excess, which occurs only in ALD and the other peroxisomal disorders.

Cerebral forms of ALD, especially if asymmetric, may be misdiagnosed as gliomas or other mass lesions. Individuals have received brain biopsy and, rarely, other therapies before the correct diagnosis was made. Measurement of VLCFAs in plasma is the most reliable differentiating test.

Adolescent or adult cerebral ALD can be confused with psychiatric disorders, dementing disorders, multiple sclerosis, or epilepsy. The first clue to the diagnosis of ALD may be the demonstration of characteristic white matter lesions by neuroimaging; VLCFA assays are confirmatory.

ALD *cannot* be distinguished clinically from other forms of Addison disease; it is recommended that assays of VLCFA levels be performed

in all male patients with Addison disease. ALD patients *do not* usually have antibodies to adrenal tissue in their plasma.

Complications

An avoidable complication is the occurrence of adrenal insufficiency. The most difficult neurologic problems are those related to bed rest, contracture, coma, and swallowing disturbances. Other complications involve behavioral disturbances and injuries associated with defects of spatial orientation, impaired vision and hearing, and seizures.

Treatment

Corticosteroid replacement for adrenal insufficiency or adrenocortical hypofunction is effective. It may be lifesaving and may increase general strength and well-being, but it does not alter the course of the neurologic disability.

Bone Marrow Transplantation

Bone marrow transplantation (BMT) or hematopoietic stem cell therapy (HSCT) benefits patients who show early evidence of the inflammatory demyelination characteristic of the rapidly progressive neurologic disability in young males and adolescents with the cerebral ALD phenotype. BMT carries risk, and patients must be evaluated and selected with care. The mechanism of the beneficial effect is incompletely understood. Bone marrow–derived cells do express ALDP, the protein that is deficient in ALD; approximately 50% of brain microglial cells are bone marrow derived. The favorable effect may be caused by modification of the brain inflammatory response. Follow-up of young males and adolescents who had early cerebral involvement has shown stabilization. On the other hand, BMT does not arrest the course in those who already had severe brain involvement and may accelerate disease progression under these circumstances. The ALD MRI score and the use of performance measures on IQ testing have shown some predictive ability for boys likely to benefit from this procedure. Transplant is not recommended in patients with performance IQ significantly <80. Unfortunately, in more than half the patients who are diagnosed because of neurologic symptoms, the illness is so advanced at diagnosis that they are not candidates for transplant.

Consideration of BMT is most relevant in neurologically asymptomatic or mildly involved patients. Screening at-risk relatives of symptomatic patients identifies these patients most frequently. Screening by measurement of plasma VLCFA levels in patients with Addison disease may also identify candidates for BMT. Because of its risk (10–20% mortality) and because up to 50% of untreated patients with ALD do not develop inflammatory brain demyelination, transplant is not recommended in patients who are free of demonstrable brain involvement on MRI. MRI is also of key importance for the crucial decision of whether transplant should be performed. MRI abnormalities precede clinically evident neurologic or neuropsychologic abnormalities. The brain MRI should be monitored at 6-month intervals in neurologically asymptomatic young males and adolescents age 3-15 years. If the MRI is normal, BMT is not indicated. If brain MRI abnormalities develop, the young male should be evaluated by a center familiar with transplant for ALD. This should include MRI, neurologic, and neuropsychologic evaluations. It is not known whether BMT has a favorable effect on the noninflammatory spinal cord involvement in adults with the adrenomyeloneuropathy phenotype.

Autologous hematopoietic stem cell gene therapy **(elivaldogene autotemcel)** is approved for patients 4-17 years of age to slow the neurologic progression of early, active cerebral adrenoleukodystrophy.

Supportive Therapy

The progressive behavioral and neurologic disturbances associated with the childhood form of ALD are extremely difficult for the family. ALD patients require the establishment of a comprehensive management program and partnership among the family, physician, visiting nursing staff, school authorities, and counselors. In addition, parent support groups (e.g., United Leukodystrophy Foundation) are often helpful. Communication with school authorities is important because under the provisions of Public Law 94-142, children with ALD qualify for special services as "other health impaired" or "multi-handicapped." Depending on the rate of progression of the disease, special needs might range from relatively low-level resource services within a regular school program to home- and hospital-based teaching programs for children who are not mobile.

Management challenges vary with the stage of the illness. The early stages are characterized by subtle changes in affect, behavior, and attention span. Counseling and communication with school authorities are of prime importance. Changes in the sleep–wake cycle can be benefited by the judicious use of nighttime sleep medications.

As the leukodystrophy progresses, the modulation of muscle tone and support of bulbar muscular function are major concerns. Baclofen in gradually increasing doses (5 mg twice a day to 25 mg four times a day) is an effective pharmacologic agent for the treatment of acute episodic painful muscle spasms. Other agents may also be used, with care taken to monitor the occurrence of side effects and drug interactions. As the leukodystrophy progresses, bulbar muscular control is lost. Although initially this can be managed by changing the diet to soft and pureed foods, most patients eventually require a gastrostomy tube. At least 30% of patients have focal or generalized seizures that usually readily respond to standard anticonvulsant medications.

Genetic Counseling and Prevention

Genetic counseling and appropriate monitoring are of crucial importance. Extended-family screening should be offered to all at-risk relatives of symptomatic patients; one program led to the identification of >250 asymptomatic affected males and 1,200 women heterozygous for ALD. The plasma assay permits reliable identification of affected males in whom plasma VLCFA levels are increased already on the day of birth. Identification of asymptomatic males permits institution of steroid replacement therapy when appropriate and prevents adrenal crisis, which may be fatal. Monitoring of brain MRI also permits identification of patients who are candidates for BMT at a stage when this procedure has the greatest chance of success. Plasma VLCFA assay is recommended in all male patients with Addison disease. ALD has been shown to be the cause of adrenal insufficiency in >25% of boys with Addison disease of unknown cause. Identification of women heterozygous for ALD is more difficult than that of affected males. Plasma VLCFA levels are normal in 15–20% of heterozygous women, and failure to note this has led to serious errors in genetic counseling. DNA analysis permits accurate identification of carriers, provided that the pathogenic variant has been defined in a family member, and this is the procedure recommended for the identification of heterozygous women.

Prenatal diagnosis of affected male fetuses can be achieved by determination of the known pathogenic variant or by the measurement of VLCFA levels in cultured amniocytes or chorionic villus cells. Whenever a new patient with ALD is identified, a detailed pedigree should be constructed and efforts made to identify all at-risk female carriers and affected males. These investigations should be accompanied by careful and sympathetic attention to social, emotional, and ethical issues during counseling.

106.3 Disorders of Lipoprotein Metabolism and Transport

Lee A. Pyles

EPIDEMIOLOGY OF BLOOD LIPIDS AND CARDIOVASCULAR DISEASE

There is a strong association between average intake of saturated fats, plasma cholesterol, and mortality from coronary heart disease (CHD). Of all common chronic diseases, none is so clearly influenced by both environmental *and* genetic factors as CHD. This multifactorial disorder is strongly associated with increasing age and male gender, although it is increasingly apparent that heart disease is underrecognized in women. Tobacco use confers a twofold higher lifetime risk.

Sedentary activity and high intake of processed sugars leading to adiposity increase risk through differences in the plasma levels of atherogenic lipoproteins. Family history reflects the combined influence of lifestyle and genetic predisposition to early heart disease. Risk of premature heart disease associated with positive family history is 1.7 times higher than in families with no such history.

Atherosclerosis begins during childhood. The Johns Hopkins Precursors Study demonstrated that White male medical students with blood cholesterol levels in the lowest quartile showed only a 10% incidence of CHD 3 decades later, whereas those in the highest quartile had a 40% incidence. The Pathobiological Determinants of Atherosclerosis in Youth Study demonstrated a significant relationship between the weight of the abdominal fat pad and the extent of atherosclerosis found at autopsy on individuals 15-34 years of age. The Bogalusa Heart Study of more than 3,000 Black and White children and adolescents has provided the most comprehensive longitudinal data relating the presence and severity of CHD risk factors with semi-quantifiable severity of atherosclerosis. Coronary atherosclerosis was present in 8.5% of military autopsies performed after combat or unintentional injuries.

The *fetal origins hypothesis* is based on the observation that infants born with low birthweight have a higher incidence of heart disease as adults. Epidemiologic studies support the idea that prenatal and early postnatal conditions may affect adult health status. Children who are large for gestational age at birth and exposed to an intrauterine environment of either diabetes or maternal obesity are at increased risk of eventually developing **metabolic syndrome** (insulin resistance, type 2 diabetes, obesity, CHD). Breastfeeding preterm infants confers a long-term cardioprotective benefit 13-16 years later. Those adolescents who were breastfed as infants had lower C-reactive protein (CRP) concentrations and a 14% lower low-density lipoprotein (LDL)/high-density lipoprotein (HDL) ratio than formula-fed infants. The impact of early nutrition and other lifestyle variables on gene expression via *epigenetics* is one mechanism by which adult metabolism and body composition may be influenced.

Secondary causes of hyperlipidemia may be the result of drugs (cyclosporine, corticosteroids, isotretinoin, protease inhibitors, alcohol, thiazide diuretics, β-blocking agents, valproate) or various diseases (nephrotic syndrome, hypothyroidism, Cushing syndrome, anorexia nervosa, obstructive jaundice). Psychotropic medications, including second-generation antipsychotics such as olanzapine, are also associated with dyslipidemia, obesity, and insulin resistance.

BLOOD LIPIDS AND ATHEROGENESIS

Numerous epidemiologic studies demonstrate the association of hypercholesterolemia, referring to elevated total, non-HDL, and LDL blood cholesterol, with atherosclerotic disease. Atherosclerosis affects primarily the coronary arteries but may also involve the aorta, arteries of the lower extremities, and carotid arteries.

The early stage of development of atherosclerosis is thought to begin with vascular endothelial dysfunction and intima-media thickness, which has been shown to occur in preadolescent children with risk factors such as obesity or familial hypercholesterolemia. The complex process of penetrating the intimal lining of the vessel may result from a variety of insults, including the presence of highly toxic oxidized LDL particles. Lymphocytes and monocytes penetrate the damaged endothelial lining, where they become macrophages laden with LDL lipids and then become foam cells. Such accumulation is counterbalanced by HDL particles capable of removing lipid deposits from the vessel wall. Fundamental to plaque formation is an inflammatory process (elevated CRP) involving macrophages and the arterial wall. The deposition of lipid within the subendothelial lining of the arterial wall appears macroscopically as fatty streaks, which may to some degree be reversible. A later stage of plaque development involves disruption of arterial smooth muscle cells stimulated by the release of tissue cytokines and growth factors. The *atheroma* is composed of a core of fatty substance separated from the lumen by collagen and smooth muscle (Fig. 106.6). Growth of the atherosclerotic plaque may result in ischemia of the tissue supplied by the artery. Chronic inflammation within the atheroma results in plaque instability and subsequent rupture. Platelet adherence leads to clot formation at the site of rupture, resulting in myocardial infarction (MI) or a cerebrovascular accident (CVA), depending on the site of thrombosis or thromboembolism.

PLASMA LIPOPROTEIN METABOLISM AND TRANSPORT

Lipoproteins are soluble complexes of lipids and proteins that effect transport of fat absorbed from the diet, or synthesis by the liver and adipose tissues, for utilization and storage. Dietary fat is transported from the small intestine as chylomicrons. Lipids synthesized by the liver as very low-density lipoproteins (VLDLs) are catabolized to intermediate-density lipoproteins (IDLs) and LDLs. HDL is fundamentally involved in VLDL and chylomicron metabolism and cholesterol transport. Nonesterified free fatty acids are metabolically active lipids derived from lipolysis of triglycerides stored in adipose tissue and bound to albumin for circulation in the plasma (Fig. 106.7).

Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins (Fig. 106.8). The density of the several classes of lipoproteins is inversely proportional to the ratio of lipid to protein, which is generally denser (Fig. 106.9).

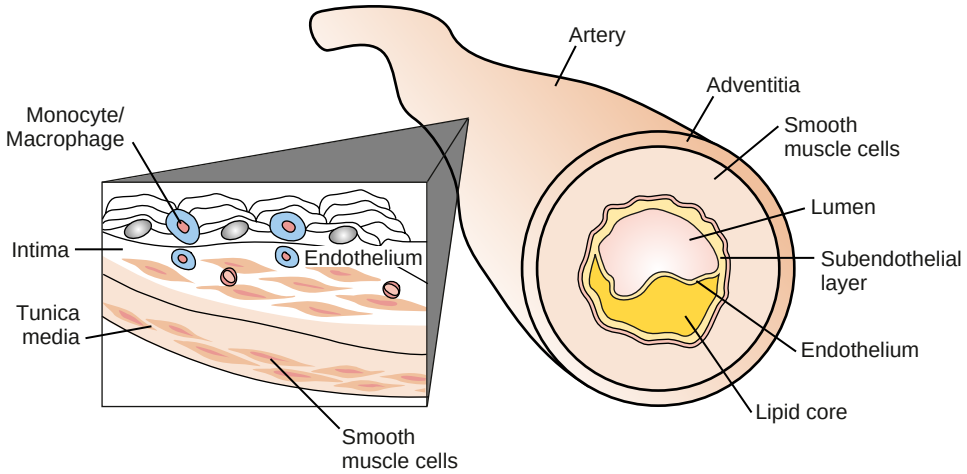

Fig. 106.6 The early stage of development of atherosclerosis begins with penetration of the intimal lining of the vessel by inflammatory cells. Deposition of lipid within the subendothelial lining of the arterial wall eventually leads to disruption of smooth muscle cells to form an atheromatous lipid core that impinges on the lumen. Chronic inflammation leads to plaque instability, setting the stage for plaque rupture and complete occlusion of the vessel lumen by clot formation.

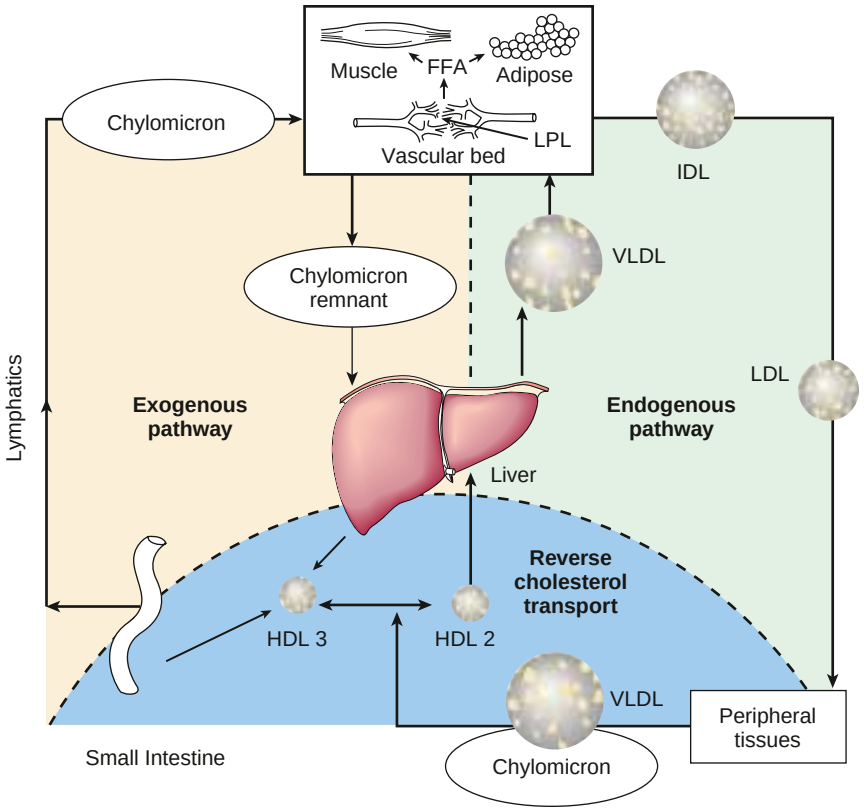

Fig. 106.7 The exogenous, endogenous, and reverse cholesterol pathways. The exogenous pathway transports dietary fat from the small intestine as chylomicrons to the periphery and the liver. The endogenous pathway denotes the secretion of very low-density lipoprotein (VLDL) from the liver and its catabolism to intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL). Triglycerides are hydrolyzed from the VLDL particle by the action of lipoprotein lipase (LPL) in the vascular bed, yielding free fatty acids (FFAs) for utilization and storage in muscle and adipose tissue. High-density lipoprotein (HDL) metabolism is responsible for the transport of excess cholesterol from the peripheral tissues back to the liver for excretion in the bile. Nascent HDL-3 particles derived from the liver and small intestine are esterified to more mature HDL-2 particles by enzyme-mediated movement of chylomicron and VLDL into the HDL core, which is removed from the circulation by endocytosis.

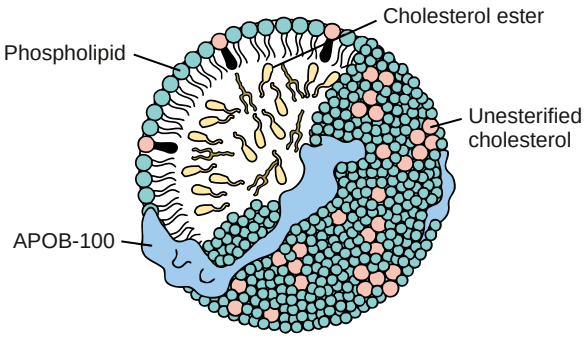

Fig. 106.8 Schematic of low-density lipoprotein. Lipoprotein consists of a central core of cholesteryl esters surrounded by phospholipids, cholesterol, and protein.

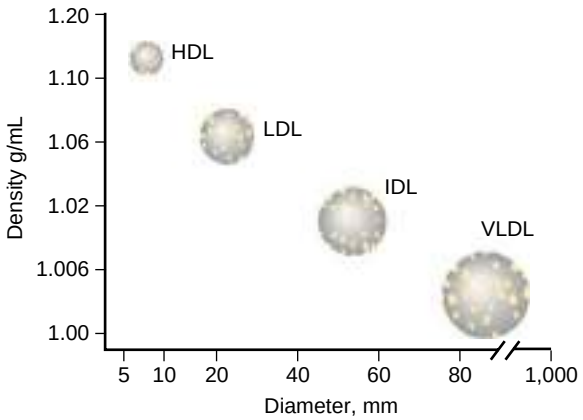

Fig. 106.9 The density of the several classes of lipoprotein is inversely proportional to the ratio of lipid to protein. As lipid is less dense than protein, the more lipid contained in the particle increases its size and decreases its density. HDL, High-density lipoprotein; LDL, low-density lipoprotein; IDL, intermediate-density lipoprotein; VLDL, very low-density lipoprotein.

Constituent proteins known as *apolipoproteins* are responsible for a variety of metabolic functions in addition to their structural role, including as cofactors or inhibitors of enzymatic pathways and mediators of lipoprotein binding to cell surface receptors (Table 106.6). **ApoA** is the major apolipoprotein (Apo) of HDL. **ApoB** is present in LDL, VLDL, IDL, and chylomicrons. ApoB-100 is derived from the liver, whereas apoB-48 comes from the small intestine. ApoC-I, C-II, and C-III are small peptides important in triglyceride metabolism. Loss of function and disruptive pathogenic variants of the *APOC3* gene are associated with low levels of triglycerides and a reduced risk of ischemic CHD. Likewise, **apoE**, which is present in VLDL, HDL, chylomicrons, and chylomicron remnants, plays an important role in the clearance of triglycerides.

Transport of Exogenous (Dietary) Lipids

All dietary fat except medium-chain triglycerides is efficiently carried into the circulation by way of lymphatic drainage from the intestinal mucosa. Triglyceride and cholesteryl esters combine with apoA and apoB-48 in the intestinal mucosa to form chylomicrons, which are carried into the peripheral circulation via the lymphatic system. HDL particles contribute apoC-II to the chylomicrons, required for the activation of *lipoprotein lipase* (LPL) within the capillary endothelium of adipose, heart, and skeletal muscle tissue. Free fatty acids are oxidized, esterified for storage as triglycerides, or released into the circulation bound to albumin for transport to the liver. After hydrolysis of the triglyceride core from the chylomicron, apoC particles are recirculated back to HDL. The subsequent contribution of apoE from HDL to the remnant chylomicron facilitates binding of the particle to the hepatic LDL receptor (LDL-R). Within the hepatocyte, the chylomicron remnant may be incorporated into membranes, resecreted as lipoprotein

Table 106.6 Characteristics of the Major Lipoproteins

LIPOPROTEIN	SOURCE	SIZE (nm)	DENSITY (g/mL)	COMPOSITION		
				PROTEIN (%)	LIPID (%)	APOLIPOPROTEINS
Chylomicrons	Intestine	80-1,200	<0.95	1-2	98-99	C-I, C-II, C-III, E, A-I, A-II, A-IV, B-48
Chylomicron remnants	Chylomicrons	40-150	<1.0006	6-8	92-94	B-48, E
VLDL	Liver, intestine	30-80	0.95-1.006	7-10	90-93	B-100, C-I, C-II, C-III
IDL	VLDL	25-35	1.006-1.019	11	89	B-100, E
LDL	VLDL	18-25	1.019-1.063	21	79	B-100
HDL	Liver, intestine VLDL, chylomicrons	5-20	1.125-1.210	32-57	43-68	A-I, A-II, A-IV C-I, C-II, C-III D, E

HDL, High-density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; VLDL, very low-density lipoproteins.

back into the circulation, or secreted as bile acids. Normally, all dietary fat is disposed of within 8 hours after the last meal, an exception being individuals with a disorder of chylomicron metabolism. **Postprandial hyperlipidemia** is a risk factor for atherosclerosis. Abnormal transport of chylomicrons and their remnants may result in their absorption into the blood vessel wall as *foam cells,* caused by the ingestion of cholesteryl esters by macrophages, the earliest stage in the development of fatty streaks.

Transport of Endogenous Lipids from the Liver

The formation and secretion of VLDL from the liver and its catabolism to IDL and LDL particles describe the *endogenous* lipoprotein pathway. Fatty acids used in the hepatic formation of VLDL are derived primarily by uptake from the circulation. VLDL appears to be transported from the liver as rapidly as it is synthesized, and it consists of triglycerides, cholesteryl esters, phospholipids, and apoB-100. Nascent particles of VLDL secreted into the circulation combine with apoC and apoE. The size of the VLDL particle is determined by the amount of triglyceride present, progressively shrinking in size as triglyceride is hydrolyzed by the action of LPL, yielding free fatty acids for utilization or storage in muscle and adipose tissue. Hydrolysis of approximately 80% of the triglyceride present in VLDL particles produces IDL particles containing an equal amount of cholesterol and triglyceride. The remaining remnant IDL is converted to LDL for delivery to peripheral tissues or to the liver. ApoE is attached to the remnant IDL particle to allow binding to the cell and subsequent incorporation into the lysosome. Individuals with a deficiency of either apoE2 or hepatic triglyceride lipase accumulate IDL in the plasma.

LDL particles account for approximately 70% of the plasma cholesterol in normal individuals. LDL receptors are present on the surfaces of nearly all cells. Most LDL is taken up by the liver, and the rest is transported to peripheral tissues such as the adrenal glands and gonads for steroid synthesis. Dyslipidemia is greatly influenced by LDL-R activity. The efficiency with which VLDL is converted into LDL is also important in lipid homeostasis. The normal newborn LDL level of 50 mg/dL is probably adequate for steroid synthesis throughout the life cycle.

High-Density Lipoprotein and Reverse Cholesterol Transport

Because hepatic secretion of lipid particles into the bile is the only mechanism by which cholesterol can be removed from the body, transport of excess cholesterol from the peripheral cells is a vitally important function of HDL. HDL is heavily laden with apoA-I–containing lipoproteins, which is nonatherogenic, in contrast to B lipoproteins. Cholesterol-poor nascent HDL particles secreted by the liver and small intestine are esterified to more mature HDL-2 particles by the action of the enzyme lecithin-cholesterol acyltransferase **(LCAT)**, which facilitates movement of chylomicrons and VLDL into the HDL core. HDL-2 may transfer cholesteryl esters back to apoB lipoproteins mediated by cholesteryl ester transfer protein (CETP), or the cholesterol-rich particle may be removed from the plasma by endocytosis, completing reverse cholesterol transport. Low HDL may be genetic (deficiency of apoA-I) or secondary to increased plasma triglyceride.

LCAT deficiency results in diminished maturation of HDL particles, affecting their ability to do reverse cholesterol transport. This reduces its protective effect on atherosclerosis. There are rare reports, however, of less-than-expected severity of atherosclerosis despite low HDL secondary to LCAT deficiency, suggesting that the relationship may, for unknown reasons, be variable.

HYPERLIPOPROTEINEMIAS

Hypercholesterolemia

See Table 106.7.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a monogenic autosomal dominant disorder characterized by strikingly elevated LDL cholesterol (LDL-C), premature cardiovascular disease (CVD), and tendon xanthomas. It is predominantly associated with defects of LDL-R activity but also includes defects in the genes for apoB *(APOB)* and the proprotein convertase subtilisin/kexin type 9 (PCSK-9), a protein important in LDL endocytosis. Of the almost 1,200 *LDLR* pathogenic variants described, some result in failure of synthesis of the LDL-R (receptor negative) and others cause defective binding or release at the lipoprotein-receptor interface. Receptor-negative pathogenic variants result in more severe phenotypes than receptor-defective pathogenic variants. Data from the Netherlands has confirmed the importance of LDL reduction in FH; the major adverse coronary event risk for affected siblings with statin treatment begun at age 10 years mirrored that of unaffected siblings rather than the risk profile of the affected parent.

Homozygous Familial Hypercholesterolemia

FH homozygotes inherit two abnormal LDL receptor genes, resulting in markedly elevated plasma cholesterol levels ranging between 500 and 1,200 mg/dL. Triglyceride levels are normal to mildly elevated, and HDL levels may be slightly decreased. The condition occurs in 1 in 500,000 persons. Receptor-negative patients have <2% normal LDL-R activity, whereas those who are receptor defective may have as much as 25% normal activity and consequently a better prognosis.

However, the prognosis is poor regardless of the specific LDL-R aberration. Severe atherosclerosis involving the aortic root and coronary arteries is present by early to middle childhood. These children usually present with **xanthomas**, which may cause thickening of the Achilles tendon or extensor tendons of the hands, or cutaneous lesions on the hands, elbows, knees, or buttocks (Figs. 106.10-106.12). Corneal arcus may be present. Family history is informative because premature heart disease is strongly prevalent among relatives of both parents. The diagnosis may be confirmed genetically or by measuring LDL-R

Table 106.7 Hyperlipoproteinemias

DISORDER	LIPOPROTEINS ELEVATED	CLINICAL FINDINGS	GENETICS	ESTIMATED INCIDENCE
Familial hypercholesterolemia	LDL	Tendon xanthomas, CHD	AD	1 in 500
Familial defective ApoB-100	LDL	Tendon xanthomas, CHD	AD	1 in 1,000
Autosomal recessive hypercholesterolemia	LDL	Tendon xanthomas, CHD	AR	<1 in 1,000,000
Sitosterolemia	LDL	Tendon xanthomas, CHD	AR	<1 in 1,000,000
Polygenic hypercholesterolemia	LDL	CHD		1 in 30?
Familial combined hyperlipidemia	LDL, TG	CHD	AD	1 in 200
Familial dysbetalipoproteinemia	LDL, TG	Tuberoeruptive xanthomas, peripheral vascular disease	AD	1 in 10,000
Familial chylomicronemia (Frederickson type I)	TG ↑↑	Eruptive xanthomas, hepatosplenomegaly, pancreatitis	AR	1 in 1,000,000
Familial hypertriglyceridemia (Frederickson type IV)	TG ↑	±CHD	AD	1 in 500
Familial hypertriglyceridemia (Frederickson type V)	TG ↑↑	Xanthomas ± CHD	AD	—
Familial hepatic lipase deficiency	VLDL	CHD	AR	<1 in 1,000,000

AD, Autosomal dominant; AR, autosomal recessive; CHD, coronary heart disease; LDL, low-density lipoproteins, TG, triglycerides; VLDL, very low-density lipoproteins.

Fig. 106.10 Homozygous familial hypercholesterolemia. Tendon xanthomas in a 5-year-old boy with homozygous FH noted at the knee (**A**), wrist (**B**), and Achilles (**C**). *(Modified from Macchiaiolo M, Gagliardi MG, Toscano A, et al. Homozygous familial hypercholesterolaemia. Lancet. 2012;379:1330.)*

Fig. 106.11 Striate palmar xanthomata. *(From Durrington P. Dyslipidaemia, Lancet. 2003;362:717–731.)*

activity in cultured skin fibroblasts. Phenotypic expression of the disease may also be assessed by measuring receptor activity on the surface of lymphocytes by using cell-sorting techniques.

Untreated homozygous patients rarely survive to adulthood. Symptoms of coronary insufficiency may occur early, and sudden death is common. LDL apheresis to remove LDL particles selectively from the

circulation is recommended for many children because it slows the progression of atherosclerosis. Liver transplantation is also successful in decreasing LDL-C levels, but complications related to immunosuppression are common. HMG-CoA reductase inhibitors may be modestly effective depending on the specific class of LDL-R defect present. Combination therapy with *ezetimibe,* selectively blocking cholesterol adsorption in the gut, usually results in further decline in LDL levels and has replaced the use of bile acid sequestrants. Clinical trials using microsomal triglyceride transfer protein inhibition with *lomitapide* (an oral agent) resulted in significant reduction of all apoB lipoproteins, including LDL, but hepatic fat deposition as a side effect limits this pharmacologic approach. *Mipomersen* (subcutaneous injection), an antisense oligonucleotide that binds to the apolipoprotein B mRNA, reduces the synthesis of apoB and thus also VLDL and LDL. LDL cholesterol levels may decline approximately 25% with this treatment. Adverse effects include flulike symptoms, hepatic steatosis, and cirrhosis.

Heterozygous Familial Hypercholesterolemia

Heterozygous FH is the most common single-gene disorder associated with acute coronary syndromes and atherosclerotic CHD in adults. Its prevalence is approximately 1 in 250 individuals worldwide, but the frequency may be greater in select populations, such as French Canadians, Afrikaners, Ashkenazi Jews, and Christian Lebanese, as a result of the founder effect of unique pathogenic variants. Heart disease accounts for more than half of all deaths in Western society, with the pathogenesis having both environmental and genetic influences.

Because heterozygous FH is a dominant condition with nearly full penetrance, 50% of first-degree relatives of affected individuals will have the disease, as will 25% of second-degree relatives. An estimated 20 million people have FH worldwide. Symptoms of CHD usually occur at the mean age of 45-48 years in males and a decade later in females. Genetic testing of both adult and pediatric patients who fulfill clinical diagnostic criteria for the diagnosis of heterozygous FH is variably positive dependent on the population under investigation.

One cannot overemphasize the importance of family history for suspecting the possibility of FH, especially given the low rate of cholesterol screening for children in primary care offices. Because the risk of CHD in individuals with FH can be up to 20 times greater than in the general population, guidelines have advocated for universal screening for cholesterol in childhood. There is also an interest in genetic testing for persons with suspected FH because of variability in phenotype based on genotype.

Plasma levels of LDL-C also do not allow unequivocal diagnosis of FH heterozygotes; values are generally twice normal for age because of one absent or dysfunctional allele. The U.S. MED-PED *(Make Early Diagnosis–Prevent Early Death)* Program has formulated diagnostic criteria.

Similar criteria with minor variations exist in the United Kingdom (Simon Broome criteria) and Holland (Dutch Lipid Clinic Network criteria). Within well-defined FH families, the diagnosis is reliably established according to LDL cutoff points. More stringent criteria are required to establish the diagnosis in previously undiagnosed families, requiring strong evidence of an autosomal inheritance pattern and higher LDL cutoff points. At a total cholesterol level of 310 mg/dL, only 4% of adults in the general population would have FH, whereas 95% of adults who were first-degree relatives of known cases would have the disease.

Very high cholesterol levels in children should prompt extensive screening of adult first- and second-degree relatives ("reverse cascade" cholesterol screening). In the general population, a child younger than age 18 years with total plasma cholesterol of 270 mg/dL and/or LDL-C of 200 mg/dL has an 88% chance of having FH (Table 106.8). *Formal clinical diagnosis of FH is based on the presence of two or more family members having elevated LDL-C levels* (the 95th percentile LDL-C level cutoff points for children vary with age and are lower than for adults; Table 106.9). The criteria for probable FH in a child whose first-degree relative has known FH require only modest elevation of total cholesterol to 220 mg/dL (LDL-C 160 mg/dL; see Table 106.8). The challenge of childhood FH diagnosis is heightened by the lack of clinical stigmata such as xanthomata that are employed in the Simon Broome and Dutch Lipid Clinic Network schema and highlights the needed shift toward genetic diagnosis.

Treatment of children with FH should begin with a rigorous low-fat diet. Diet alone is rarely sufficient for decreasing blood cholesterol levels to acceptable levels (LDL-C <130 mg/dL). Ezetimibe blocks cholesterol adsorption in the gastrointestinal (GI) tract and has a low risk of side effects. Data suggest that ezetimibe will lower total cholesterol by 20-30 mg/dL. *HMG-CoA reductase inhibitors (statins) are the drug of choice for treatment of FH because of their remarkable effectiveness and acceptable risk profile.* This class of drugs in children over age 10 years is as effective in children as in adults, and the risks of elevated hepatic enzymes and myositis are no greater than in adults. Another class of drugs, the proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitors, are monoclonal antibodies (mAbs) that block the action of PCSK-9 to downregulate the LDL-R. These agents boost LDL-R levels and result in a marked decrease in plasma LDL-C levels. PCSK-9 inhibitors have a role in adults intolerant of statins and those with subtherapeutic statin effect. *Use of evolocumab in children over age 10 is FDA approved.* In addition, tobacco avoidance and cessation of use of tobacco in the family should be stressed from the time of diagnosis.

Familial Defective ApoB-100

Familial defective apoB-100 is an autosomal dominant condition indistinguishable from heterozygous *LDLR* FH. LDL cholesterol levels are increased, triglycerides are normal, adults often develop tendon xanthomas, and premature CHD occurs. Familial defective apoB-100 is caused by a pathogenic variant in the receptor-binding region of apoB-100, the ligand of the LDL receptor, with an estimated frequency of 1 in 700 people in Western cultures. It is usually caused by missense substitution of apoB-100 (p.Arg3527Gln, previously numbered p.Arg3500Gln), which results in reduced ability of the LDL-R to bind LDL-C, thus impairing its removal from the circulation. Specialized laboratory testing can distinguish familial defective apoB-100 from FH, but this is not necessary, except in research settings, because treatment is the same.

Autosomal Recessive Hypercholesterolemia

This rare condition, caused by a defect in LDL-R–mediated endocytosis in the liver, clinically presents with severe hypercholesterolemia at levels intermediate between those found in homozygous and heterozygous FH. It is disproportionately present among Sardinians, reported in other Mediterranean populations, and is modestly responsive to treatment with HMG-CoA reductase inhibitors.

Sitosterolemia

A rare autosomal recessive condition characterized by excessive intestinal adsorption of plant sterols, sitosterolemia is caused by pathogenic variants in the adenosine triphosphate (ATP)–binding cassette transporter system (*ABCG5* or *ABCG8*), which is responsible for limiting adsorption of plant sterols in the small intestine and promotes biliary excretion of the small amounts adsorbed. Plasma cholesterol levels may be severely elevated, resulting in tendon xanthomas and premature atherosclerosis. Other features include hemolytic anemia, macrothrombocytopenia (large platelets, reduced number), and hemorrhage. Diagnosis can be confirmed by measuring elevated plasma sitosterol levels. Treatment with HMG-CoA reductase inhibitors is not effective, but cholesterol adsorption inhibitors, such as ezetimibe, and bile acid sequestrants are effective.

Polygenic Hypercholesterolemia

Primary elevation in LDL-C among children and adults is most often polygenic; the small effects of many genes are affected by environmental influences (diet). Plasma cholesterol levels are modestly elevated; triglyceride levels are normal. Polygenic hypercholesterolemia aggregates in families sharing a common lifestyle but does not follow predictable hereditary patterns found in single-gene lipoprotein defects. Treatment of children with polygenic hypercholesterolemia is directed

toward adoption of a healthy lifestyle: reduced total and saturated fat consumption and at least 1 hour of physical activity daily. Cholesterol-lowering medication is rarely necessary.

Hypercholesterolemia with Hypertriglyceridemia

Familial Combined Hyperlipidemia

This autosomal dominant condition is characterized by moderate elevation in plasma LDL-C and triglycerides and reduced plasma HDL-C. Familial combined hyperlipidemia (FCHL) is the most common primary lipid disorder, affecting approximately 1 in 200 people. Family history of premature heart disease is typically positive; the formal diagnosis requires that at least two first-degree relatives have evidence of one of three variants of dyslipidemia: (1) >90th percentile plasma LDL-C, (2) >90th percentile LDL-C and triglycerides, and (3) >90th percentile triglycerides. Individuals can switch from one phenotype to another. Xanthomas are not a feature of FCHL. Elevated plasma apoB levels with increased small, dense LDL particles support the diagnosis.

Children and adults with FCHL have coexisting adiposity, hypertension, and hyperinsulinemia, suggesting the presence of **metabolic syndrome**. Formal diagnosis in adults, as defined by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III, identifies six major components: abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance with or without impaired glucose tolerance, evidence of vascular inflammation, and prothrombotic state. An estimated 30% of overweight adults fulfill criteria for the diagnosis of metabolic syndrome, including 65% of those with FCHL. *There is no official definition of metabolic syndrome for children.* Absolute cutoffs for diagnosis in children do not account for continuous variables in aging, sexual maturation, and race/ethnicity.

FCHL and type 2 diabetes share many features of metabolic syndrome, suggesting that they are less distinct entities than originally conceptualized. Genetic association studies reveal evidence for a common genetic background. The resultant metabolic overlap is associated with ectopic fat accumulation and insulin resistance. The mechanisms associating visceral adiposity with metabolic syndrome and type 2 diabetes are not fully understood. It is assumed that hypercholesterolemia and, with less certainty, hypertriglyceridemia confer risk for CVD in patients with FCHL. When features of metabolic syndrome are included in logistic models, shared etiologic features such as increased visceral adiposity become apparent. Visceral adiposity increases with age, and its importance in children as a risk factor for heart disease and diabetes is limited by the relative paucity of data. Body mass index (BMI) remains the surrogate for adiposity in the pediatric clinical setting.

The cornerstone of management is lifestyle modification. This includes a diet low in saturated fats, *trans* fats, and cholesterol, as well as reduced consumption of processed sugars. Increased dietary intake of fruits and vegetables is important, as is 1 hour of moderate physical activity daily. Compliance among children and their parents is often a problem, but small incremental steps are more likely to succeed than aggressive weight loss strategies. It is very important that the child's caregivers participate in the process. Plasma triglyceride levels are usually quite responsive to dietary restriction, especially reduction in the amount of sweetened drinks consumed. Blood cholesterol levels may decrease by 10–15%, but if LDL-C remains >160 mg/dL, drug therapy should be considered.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia (FDBL) is caused by pathogenic variants in *APOE,* which, when exposed to environmental influences (e.g., high-fat high-caloric diet, excessive alcohol intake), results in a mixed type of hyperlipidemia. Patients tend to have elevated plasma cholesterol and triglycerides to a relatively similar degree. HDL-C is typically normal, in contrast to other causes of hypertriglyceridemia associated with low HDL. This rare disorder affects approximately 1 in 10,000 persons. ApoE mediates removal of chylomicron and VLDL remnants from the circulation by binding to hepatic surface receptors. The polymorphic *APOE* gene expresses in three isoforms: *apoE3, apoE2,* and *apoE4. E4* is the "normal" allele present in the majority of the population. The *apoE2* isoform has lower affinity for the LDL receptor, and its frequency is approximately 7%. Approximately 1% of the population is

homozygous for *apoE2/E2,* the most common pathogenic variant associated with FDBL, but only a minority expresses the disease. Expression requires precipitating illnesses such as diabetes, obesity, renal disease, or hypothyroidism. Individuals homozygous for *apoE4/E4* are at risk for late-onset Alzheimer disease and dementia from repeated sports-related head injuries.

Most patients with FDBL present in adulthood with distinctive xanthomas. Tuberoeruptive xanthomas resemble small, grapelike clusters on the knees, buttocks, and elbows. Prominent orange-yellow discoloration of the creases of the hands (palmar xanthomas) is also typically present. Atherosclerosis, often presenting with peripheral vascular disease, usually occurs in the fourth or fifth decade. Children may present with a less distinctive rash and generally have precipitating illnesses.

The diagnosis of FDBL is established by lipoprotein electrophoresis, which demonstrates a broad beta band containing remnant lipoproteins. Direct measurement of VLDL by ultracentrifugation can be performed in specialized lipid laboratories. A VLDL/total triglyceride ratio >0.30 supports the diagnosis. *APOE* genotyping for *apoE2* homozygosity can be performed, confirming the diagnosis in the presence of the distinctive physical findings. A negative result does not necessarily rule out the disease, as other pathogenic variants in *APOE* may cause even more serious manifestations.

Pharmacologic treatment of FDBL is necessary to decrease the likelihood of symptomatic atherosclerosis in adults. HMG-CoA reductase inhibitors, nicotinic acid, and fibrates are all effective. FDBL is quite responsive to recommended dietary restriction.

Hypertriglyceridemias

The familial disorders of triglyceride-rich lipoproteins include both common and rare variants of the Frederickson classification system. These include familial chylomicronemia (type I), familial hypertriglyceridemia (type IV), and the more severe combined hypertriglyceridemia and chylomicronemia (type V). Hepatic lipase deficiency also results in a similar combined hyperlipidemia.

Familial Chylomicronemia (Type I Hyperlipidemia)

This rare single-gene defect, like FH, is caused by pathogenic variants affecting clearance of apoB-containing lipoproteins. A deficiency or absence of lipoprotein lipase *(LPL)* or its cofactor apoC-II *(APOC2)*, which facilitates lipolysis by LPL, causes severe elevation of triglyceride-rich plasma chylomicrons. HDL-C levels are decreased. Clearance of these particles is greatly delayed, so the plasma is noted to have a turbid appearance even after prolonged fasting (Fig. 106.13). Chylomicronemia caused by LPL deficiency is associated with modest elevation in triglycerides, whereas this is not the case when the cause is deficient or absent apoC-II. Both are autosomal recessive conditions with a frequency of approximately 1 in 1 million. The disease usually presents during childhood with acute pancreatitis. Eruptive xanthomas on the arms, knees, and buttocks may be present, and there may be hepatosplenomegaly. The diagnosis is established by assaying triglyceride lipolytic activity. **Treatment** of chylomicronemia is by vigorous dietary fat restriction supplemented by fat-soluble vitamins. Medium-chain triglycerides that are adsorbed into the portal venous system may augment total fat intake, and administration of fish oils may also be beneficial.

Familial Hypertriglyceridemia (Type IV Hyperlipidemia)

Familial hypertriglyceridemia (FHTG) is an autosomal dominant disorder of unknown etiology that occurs in approximately 1 in 500 individuals. It is characterized by elevation of plasma triglycerides >90th percentile (250-1,000 mg/dL range), often accompanied by slight elevation in plasma cholesterol and low HDL. FHTG does not usually manifest until adulthood, although it can be detected in approximately 20% of affected children. In contrast to FCHL, FHTG is not thought to be highly atherogenic. It is most likely caused by defective breakdown of VLDL or, less often, by overproduction of this class of lipoproteins.

The diagnosis should include the presence of at least one first-degree relative with hypertriglyceridemia. FHTG should be distinguished from FCHL and FDBL, which require more vigorous treatment to prevent coronary or peripheral vascular disease. The differentiation is usually possible on clinical grounds, in that lower LDL-C levels accompany FHTG, but measurement of normal apoB levels in FHTG may be helpful in ambiguous situations.

Fig. 106.13 Milky plasma from a patient with acute abdominal pain. *(From Durrington P. Dyslipidaemia, Lancet. 2003;362:717–731.)*

A more severe hypertriglyceridemia characterized by increased levels of chylomicrons and VLDL particles (Frederickson **type V**) may occasionally be encountered. Triglyceride levels are often >1,000 mg/dL. The disease is rarely seen in children. In contrast to chylomicronemia (Frederickson **type I**), LPL or apoC-II deficiency is not present. These patients often develop eruptive xanthomas in adulthood, whereas **type IV** hypertriglyceridemia individuals do not. Acute pancreatitis may be the presenting illness. As with other hypertriglyceridemias, excessive alcohol consumption and estrogen therapy can exacerbate the disease.

Secondary causes of *transient hypertriglyceridemia* should be ruled out before making a diagnosis of FHTG. A diet high in simple sugars and carbohydrates or excessive alcohol consumption, as well as estrogen therapy, may exacerbate hypertriglyceridemia. Adolescents and adults should be questioned about excessive consumption of soda and other sweetened drinks, as it is common to encounter people who drink supersized drinks or multiple 12 oz cans of sweetened drinks daily. Cessation of this practice often results in a dramatic fall in triglyceride levels and weight among those who are obese. HDL-C levels will tend to rise as BMI stabilizes.

Pediatric diseases associated with hyperlipidemia include hypothyroidism, nephrotic syndrome, biliary atresia, glycogen storage disease, Niemann-Pick disease (NPD), Tay-Sachs disease, systemic lupus erythematosus, hepatitis, and anorexia nervosa (Table 106.10). Certain medications exacerbate hyperlipidemia, including isotretinoin (Accutane), thiazide diuretics, second-generation antipsychotic agents, oral contraceptives, corticosteroids, β blockers, immunosuppressants, and protease inhibitors used in HIV treatment.

Treatment of hypertriglyceridemia in children rarely requires medication unless levels >1,000 mg/dL persist after dietary restriction of fats,

sugars, and carbohydrates, accompanied by increased physical activity. In such patients the aim is to prevent episodes of pancreatitis. The common use of fibrates (fenofibric acid) and niacin in adults with hypertriglyceridemia is not recommended in children. HMG-CoA reductase inhibitors are variably effective in lowering triglyceride levels, and there is considerably more experience documenting the safety and efficacy of this class of lipid-lowering medications in children. In adults, the U.S. Food and Drug Administration (FDA) has approved prescription (Lovaza, Vascepa) and nonprescription fish oils as adjuncts to diet in the treatment of severe hypertriglyceridemias.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a very rare autosomal recessive condition caused by pathogenic variants in *LMF1* resulting in elevation in both plasma cholesterol and triglycerides. Hepatic lipase hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL, preventing their conversion to LDL. HDL-C levels tend to be increased rather than decreased, suggesting the diagnosis. Laboratory confirmation is established by measuring hepatic lipase activity in heparinized plasma.

Disorders of High-Density Lipoprotein Metabolism

Primary Hypoalphalipoproteinemia

Isolated low HDL-C is a familial condition that often follows a pattern suggestive of autosomal dominant inheritance but may occur independent of family history. It is the most common disorder of HDL metabolism. It is defined as HDL-C <10th percentile for gender and age with normal plasma triglycerides and LDL-C. Whether it is associated with more rapid atherosclerosis is uncertain. Primary hypoalphalipoproteinemia appears to be related to a reduction in apoA-I synthesis and increased catabolism of HDL. Secondary causes of low HDL-C, such as metabolic syndrome, and rare diseases such as LCAT deficiency and Tangier disease must be ruled out.

Familial Hyperalphalipoproteinemia

This is an unusual condition conferring decreased risk for CHD among family members. Plasma levels of HDL-C exceed 80 mg/dL.

Familial Apolipoprotein A-I Deficiency

Pathogenic variants in the *APOA1* gene may result in complete absence of plasma HDL. Nascent HDL is produced in the liver and small intestine. Free cholesterol from peripheral cells is esterified by LCAT, enabling formation of mature HDL particles. ApoA-I is required for normal enzymatic functioning of LCAT. The resultant accumulation of free cholesterol in the circulation eventually leads to corneal opacities, planar xanthomas, and premature atherosclerosis. Some patients, however, may have pathogenic variants of *APOA1* that result in very rapid catabolism of the protein not associated with atherogenesis, despite HDL-C levels in the 15-30 mg/dL range.

Tangier Disease

This autosomal dominant disease is associated with HDL-C levels <5 mg/dL. It is caused by pathogenic variants in *ABCA1,* which encodes a protein that facilitates the binding of cellular cholesterol to apoA-I. This results in free cholesterol accumulation in the reticuloendothelial system, manifested by tonsillar hypertrophy of a distinctive orange color and hepatosplenomegaly. Intermittent peripheral neuropathy may occur from cholesterol accumulation in Schwann cells. Diagnosis should be suspected in children with enlarged orange tonsils and extremely low HDL-C levels.

Familial Lecithin–Cholesterol Acyltransferase Deficiency

Pathogenic variants of *LCAT* interfere with the esterification of cholesterol, thereby preventing formation of mature HDL particles. This is associated with rapid catabolism of apoA-I. Free circulating cholesterol in the plasma is greatly increased, which leads to corneal opacities and HDL-C levels <10 mg/dL. Partial LCAT deficiency is known as "fish-eye" disease because of the corneal opacities. Complete deficiency causes hemolytic anemia and progressive renal insufficiency early in adulthood. This rare disease is not thought to cause premature atherosclerosis. Laboratory confirmation is based on a demonstration of decreased cholesterol esterification in the plasma.

Cholesteryl Ester Transfer Protein Deficiency

Pathogenic variants of the *CETP* gene result in cholesteryl ester transfer protein (CETP) deficiency. CETP facilitates the transfer of lipoproteins from mature HDL to and from VLDL and chylomicron particles, thus ultimately regulating the rate of cholesterol transport to the liver for excretion in the bile. About half of mature HDL-2 particles are directly removed from the circulation by HDL receptors on the surface of the liver. The other half of cholesteryl esters in the core of HDL exchange with triglycerides in the core of apoB lipoproteins (VLDL, IDL, LDL) for transport to the liver. Homozygous deficiency of CETP has been observed in subsets of the Japanese population with extremely high HDL-C levels (>150 mg/dL).

Conditions Associated with Low Cholesterol

Disorders of apoB-containing lipoproteins and intracellular cholesterol metabolism are associated with low plasma cholesterol.

Abetalipoproteinemia

This rare autosomal recessive disease is caused by pathogenic variants in the *MTTP* gene that encodes the microsomal triglyceride transfer protein necessary for the transfer of lipids to nascent chylomicrons in the small intestine and VLDL in the liver. This results in an absence of chylomicrons, VLDL, LDL, and apoB and very low levels of plasma cholesterol and triglycerides. Fat and fat-soluble vitamin malabsorption, diarrhea, and failure to thrive present in early childhood. Spinocerebellar degeneration, secondary to vitamin E deficiency, manifests in loss of deep tendon reflexes progressing to ataxia and lower-extremity spasticity by adulthood. Patients with abetalipoproteinemia also acquire a progressive pigmented retinopathy associated with decreased night and color vision and eventual blindness. The neurologic symptoms and retinopathy may be mistaken for Friedreich ataxia. Differentiation from Friedreich ataxia is suggested by the presence of malabsorption and acanthocytosis on peripheral blood smear

in abetalipoproteinemia. Many of the clinical manifestations of the disease are a result of malabsorption of fat-soluble vitamins, such as vitamins E, A, and K. *Early treatment with supplemental vitamins, especially E, may significantly slow the development of neurologic sequelae.* Vitamin E is normally transported from the small intestine to the liver by chylomicrons, where it is dependent on the endogenous VLDL pathway for delivery into the circulation and peripheral tissues. Parents of children with abetalipoproteinemia have normal blood lipid and apoB levels.

Familial Hypobetalipoproteinemia

Familial homozygous hypobetalipoproteinemia is associated with symptoms very similar to those of abetalipoproteinemia, but the inheritance pattern is autosomal dominant caused by pathogenic variants in *APOB*. It is distinguishable from abetalipoproteinemia in that heterozygous parents of probands have plasma LDL-C and apoB levels less than half of normal. However, few symptoms or sequelae are associated with the heterozygous condition.

The selective inability to secrete apoB-48 from the small intestine results in a condition resembling abetalipoproteinemia or homozygous hypobetalipoproteinemia. Sometimes referred to as **Anderson disease** or chylomicron retention disease, caused by recessive alterations of the *SAR1B* gene, the failure of chylomicron absorption causes steatorrhea and fat-soluble vitamin deficiency. The blood level of apoB-100, derived from normal hepatocyte secretion, is normal in this condition.

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome **(SLOS)** is an autosomal recessive disorder that includes microcephaly, polydactyly, holoprosencephaly, seizures and developmental delay. Phenotypic variance ranges from microcephaly, cardiac and brain malformation, and multiorgan system failure to only subtle dysmorphic features and mild developmental delay. It is associated with low plasma cholesterol and accumulated precursors (Tables 106.11 and 106.12) (see Chapter 628.2). Pathogenic variants in the *DHCR7* (7-dehydrocholesterol-Δ7 reductase) gene result in deficiency of the microsomal enzyme DHCR7, which is necessary to complete the final step in cholesterol synthesis. Hypotheses to connect the role of cholesterol synthesis in SLOS congenital malformations have implicated the ligand sonic hedgehog (SHH), for which developmental signaling activity is dependent on cholesterol modification. The incidence of SLOS is estimated to be 1 in 20,000-60,000 births.

Spontaneous abortion of SLOS fetuses may occur. **Type II** SLOS often leads to death by the end of the neonatal period. Survival is unlikely when the plasma cholesterol level is <20 mg/dL. Laboratory measurement should be performed by gas chromatography, because standard techniques for lipoprotein assay include measurement of cholesterol precursors, which may yield a false-positive result. Milder cases may not present until late childhood. **Treatment** includes supplemental dietary cholesterol (egg yolk) and HMG-CoA reductase inhibition to prevent the synthesis of toxic precursors proximal to the enzymatic block.

Disorders of Intracellular Cholesterol Metabolism

Cerebrotendinous Xanthomatosis

This autosomal recessive disorder presents in late adolescence with tendon xanthomas, cataracts, and progressive neurodegeneration. It is caused by tissue accumulation of bile acid intermediates that are shunted into production of cholestanol that in turn result from pathogenic variants in the gene for sterol 27-hydroxylase *(CYP27A1)*. This enzyme is necessary for normal mitochondrial synthesis of bile acids in the liver. Early treatment with chenodeoxycholic acid reduces cholesterol levels and prevents the development of symptoms.

Wolman Disease and Cholesterol Ester Storage Disease

These autosomal recessive disorders are caused by pathogenic variants in *LIPA* that result in lack of lysosomal acid lipase. After LDL cholesterol is incorporated into the cell by endocytosis, it is delivered to lysosomes, where it is hydrolyzed by lysosomal lipase. Failure of hydrolysis because of complete absence of the enzyme causes accumulation of cholesteryl esters within the cells. Hepatosplenomegaly, steatorrhea, and failure to thrive occur during early infancy, leading to death by the end of the first year. In cholesterol ester storage disease, a less severe form than Wolman disease, there is low but detectable acid lipase activity (see Chapter 106.4).

Syndactyly of toes II/III
Postaxial polydactyly (<50%)
Equinovarus deformity (<50%)
GENITAL ANOMALIES
Hypospadias
Cryptorchidism
Sexual ambiguity (<50%) or XY sex reversal
DEVELOPMENT
Prenatal and postnatal growth retardation
Feeding problems
Intellectual disability
Behavioral abnormalities

From Haas D, Kelley RI, Hoffmann GF. Inherited disorders of cholesterol biosynthesis. *Neuropediatrics.* 2001;32:113–122.

Niemann-Pick Disease Type C

This disorder of intracellular cholesterol transport is characterized by accumulation of cholesterol and sphingomyelin in the CNS and reticuloendothelial system. Death from this autosomal recessive neurologic disease usually occurs by adolescence (see Chapter 106.4).

Lipoprotein Patterns in Children and Adolescents

Derived primarily from the Lipid Research Clinics Population Studies, Table 106.9 shows the distribution of lipoprotein levels in American youth at various ages. Total plasma cholesterol rises rapidly from a mean of 68 mg/dL at birth to a level approximately twice that by the end of the neonatal period. A very gradual rise in total cholesterol level occurs until puberty, when the mean level reaches 160 mg/dL. Total cholesterol falls transiently during puberty in males because of a small decrease in HDL-C and in females secondary to a slight fall in LDL-C. Blood cholesterol levels track reasonably well as individuals age.

High blood cholesterol tends to aggregate in families, a reflection of genetic and environmental influences.

Acceptable total cholesterol among children and adolescents is <170 mg/dL; borderline is 170-199 mg/dL; and high is >200 mg/dL. Acceptable LDL-C is <110 mg/dL; borderline is 110-129 mg/dL; and high is >130 mg/dL. HDL-C should be >40 mg/dL.

Blood Cholesterol Screening

A lipid profile should be checked for all children between ages 9 and 11 years and then another between ages 17 and 21 years because cholesterol levels may vary after puberty. However, if a child would have met the selective criteria from the previous risk-based guidelines (premature coronary artery disease [CAD] in a parent or grandparent, a parent with cholesterol >240 mg/dL), screening can occur as early as age 2

years. Data also suggest that obtaining a nonfasting lipid profile can be just as useful in detecting severe genetic dyslipidemias as a fasting lipid profile and thus can be used as first-line screening in children. Fasting lipid profiles may also be used depending on parental, child, and clinician preference, especially if there is concern for hypertriglyceridemia, because triglycerides are affected more by fasting status. Abnormal lipid panels should be repeated, and especially when the concern is the triglycerides, the second panel should be obtained ≥2 weeks later in the fasted state. Treatment other than lifestyle modification is not initiated based on a single lipid panel determination.

Risk Assessment and Treatment of Hyperlipidemia

The NCEP recommends a population-based approach toward a healthy lifestyle applicable to all children and an individualized approach directed at those children at high risk (Fig. 106.14). The important focus on maintenance of a healthy lifestyle rather than aggressive weight reduction is recommended by the American Academy of Pediatrics (AAP).

All children with dyslipidemias are stratified according to the presence of high-level or moderate-level risk factors to determine their ultimate treatment. **High-level risk factors** are defined as hypertension requiring drug therapy (blood pressure ≥99th percentile + 5 mm Hg), current cigarette smoker, BMI at the ≥97th percentile, the presence of type 1 or type 2 diabetes mellitus, chronic kidney disease, postorthoptic heart transplant, and/or Kawasaki disease with current aneurysms. **Moderate-level risk factors** are defined as hypertension that does not require drug therapy, BMI at the ≥95th percentile but <97th percentile, HDL-C <40 mg/dL, Kawasaki disease (and possibly multisystem inflammatory syndrome in children [MIS-C]) with regressed coronary aneurysms, chronic inflammatory disease, HIV infection, and/or the presence of nephrotic syndrome.

The initial treatment for dyslipidemia in a child always begins with a 6-month trial of lifestyle modification, namely, improvements in dietary and physical activity patterns. Being overweight confers a special risk of CVD because of the strong association with insulin resistance syndrome (metabolic syndrome). Although there is no standardized definition of metabolic syndrome for youth, it is likely that half of all severely obese children are insulin resistant. Data from the CARDIAC project noted that 49% of fifth-grade children with the hyperpigmented rash, acanthosis nigricans, had three or more factors for insulin resistance syndrome when using the definition classically used for adults, including evidence of insulin resistance, hypertension, HDL-C <40 mg/dL, and triglycerides >150 mg/dL, in addition to obesity.

The Cardiovascular Health Integrated Lifestyle Diet-1 **(CHILD-1)** diet is the first level of dietary change to be recommended for all children with dyslipidemias. The CHILD-1 diet is specially designed for children with risk factors for CAD and focuses on limiting dietary cholesterol to 300 mg/day, limiting sugary drink consumption, using reduced-fat/skim milk, avoiding foods high in *trans*-type fats, limiting foods high in sodium, and encouraging consumption of foods high in fiber. Specific recommendations depend on the child's age. American Heart Association (AHA) diet guidelines for all persons of all ages recommend these measures plus avoidance of highly processed foods. Specific amounts or percentages of saturated vs monosaturated or polyunsaturated fats are not addressed.

The use of the Cardiovascular Health Integrated Lifestyle Diet-2 **(CHILD-2)** diet is recommended if the CHILD-1 diet alone is unsuccessful. Although similar in many aspects to the CHILD-1 diet, the CHILD-2 diet is geared toward a specific dyslipidemia type; the **CHILD-2 LDL** diet is recommended for children with elevated LDL levels and the **CHILD-2 TG** diet for those presenting with elevated triglycerides. The basic recommendations of calorie consumption for the CHILD-2 diet are as follows: only 25–30% of calories from fat, ≤7% of calories from saturated fat, 10% of calories from monounsaturated fat, and <200 mg/day of cholesterol. If the CHILD-2 LDL diet is recommended, the use of plant sterols and water-soluble fiber is emphasized. If the CHILD-2 TG diet is recommended, increasing consumption of omega-3 fatty acids and complex rather than simple carbohydrates is emphasized.

If followed, these dietary recommendations will provide adequate calories for optimal growth and development without promoting obesity. Compliance on the part of children and their caregivers is challenging. *Children learn eating habits from their parents*. Successful adoption of a healthier lifestyle is much more likely to occur if meals and snacks in the home are applicable to the entire family rather than an individual child. A regular time for meals together as a family is desirable. Grandparents and other nonparental caregivers sometimes need to be reminded not to indulge the child who is on a restricted diet. Additionally, the rise in obesity is prompting some school districts to restrict sweetened drink availability and offer more nutritious cafeteria selections.

Changes in physical activity habits are also an important part of the initial lifestyle modification. The National Association for Sport and Physical Education recommends that children should accumulate at least 60 minutes of age-appropriate physical activity on most days of the week. Extended periods (≥2 hr) of daytime inactivity are discouraged, as is >2 hours of television and other forms of screen time.

Pharmacologic Therapy. See Tables 106.13 and 106.14.

Pharmacologic therapy with cholesterol-lowering medication is the cornerstone of treatment for children who fail to respond to 6 months of rigorous lifestyle modification. It should be considered when one of the following conditions are met (also shown in Fig. 106.14):

- LDL cholesterol remains >190 mg/dL
- LDL cholesterol remains >160 mg/dL with the presence of one high-level risk factor *and/or* at least two moderate-level risk factors
- LDL cholesterol remains >130 mg/dL with the presence of at least two high-level risk factors, one high-level risk factor, *and* at least two moderate-level risk factors, *or* evidence of CAD

HMG-CoA reductase inhibitors, also known as "statins," are remarkably effective in lowering LDL-C levels and reducing plaque

Table 106.13 Drugs Used for the Treatment of Hyperlipidemia

DRUG	MECHANISM OF ACTION	INDICATION	STARTING DOSE
HMG-CoA reductase inhibitors (statins)	↓ Cholesterol and VLDL synthesis ↑ Hepatic LDL receptors	Elevated LDL	5-80 mg every night at bedtime
Bile acid sequestrants: Cholestyramine Colestipol	↑ Bile and excretion	Elevated LDL	 4-32 g daily 5-40 g daily
Nicotinic acid	↓ Hepatic VLDL synthesis	Elevated LDL Elevated TG	100-2,000 mg three times daily
Fibric acid derivatives: Gemfibrozil	↑ LPL ↓ VLDL	Elevated TG	600 mg twice daily
Fish oils	↓ VLDL production	Elevated TG	3-10 g daily
Cholesterol absorption inhibitors:			
Ezetimibe	↓ Intestinal absorption cholesterol	Elevated LDL	10 mg daily
PCSK-9 inhibitor Evolocumab	Upregulation of hepatic LDL receptors to enhance removal of LDL from circulation	Refractory or intolerant to statin	140 mg every 2 weeks or 420 mg subcutaneous injection monthly

LDL, Low-density lipoprotein(s); LPL, lipoprotein lipase; TG, triglycerides; VLDL, very-low-density lipoprotein.

Table 106.14 Adverse Effects of Cholesterol-Lowering Drugs

STATINS
Myalgia, myositis, transaminase elevations, hepatic dysfunction, increased risk of diabetes mellitus
Rare: Rhabdomyolysis, hemorrhagic stroke

EZETIMIBE
Diarrhea, arthralgia, rhabdomyolysis, hepatitis, pancreatitis, thrombocytopenia

PCSK9 INHIBITORS
Nasopharyngitis, upper respiratory tract infection, influenza, back pain, injection site reactions, rash, allergic skin reactions, cognitive effects, antidrug antibodies

BILE ACID SEQUESTRANTS
Constipation, heartburn, nausea, eructation, bloating
Adverse effects are more common with colestipol and cholestyramine and may diminish over time.

FIBRIC ACID DERIVATIVES
Gastrointestinal (GI) disturbances, cholelithiasis, hepatitis, myositis

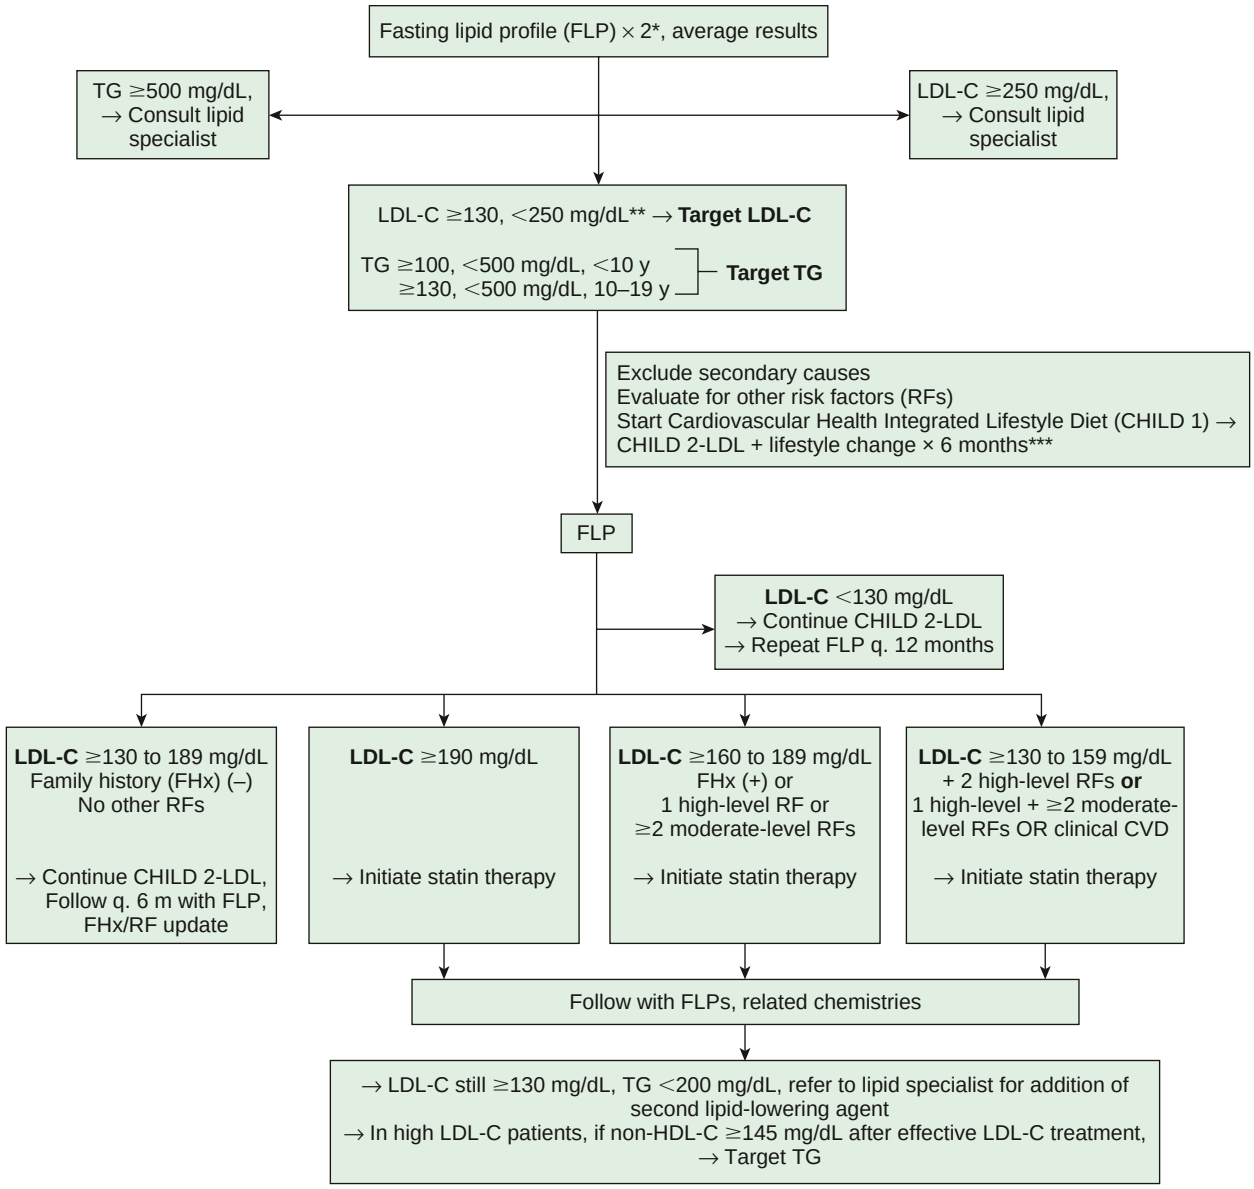
NIACIN
Skin flushing, pruritus, GI disturbances, blurred vision, fatigue, glucose intolerance, hyperuricemia, hepatic toxicity, exacerbation of peptic ulcers
Adverse effects, especially flushing, occur more frequently with immediate-release products.
Rare: Dry eyes, hyperpigmentation

FISH OIL
Eructation, dyspepsia, unpleasant aftertaste

From The Medical Letter. Lipid-lowering drugs. *Med Lett.* 2016;58:133–140, Table 2, p. 136.

inflammation, thereby reducing the likelihood of a sudden coronary event in an at-risk adult within weeks of starting the medication. As a class, they work by blocking the intrahepatic biosynthesis of cholesterol, thereby stimulating the production of more LDL receptors on the cell surface and facilitating the uptake of LDL-C from the bloodstream. The NCEP Adult Treatment Panel advocates aggressive lowering of LDL to <70 mg/dL in individuals with known CAD. This information is relevant because a child who fulfills criteria for consideration of cholesterol-lowering medication will almost always have inherited the condition from one of the child's parents. Not infrequently, when providing care for the child, questions arise about screening and treatment of parents or grandparents. Statins are equally effective in children, capable of lowering LDL-C levels by 50% when necessary. They are considered first-line therapy for children who meet criteria for pharmacologic therapy. They also will effect a modest reduction in triglycerides and an inconsistent increase in HDL-C. Their side effect profile, mainly liver dysfunction and rarely rhabdomyolysis with secondary renal failure, should be taken into consideration before prescribing the drug. However, there has been no evidence that complications are any more frequent in children than in adults, and skeletal muscle discomfort seems to be somewhat less of a problem. Drug interactions may occur as well, so careful attention should be paid to a child's active prescriptions to avoid potentiation of the side effects. Children should have liver enzymes monitored regularly and creatine phosphokinase measured if muscle aches or weakness occurs. Liver (muscle) enzymes may be allowed to rise threefold before discontinuing the drug. There is a suggested link between the use of statins and increased risk of developing type 2 diabetes mellitus in adults, but these results have not been replicated in children. Sex hormones have been measured in children receiving statins and are unchanged. It should be reemphasized that children with modest elevations in cholesterol, such as that seen in polygenic hypercholesterolemia, are not, as a rule, candidates for statins because of their side effect profile and the childhood response to lifestyle modifications. Statins should be started at the lowest effective dose and allowed at least 8 weeks to achieve their peak effect. If LDL levels are not at goal, which in children who are treated is generally established to be <130 mg, the medication may be titrated upward with careful monitoring of side effects.

Other cholesterol-lowering medications, such as nicotinic acid and fibrates, have been used far less often in children than bile acid sequestrants and statins. Nicotinic acid and fibrates have been used selectively in children with marked hypertriglyceridemia (>500 mg/dL) at risk for acute pancreatitis, though dietary restriction of complex sugars (stressing elimination of sugar-sweetened beverages) and carbohydrates will usually result in significant lowering of triglyceride levels. Guidelines recommend treatment of LDL-C as the initial priority, and after LDL levels are at goal, then if triglycerides remain between 200 and 499 mg/dL and non-HDL cholesterol ≥145 mg/dL, pharmacologic treatment to reduce triglyceride levels is indicated. Omega-3 fatty acid supplementation, available in both over-the-counter and prescription form, is a safe and useful treatment thought to reduce triglyceride levels by decreasing the hepatic synthesis of triglycerides. LDL-C levels in adults



* Obtain FLPs at least 2 weeks but no more than 3 months apart.
** Use of drug therapy is limited to children ≥10 y with defined risk profiles.
*** In a child with LDL-C >190 mg/dL and other RFs, trial of CHILD 2-LDL may be abbreviated.

Fig. 106.14 Dyslipidemia treatment algorithm: Target LDL-C (low-density lipoprotein cholesterol). Note: Values given are in mg/dL. To convert to SI units, divide results for total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and non–HDL-C by 38.6; for triglycerides (TG), divide by 88.6. *(From U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute. Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents. NIH Publication No. 12-7486A, Oct. 2012, Fig 9-1.)*

of about 70 mg/dL were recently associated with coronary artery atheromatous plaque reduction and reversal of CAD. Knowledge in this area will continue to evolve.

Ezetimibe has proved to be useful in the pediatric population because of its efficacy and low side effect profile. Ezetimibe reduces plasma LDL-C by blocking sterol absorption in enterocytes. The drug is marketed as an adjunct to statins when adults are not achieving sufficient blood lipid lowering with statins alone. Sufficient reports documenting its effectiveness without side effects support recommending ezetimibe instead of a statin when moderate hypercholesterolemia is encountered or apprehension from parents makes using a statin difficult.

106.4 Lipidoses (Lysosomal Storage Disorders)

Margaret M. McGovern and Robert J. Desnick

The lysosomal lipid storage diseases are diverse disorders each caused by an inherited deficiency of a lysosomal hydrolase leading to the intralysosomal accumulation of the enzyme's particular substrate (Tables 106.15 and 106.16). With the exceptions of Wolman disease and cholesterol ester storage disease (see Chapter 106.3), the lipid substrates share a common structure that includes a ceramide backbone (2-N-acylsphingosine) from which the various sphingolipids are derived by substitution of hexoses, phosphorylcholine, or one or more

sialic acid residues on the terminal hydroxyl group of the ceramide molecule. The pathway of sphingolipid metabolism in nervous tissue (Fig. 106.15) and in visceral organs (Fig. 106.16) is known. Each catabolic step, with the exception of the catabolism of lactosylceramide, has a genetically determined metabolic defect and a resultant disease. Because sphingolipids are essential components of all cell membranes, the inability to degrade these substances and their subsequent accumulation results in the physiologic and morphologic alterations and characteristic clinical manifestations of the lipid storage disorders (see Tables 106.15 and 106.16). Progressive lysosomal accumulation of glycosphingolipids in the CNS leads to neurodegeneration, whereas storage in visceral cells can lead to organomegaly, pulmonary infiltration, skeletal abnormalities, and other manifestations.

Diagnostic assays for the identification of affected individuals has relied on the measurement of the specific enzymatic activity in isolated leukocytes or cultured fibroblasts or lymphoblasts. An approach to differentiating these disorders is noted in Figure 106.17. In addition, next generation sequencing of lysosomal genes as well as metabolomic/protomic approaches have helped determine a specific diagnosis. For most disorders, carrier identification and prenatal diagnosis are available; a specific diagnosis is essential to permit genetic counseling. The characterization of the genes that encode the specific enzymes required for sphingolipid metabolism permit the development of therapeutic options, such as recombinant enzyme replacement therapy, as well as the potential of cell or gene therapy. Identification of specific disease-causing pathogenic variants improve diagnosis, prenatal detection, and carrier identification. For several disorders (Gaucher, Fabry, and NPD), it has been possible to make genotype-phenotype correlations that predict disease severity and allow more precise genetic counseling. Inheritance is autosomal recessive except for X-linked Fabry disease.

GM_1 GANGLIOSIDOSIS

GM_1 gangliosidosis most frequently presents in early infancy but has been described in patients with juvenile- and adult-onset subtypes (Fig. 106.18, Table 106.17). Inherited as an autosomal recessive trait, each subtype results from a different gene pathogenic variant that leads to the deficient activity of β-galactosidase, a lysosomal enzyme encoded by the gene *GLB1*. Although the disorder is characterized by the pathologic accumulation of GM_1 gangliosides in the lysosomes of both neural and visceral cells, GM_1 ganglioside accumulation is most marked in the brain. In addition, keratan sulfate, a mucopolysaccharide, accumulates in liver and is excreted in the urine of patients with GM_1 gangliosidosis.

The clinical manifestations of the infantile form of GM_1 gangliosidosis may be evident in the newborn as hepatosplenomegaly, edema, and skin eruptions (angiokeratoma). It most frequently presents in the first 6 months of life with developmental delay followed by progressive psychomotor retardation and the onset of tonic-clonic seizures. Typical facies is characterized by low-set ears, frontal bossing, a depressed nasal bridge, and an abnormally long philtrum. Up to 50% of patients have a macular cherry red spot. Hepatosplenomegaly and skeletal abnormalities similar to those of the mucopolysaccharidoses (see Chapter 109), including anterior beaking of the vertebrae, enlargement of the sella turcica, and thickening of the calvarium, are present. By the end of the first year of life, most patients are blind and deaf, with severe neurologic impairment characterized by decerebrate rigidity. Death usually occurs by 3-4 years of age. The *juvenile-onset* form of GM_1 gangliosidosis is clinically distinct, with a variable age at onset. Affected patients present primarily with neurologic symptoms including ataxia, dysarthria, intellectual disabilities, and spasticity. Deterioration is slow; patients may survive through the fourth decade of life. These patients lack the visceral involvement, facial abnormalities, and skeletal features seen in type 1 disease. *Adult-onset* patients have been described who present with gait and speech abnormalities, dystonia, and mild skeletal abnormalities. There is no specific treatment for any form of GM_1 gangliosidosis.

The diagnosis of GM_1 gangliosidosis should be suspected in infants with typical clinical features and is confirmed by the demonstration of biallelic pathogenic variants in *GLB1* and, as needed, demonstration of deficiency of β-galactosidase activity in peripheral leukocytes. Other disorders that share some of the features of the GM_1 gangliosidoses include Hurler disease (mucopolysaccharidosis type I), I-cell disease, and NPD type A, each of which can be distinguished by the demonstration of their specific genetic variants and enzymatic deficiencies. Carriers of the disorder are detected by the measurement of the enzymatic activity in peripheral leukocytes or by identifying the specific gene pathogenic variants. Prenatal diagnosis is accomplished by testing of known pathogenic variants or by determination of the enzymatic activity in cultured amniocytes or chorionic villi. Currently only supportive therapy is available for patients with GM_1 gangliosidosis.

THE GM_2 GANGLIOSIDOSES

The GM_2 gangliosidoses include the autosomal recessive Tay-Sachs disease and Sandhoff disease. Each results from the deficiency of β-hexosaminidase activity and the lysosomal accumulation of GM_2 gangliosides, particularly in the CNS. Both disorders have been classified into infantile-, juvenile-, and adult-onset forms based on the age at onset and clinical features. β-Hexosaminidase occurs as two isozymes: β-hexosaminidase A, which is composed of one α and one β subunit, and β-hexosaminidase B, which has two β subunits. β-Hexosaminidase A deficiency results from pathogenic variants in the α subunit and causes Tay-Sachs disease, whereas pathogenic variants in the β-subunit gene result in the deficiency of both β-hexosaminidases A and B and cause Sandhoff disease. Both are autosomal recessive traits, with Tay-Sachs disease having a predilection for the Ashkenazi Jewish population, where the carrier frequency is about 1/25.

More than 100 pathogenic variants in *HEXA* have been identified for Tay-Sachs disease. Most are associated with the infantile forms of disease. Three pathogenic variants account for >98% of mutant alleles among Ashkenazi Jewish carriers, including one allele associated with the adult-onset form. Pathogenic variants that cause the subacute or chronic forms result in enzyme proteins with residual enzymatic activities, the levels of which correlate with the severity of the disease.

Patients with the infantile form of Tay-Sachs disease have clinical manifestations in infancy including loss of motor skills, increased startle reaction, and macular pallor and retinal cherry red spots (see Table 106.15). Affected infants usually develop normally until 4-5 months of age, when decreased eye contact and an exaggerated startle response to noise (hyperacusis) are noted. Macrocephaly, not associated with hydrocephalus, may develop. In the second year of life, seizures develop, which may be refractory to anticonvulsant therapy. Neurodegeneration is relentless, with death occurring by the age of 4 or 5 years. The juvenile- and later-onset forms initially present with ataxia and dysarthria and may not be associated with a macular cherry red spot.

The clinical manifestations of Sandhoff disease are similar to those for Tay-Sachs disease. Infants with Sandhoff disease have hepatosplenomegaly, cardiac involvement, and mild bony abnormalities. The juvenile form of this disorder presents as ataxia, dysarthria, and intellectual deterioration, but without visceral enlargement or a macular cherry red spot. More than 50 pathogenic variants in *HEXB* have been identified for Sandhoff disease.

The diagnosis of infantile Tay-Sachs disease and Sandhoff disease is usually suspected in an infant with neurologic features and a cherry red spot. Definitive diagnosis is made by genetic testing or by determination of enzyme activities in peripheral leukocytes. The two disorders can be distinguished enzymatically, because in Tay-Sachs disease only the β-hexosaminidase A isozyme is deficient, whereas in Sandhoff disease both the β-hexosaminidase A and B isozymes are deficient. At-risk pregnancies for both disorders can be prenatally diagnosed by testing known pathogenic variants or determining enzyme levels in fetal cells obtained by amniocentesis or chorionic villus sampling. Identification of carriers in families is also possible by genetic or enzymatic determination. For Tay-Sachs disease, carrier screening of all couples in which at least one member is of Ashkenazi Jewish descent is recommended before the initiation of pregnancy to identify couples at risk. The incidence of Tay-Sachs disease has been markedly reduced since the introduction of carrier screening programs in the Ashkenazi Jewish population. Newborn screening may be possible by measuring specific glycosphingolipid markers or the relevant enzymatic activities in dried

Table 106.16 Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

DISORDER	ONSET	FACIES	NEUROLOGIC FINDINGS	DISTINCTIVE FEATURES
Niemann-Pick A disease	Early infancy	Frontal bossing	Difficulty feeding, apathy, deafness, blindness, hypotonia	Brownish-yellow skin, xanthomas
Niemann–Pick C disease	Birth to 3 mo	Normal	Developmental delay, vertical gaze paralysis, hypotonia, later spasticity	–
Gaucher disease type 2	In utero to 6 mo	Normal	Poor suck and swallow, weak cry, squint, trismus, strabismus, opsoclonus, hypertonic, later flaccidity	Congenital ichthyosis, collodion skin
Krabbe disease	3-6 mo	Normal	Irritability, tonic spasms with light or noise stimulation, seizures, hypertonia, later flaccidity	Increased CSF protein level
GM1 gangliosidosis	Birth	Coarse	Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity	Gingival hypertrophy, edema, rashes
Farber disease type I	2 wk to 4 mo	Normal	Progressive psychomotor impairment, seizures, decreased reflexes, hypotonia	Joint swelling with nodules, hoarseness, lung disease, contractures, fever, granulomas, dysphagia, vomiting, increased CSF protein level
Farber disease types II and III	Birth to 9 mo (≤20 mo)	Normal	—	Joint swelling with nodules, hoarseness
Farber disease type IV (neonatal)	Birth	Normal	Nodules not consistent findings	Corneal opacities (1/3)
Congenital sialidosis	In utero to birth	Cognitive, edema	Intellectual impairment, hypotonia	Neonatal ascites, inguinal hernias, renal disease
Galactosialidosis	In utero to birth	Coarse	Intellectual impairment, occasional deafness, hypotonia	Ascites, edema, inguinal hernias, renal disease, telangiectasias
Wolman disease	First weeks of life	Normal	Cognitive deterioration	Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications
Infantile sialic acid storage disease	In utero to birth	Coarse, dysmorphic	Intellectual impairment, hypotonia	Ascites, anemia, diarrhea, failure to thrive
I-cell disease	In utero to birth	Coarse	Intellectual impairment, deafness	Gingival hyperplasia, restricted joint mobility, hernias
Mucolipidosis type IV	Birth to 3 mo	Normal	Intellectual impairment, hypotonia	—
Mucopolysaccharidosis type VII	In utero to childhood	Variable coarseness	Mild to severe intellectual impairment	Hernias

Table 106.16 Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation—cont'd

EYE FINDINGS	DEFECT	GENE LOCATION/MOLECULAR FINDINGS	ETHNIC PREDILECTION
Cherry-red spot (50%)	Sphingomyelinase deficiency	*SMPD1* gene at 11p15.4; 3 of 18 variants account for approximately 92% of mutant alleles in the Ashkenazi population	1:40,000 in Ashkenazi Jews with a carrier frequency of 1:60
–	Abnormal cholesterol esterification	*NPC1* gene at 18q11 accounts for >95% of cases; *HE1* gene variants may account for remaining cases	Increased in French Canadians of Nova Scotia and Spanish Americans in the Southwest United States
–	Glucocerebrosidase deficiency	1q21; large number of variants known; five variants account for approximately 97% of mutant alleles in the Ashkenazi population but approximately 75% in the non-Jewish population	Panethnic
Optic atrophy	Galactocerebrosidase deficiency	14q 24.3-q32.1; >60 variants with some common variants in specific populations	Increased in Scandinavian countries and in a large Druze kindred in Israel
Cherry red spot (50%)	β-Galactosidase deficiency	3pter-3p21; heterogeneous variants; common variants in specific populations	Panethnic
Grayish opacification surrounding the retina in some patients, subtle cherry red spot	Lysosomal acid ceramidase	8p21.3-22; nine disease-causing variants identified	Panethnic
Normal macula, corneal opacities	—	8p21.3-p22	Panethnic
—	—	Unknown	Panethnic
Corneal clouding	Neuraminidase deficiency	*NEU 1* gene (sialidase) at 6p21	Panethnic
Cherry red spot, corneal clouding	Absence of a protective protein that safeguards neuraminidase and β-galactosidase from premature degradation	20q13.1	Panethnic
—	Lysosomal acid lipase deficiency	10q23.2-q23.3; variety of variants identified	Increased in Iranian Jews and in non-Jewish and Arab populations of Galilee
—	Defective transport of sialic acid out of the lysosome	*SLC17A5* gene at 6q	Panethnic
Corneal clouding	Lysosomal enzymes lack mannose 6-phosphate recognition marker and fail to enter the lysosome (phosphotransferase deficiency, 3-subunit complex [α2 β2 γ2])	Enzyme encoded by two genes; α and β subunits encoded by gene at 12p; γ subunit encoded by gene at 16p	Panethnic
Severe corneal clouding, retinal degeneration, blindness	Unknown; some patients with partial deficiency of ganglioside sialidase	*MCOLN1* gene at 19p13.2-13.3 encoding mucolipin 1; two founder variants accounting for 95% of mutant alleles in the Ashkenazi population	Increased in Ashkenazi Jews
Variable corneal clouding	β-Glucuronidase deficiency	*GUSB* gene at 7q21.2-q22; heterogeneous variants	Panethnic

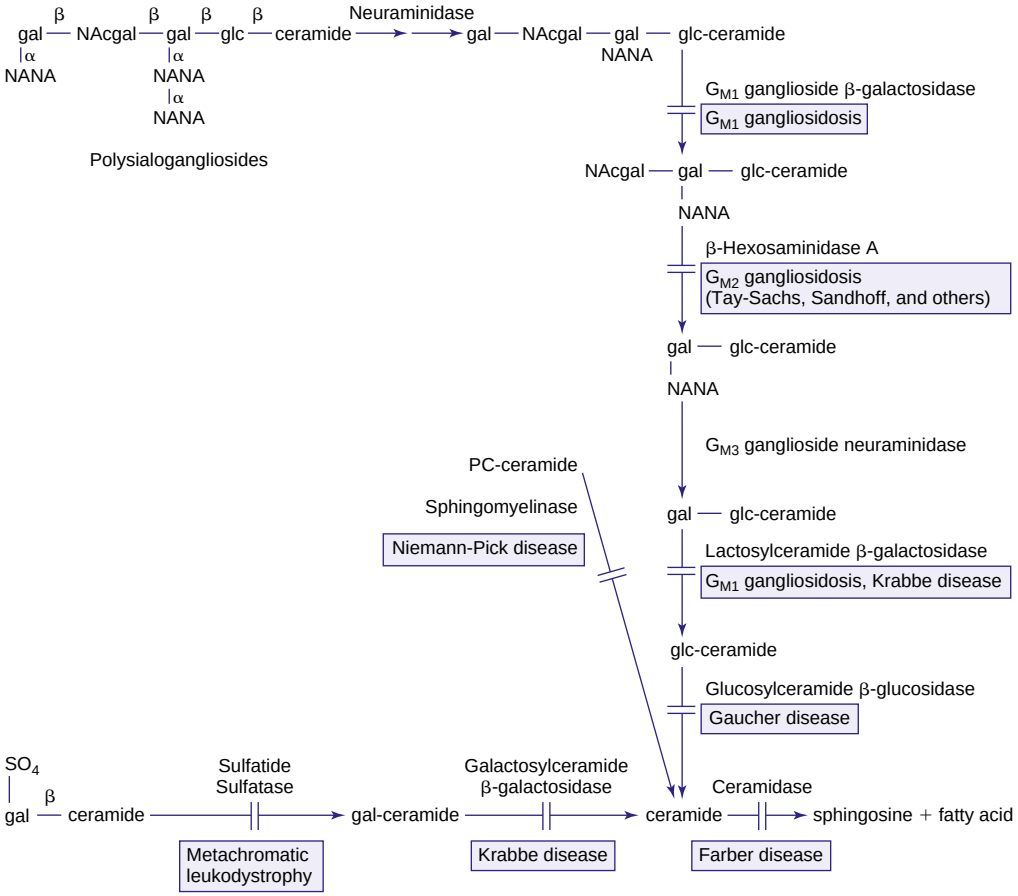

Fig. 106.15 Pathways in the metabolism of sphingolipids found in nervous tissues. The name of the enzyme catalyzing each reaction is given with the name of the substrate acted on. Inborn errors are depicted as bars crossing the reactions arrows, and the name of the associated defect or defects is given in the nearest box. The gangliosides are named according to the nomenclature of Svennerholm. Anomeric configurations are given only at the largest starting compound. Gal, galactose; glc, glucose; NAcgal, N-acetylgalactosamine; NANA, N-acetylneuraminic acid; PC, phosphorylcholine.

blood spots. There is no treatment available for Tay-Sachs disease or Sandhoff disease. The FDA has approved an investigational new drug application to initiate adeno-associated virus vector gene (beta hexosaminidase A and B) therapy for Tay-Sachs and Sandhoff disease.

GAUCHER DISEASE

This disease is a multisystemic lipidosis characterized by hematologic abnormalities, organomegaly, and skeletal involvement, the latter usually manifesting as bone pain and pathologic fractures (see Table 106.15 and 106.16). It is the most common lysosomal storage disease and the most prevalent genetic defect among Ashkenazi Jews. There are three clinical subtypes delineated by the absence or presence and progression of neurologic manifestations: type 1 or the adult, non-neuronopathic form; type 2, the infantile or acute neuronopathic form; and type 3, the juvenile or subacute neuronopathic form. All are autosomal recessive traits. Type 1, which accounts for 99% of cases, has a striking predilection for Ashkenazi Jews, with an incidence of about 1/1,000 and a carrier frequency of about 1/18.

Gaucher disease results from the deficient activity of the lysosomal hydrolase, acid β-glucosidase, which is encoded by the gene *GBA*. The enzymatic defect results in the accumulation of undegraded glycolipid substrates, particularly glucosylceramide, in cells of the reticuloendothelial system. This progressive deposition results in infiltration of the bone marrow, progressive hepatosplenomegaly, and skeletal complications. Four pathogenic variants—p.Asn370Ser, p.Leu444Pro, c.84insG, and IVS2+1G>A—account for about 95% of mutant alleles among Ashkenazi Jewish patients, permitting screening for this disorder in this population. Genotype-phenotype correlations have been noted, providing the molecular basis for the clinical heterogeneity seen in Gaucher disease type 1. Patients who are homozygous for the p.Asn370Ser pathogenic variant tend to have a later onset, with a more indolent course than patients with one copy of p.Asn370Ser and another common allele.

Clinical manifestations of type 1 Gaucher disease have a variable age at onset, from early childhood to late adulthood, with most symptomatic patients presenting by adolescence. At presentation, patients may have bruising from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated LFT results, splenomegaly, and bone pain. Occasional patients have pulmonary involvement at the time of presentation. Patients presenting in the first decade frequently are not Jewish and have growth retardation and a more malignant course. Other patients may be discovered fortuitously during evaluation for other conditions or as part of routine examinations; these patients may have a milder or even a benign course. In symptomatic patients, splenomegaly is progressive and can become massive. Most patients develop radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur. Clinically apparent bony involvement, which occurs in most patients, can present as bone pain, a pseudo-osteomyelitis pattern, or pathologic fractures. Lytic lesions can develop in the long bones, including the femur, ribs, and pelvis; osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis or bruising and is frequently overlooked until other symptoms become apparent. With the exception of the severely growth-stunted child, who may experience developmental delay secondary to the effects of chronic disease, development and intelligence are normal.

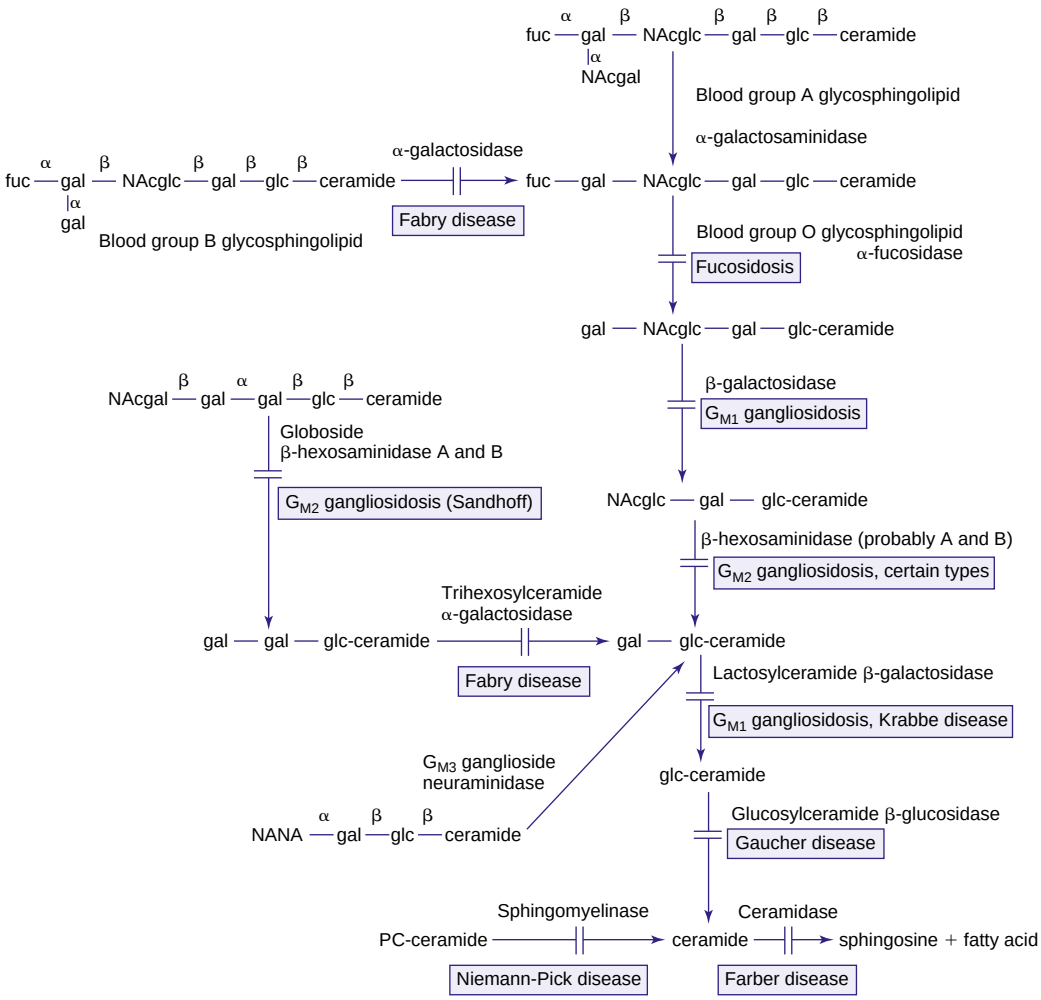

Fig. 106.16 Pathways in the degradation of sphingolipids found in visceral organs and red or white blood cells. See also the legend for Figure 106.15. Fuc, fucose; NAcglc, N-acetylglucosamine.

The pathologic hallmark of Gaucher disease is the Gaucher cell in the reticuloendothelial system, particularly in the bone marrow (Fig. 106.19). These cells, which are 20-100 μm in diameter, have a characteristic wrinkled paper appearance resulting from the presence of intracytoplasmic substrate inclusions. The cytoplasm of the Gaucher cell reacts strongly positive with the periodic acid–Schiff stain. The presence of this cell in bone marrow and tissue specimens is highly suggestive of Gaucher disease, although it also may be found in patients with granulocytic leukemia and myeloma.

Gaucher disease type 2 is much less common and does not have an ethnic predilection. It is characterized by a rapid neurodegenerative course with extensive visceral involvement and death within the first years of life. It presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor caused by laryngospasm are typical. After a several-year period of psychomotor regression, death occurs secondary to respiratory compromise. Gaucher disease type 3 presents as clinical manifestations that are intermediate to those seen in types 1 and 2, with a presentation in childhood and death by age 10-15 years. It has a predilection for the Swedish Norrbottnian population, among which the incidence is about 1/50,000. Neurologic involvement is present. Type 3 disease is further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Gaucher disease should be considered in the differential diagnosis of patients with unexplained organomegaly, who bruise easily, have bone pain, or have a combination of these conditions. Bone marrow examination usually reveals the presence of Gaucher cells. All suspected diagnoses should be confirmed by genetic testing or by determination of the acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts. In Ashkenazi Jewish individuals, the identification of carriers can be achieved best by molecular testing for the common pathogenic variants. Testing should be offered to all family members, keeping in mind that heterogeneity, even among members of the same kindred, can be so great that asymptomatic affected individuals may be diagnosed. Prenatal diagnosis is available by determination of the specific family pathogenic variants and/or enzyme activity of chorionic villi or cultured amniotic fluid cells.

Treatment of patients with Gaucher disease type 1 includes enzyme replacement therapy, with recombinant acid β-glucosidase (imiglucerase). Most extraskeletal symptoms (organomegaly, hematologic indices) are reversed by enzymes (60 IU/kg) administered by intravenous infusion every other week. Monthly maintenance enzyme replacement improves bone structure, decreases bone pain, and induces compensatory growth in affected children. A small number of patients have undergone bone marrow transplantation, which can be curative but results in significant morbidity and mortality from the procedure, making the selection of appropriate candidates limited. Although enzyme replacement does not alter the neurologic progression of patients with Gaucher disease types 2 and 3, it has been used in selected patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatments, including the use of agents designed to decrease the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase, are available for patients who cannot be treated by enzyme replacement.

NIEMANN-PICK DISEASE

Type A NPD is a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by 2-3 years of age. Type B disease is a non-neuronopathic form observed in children and adults. Type C disease is a neuronopathic form that results from defective cholesterol transport. All subtypes are inherited as autosomal recessive traits and display variable clinical features (see Tables 106.15 and 106.16).

NPD types A and B result from the deficient activity of acid sphingomyelinase, a lysosomal enzyme encoded by the gene *SMPD1*. The enzymatic defect results in the pathologic accumulation of sphingomyelin, a ceramide phospholipid, and other lipids in the monocyte-macrophage system as the primary pathologic site. The progressive deposition of sphingomyelin in the CNS results in the neurodegenerative course seen in type A and in non-neural tissue in the systemic disease manifestations of type B, including progressive lung disease in some patients. A variety of pathogenic variants in *SMPD1* that cause types A and B NPD have been identified.

The clinical manifestations and course of type A NPD is uniform and characterized by a normal appearance at birth. Hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation are evident by 6 months of age, followed by neurodevelopmental regression and death by 3 years. With advancing age, the loss of motor function and the deterioration of intellectual capabilities are progressively debilitating with spasticity and rigidity and in later stages. Affected infants lose contact with their environment. In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most are diagnosed in infancy or childhood when enlargement of the liver or spleen, or both, is detected during a routine physical examination. At diagnosis, type B NPD patients usually have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on the chest radiograph. Pulmonary symptoms usually present in adulthood. In most patients, hepatosple-nomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations.

In some type B patients, decreased pulmonary diffusion caused by alveolar infiltration becomes evident in late childhood or early

adulthood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by 15-20 years of age. Such patients have low Po_2 values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and *cor pulmonale* has been described. Severely affected patients may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia caused by secondary hypersplenism may require partial or complete splenectomy; this should be avoided if possible because splenectomy frequently causes progression of pulmonary disease, which can be life-threatening. In general, type B patients do not have neurologic involvement and have a normal IQ. Some patients with type B disease have cherry red maculae or haloes and subtle neurologic symptoms that can include peripheral neuropathy.

Type C NPD patients often present with prolonged neonatal jaundice, appear normal for 1-2 years, and then experience a slowly progressive and variable neurodegenerative course. Their hepato¬splenomegaly is less severe than that of patients with types A or B NPD, and they may survive into adulthood. The underlying biochemical defect in type C patients is an abnormality in cholesterol transport, leading to the accumulation of sphingomyelin and cholesterol in their lysosomes and a secondary partial reduction in acid sphingomyelinase activity (see Chapter 106.3).

In type B NPD patients, splenomegaly is usually the first manifestation detected. The splenic enlargement is noted in early childhood. In very mild disease, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic NPD cells in bone marrow aspirates supports the diagnosis of type B NPD. Patients with type C NPD, however, also have extensive infiltration of NPD cells in the bone marrow, and thus all suspected cases should be evaluated genetically or enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity level in peripheral leuko¬cytes, cultured fibroblasts, or lymphoblasts, or a combination of these cells. Patients with types A and B NPD have markedly decreased enzyme levels (1–10%), whereas patients with type C NPD have normal or mildly decreased acid sphingomyelinase activities. Without known genetic causes, the enzymatic identification of NPD carriers is problematic. In families in which the specific genetic lesion has been identified, however, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B NPD can be made by genetic testing and reliably by the measurement of acid sphingomyelinase activity in cultured amniocytes or chorionic villi. Historically, the diagnosis of Niemann-Pick type C has relied on the demonstration of the cholesterol transport defect in cultured fibroblasts by filipin staining but is now readily accomplished by genetic testing of the *NPC1* and *NPC2* genes and the measurement of oxidative cholesterol metabolites. There is no conclusive treatment for types A and B NPD. Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several type B NPD patients have been attempted with little or no success. Bone marrow transplantation in a small number of type B NPD patients has been shown to be successful in reducing the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and radiologically detected infiltration of the lungs. In one patient, liver biopsies taken up to 33 months after transplantation showed only a moderate reduction in stored sphingomyelin. Lung transplantation has not been performed in any severely compromised patient with type B disease, although two patients who underwent whole lung lavages with variable results have been reported. Enzyme replacement therapy (ERT) with recombinant human acid sphingomyelinase (olipudase alpha) is in clinical trials for the treatment of NPD type B. A 26-week phase 1b study in adult patients with NPD B established initial proof of concept in this patient group. In a phase 1/2 pediatric trial (ASCEND-Peds/NCT02292654) in children with chronic acid sphingomyelinase deficiency (ASMD), olipudase alfa was generally well-tolerated with improvements in disease pathology, and a phase 1/2 clinical trial in pediatric patients and a randomized phase 2/3 trial in adults (ASCEND) with ASMD documented improvement in lung function and spleen size.

Clinical trials of miglustat (Actelion, Basel, Switzerland) have been performed, and the drug has been approved in Europe for the treatment of type C disease. Treatment of type A disease with bone marrow transplantation has not been successful, presumably because of severe neurologic involvement.

FABRY DISEASE

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism characterized by angiokeratomas (telangiectatic skin lesions); hypohidrosis; corneal and lenticular opacities; acroparesthesias; and vascular disease of the kidney, heart, and/or brain (see Table 106.15). The classic phenotype is caused by deficient activity of the enzyme α-galactosidase A and has an estimated prevalence of approximately 1/50,000 males. Later-onset affected males with residual α-galactosidase A activity may present with cardiac and/or renal disease, including hypertrophic cardio¬myopathy and renal failure, and is more prevalent than the classic phenotype. Heterozygous females for the classic phenotype can be either asymptomatic or as severely affected as the males—the variability is a result of random X-inactivation. The disease results from pathogenic variants in α-galactosidase A encoded by the X-linked *GLA* gene. The enzymatic defect leads to the systemic accumulation of neutral glycosphingolipids, primarily globotriaosylceramide, particularly in the plasma and lysosomes of vascular endothelial and smooth muscle cells. The progressive vascular glycosphingolipid deposition in classically affected males results in ischemia and infarction, leading to the major disease manifestations. The cDNA and genomic sequences encoding α-galactosidase A have identified more than 500 different pathogenic variants in the α-galactosidase A gene that are responsible for this lysosomal storage disease, including amino acid substitutions, gene rearrangements, and mRNA splicing defects.

Affected males with the classic phenotype have the skin lesions, acroparesthesias, hypohidrosis, and ocular changes, whereas males with the later-onset phenotypes lack these findings and present with cardiac and/or renal disease in adulthood (Table 106.18). The classic angiokeratomas usually occur in childhood and may lead to early diagnosis (Fig. 106.20). They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised. They do not blanch with pressure, and the larger ones may show slight hyperkeratosis. Characteristically, the lesions are most dense between the umbilicus and knees, in the "bathing trunk area," but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed under slit-lamp examination, are present in affected males and in about 90% of heterozygotes. Conjunctival and retinal vascular tortuosity is common and results from the systemic vascular involvement.

Pain is the most debilitating symptom in childhood and adolescence. Fabry crises, lasting from minutes to several days, consist of agonizing, burning pain in the hands, feet, and proximal extremities and are usually associated with exercise, fatigue, fever, or a combination of these factors. These painful acroparesthesias usually become less frequent in the third and fourth decades of life, although in some men, they may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic.

The major morbid symptoms result from the progressive involvement of the vascular system. Early in the course of the disease, casts, red cells, and lipid inclusions with characteristic birefringent "Maltese crosses" appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the second through fourth decades. Cardiovascular findings may include hypertension, left ventricular hypertrophy, anginal chest pain, myocardial ischemia or infarction, and heart failure. Mitral insufficiency is the most common valvular lesion. Abnormal electrocardiographic and echocardiographic findings are common. Cerebrovascular manifestations result from multifocal small vessel involvement. Other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, retarded growth, and delayed puberty. Death most often results from uremia or vascular disease of the heart or brain. Before hemodialysis or renal transplantation, the mean age at death for affected men was 40 years. Patients with the later-onset phenotype with residual α-galactosidase A activity have cardiac and/or renal disease. The

Table 106.18 Summary of Reported Clinical Manifestations in Fabry Patients (Newborn to 4 Yr)

FABRY-RELATED SIGNS AND SYMPTOMS	EARLIEST REPORT OF SYMPTOM
Storage of globotriaosylceramide found in organs on biopsy	Prenatal
Corneal whorls/verticillata	Prenatal/newborn
Gastrointestinal problems, including nausea, vomiting, diarrhea, constipation, and abdominal pain	1.0 yr
Slow growth in boys (mean height/weight <50th percentile)	2.0 yr
Intermittent acroparesthesia/neuropathic pain triggered by stress, heat, fatigue, or exercise	2.0 yr
Hypohidrosis or anhidrosis	2.5 yr
Fabry crises of agonizing neuropathic pain typically begin in the hands and feet and may radiate proximally	2.5 yr
Heat, cold, and/or exercise intolerance	3.5 yr
Retinal vascular tortuosity	4.0 yr
Tinnitus/vertigo	4.0 yr
Low glomerular filtration rate	4.0 yr
T-wave inversion on electrocardiogram	4.0 yr
Trivial cardiac valve disease	4.0 yr
Angiokeratoma	4.4 yr

MELAS, Mitochondrial encephalopathy lactic acidosis, strokelike symptoms; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy.

cardiac manifestations include hypertrophy of the left ventricular wall and interventricular septum and electrocardiographic abnormalities consistent with cardiomyopathy. Others have had hypertrophic cardiomyopathy or myocardial infarction, or both.

The diagnosis in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence of characteristic skin lesions, and the observation of the characteristic corneal opacities and lenticular lesions. The disorder is often misdiagnosed as rheumatic fever, erythromelalgia, or neurosis (Table 106.19). The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (Fordyce disease) or from angiokeratoma circumscriptum. Angiokeratomas identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM_1 gangliosidosis, galactosialidosis, α-N-acetylgalactosaminidase deficiency, and sialidosis. Later-onset patients have been identified among patients on hemodialysis and among patients with hypertrophic cardiomyopathy or who have suffered cryptogenic strokes. Later-onset patients lack the early classic manifestations such as the angiokeratomas, acroparesthesias, hypohidrosis, and corneal opacities. The diagnosis of classic and later-onset patients is confirmed biochemically by the demonstration of markedly decreased α-galactosidase A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts.

Heterozygous females may have corneal opacities, isolated skin lesions, and intermediate activities of α-galactosidase A in plasma or cells. Rare female heterozygotes may have manifestations as severe as those in affected males. Asymptomatic at-risk females in families affected by Fabry disease, however, should be optimally diagnosed by the direct analysis of their family's specific pathogenic variant. Prenatal detection of affected males can be accomplished by the demonstration of deficient α-galactosidase A activity or the family's specific gene pathogenic variant in chorionic villi obtained in the first trimester or in cultured amniocytes obtained by amniocentesis in the second trimester of pregnancy. Fabry disease can be detected by newborn screening, and pilot studies have been conducted in Italy and Taiwan.

Treatment for Fabry disease may include the use of phenytoin and/or carbamazepine to decrease the frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis are lifesaving procedures for patients with renal failure.

Recombinant α-galactosidase is a safe and effective ERT of choice for Fabry disease at a dose of 1 mg/kg every other week. It has been shown to clear microvascular endothelial deposits of globotriaosylceramide from the kidneys, heart, and skin in patients with Fabry disease with stabilization of renal disease, regression of hypertrophic cardiomyopathy, reduction of pain, and improvement in quality of life. Migalastat, a protein-folding chaperone therapy, is an oral treatment for Fabry that can both be used as a first-line therapy in ERT-naïve patients and as an alternative to ERT in patients with a migalastat-amenable pathogenic variant.

FUCOSIDOSIS

This is a rare autosomal recessive disorder caused by the deficient activity of α-fucosidase and the accumulation of fucose-containing glycosphingolipids, glycoproteins, and oligosaccharides in the lysosomes of the liver, brain, and other organs (see Table 106.15). α-Fucosidase is encoded by the *FUCA1* gene, and specific pathogenic variants are known. Although the disorder is panethnic, most affected patients are from Italy and the United States. There is wide variability in the clinical phenotype, with the most severely affected patients presenting in the first year of life with developmental delay and somatic features similar to those of the mucopolysaccharidoses. These features include frontal bossing, hepatosplenomegaly, facial features, and macroglossia. The CNS storage results in a relentless neurodegenerative course, with death in childhood. Patients with milder disease have angiokeratomas and longer survival. No specific therapy exists for the disorder, which can be diagnosed by the demonstration of pathogenic variants in *FUCA1* or deficient α-fucosidase activity in peripheral leukocytes or cultured fibroblasts. Carrier identification studies and prenatal diagnosis are possible by determination of the enzymatic activity or the specific family pathogenic variants.

SCHINDLER DISEASE

Schindler disease is an autosomal recessive neurodegenerative disorder that results from the deficient activity of α-N-acetylgalactosaminidase and the accumulation of sialylated and asialoglycopeptides and oligosaccharides (see Table 106.15). The enzyme is encoded by the gene *NAGA*. The disease is clinically heterogeneous, and two major phenotypes have been identified. Type I disease is an infantile-onset neuroaxonal dystrophy. Affected

infants have normal development for the first 9-15 months of life followed by a rapid neurodegenerative course that results in severe intellectual disability, cortical blindness, and frequent myoclonic seizures. Type II disease is characterized by a variable age at onset, mild retardation, and angiokeratomas. There is no specific therapy for either form of the disorder. The diagnosis is by demonstration of the enzymatic deficiency in leukocytes or cultured skin fibroblasts or specific gene pathogenic variants.

METACHROMATIC LEUKODYSTROPHY (MLD)

This is an autosomal recessive white matter disease caused by a deficiency of arylsulfatase A (ASA) encoded by the gene *ARSA,* which is required for the hydrolysis of sulfated glycosphingolipids. Another form of MLD is caused by a deficiency of a sphingolipid activator protein (SAP1) encoded by the gene *PSAP,* which is required for the formation of the substrate-enzyme complex. The deficiency of this enzymatic activity results in the white matter storage of sulfated glycosphingolipids, which leads to demyelination and a neurodegenerative course. Pathogenic variants fall into two groups that correlate with disease severity.

The clinical manifestations of the late infantile form of MLD, which is most common, usually present between 12 and 18 months of age as irritability, inability to walk, and hyperextension of the knee, causing genu recurvatum. The clinical progression of the disease relates to the pathologic involvement of both central and peripheral nervous systems, giving a mixture of upper and lower motor neuron and cognitive and psychiatric signs. Deep tendon reflexes are diminished or absent. Gradual muscle wasting, weakness, and hypotonia become evident and lead to a debilitated state. As the disease progresses, nystagmus, myoclonic seizures, optic atrophy, and quadriparesis appear, with death in the first decade of life (see Table 106.15). The juvenile form of the disorder has a more indolent course with an onset that may occur as late as 20 years of age. This form of the disease presents with gait disturbances, mental deterioration, urinary incontinence, and emotional difficulties. The adult form, which presents after the second decade, is similar to the juvenile form in its clinical manifestations, although emotional difficulties and psychosis are more prominent features. Dementia, seizures, diminished reflexes, and optic atrophy also occur in both the juvenile and adult forms. The pathologic hallmark of MLD is the deposition of metachromatic bodies, which stain strongly positive with periodic acid–Schiff and Alcian blue, in the white matter of the brain. Neuronal inclusions may be seen in the midbrain, pons, medulla, retina, and spinal cord; demyelination occurs in the peripheral nervous system. Bone marrow transplantation has resulted in normal enzymatic levels in peripheral blood but there is no clear evidence for clinical efficacy in terms of the neurologic course; supportive care remains the primary intervention. Lentiviral transduced ex vivo autologous stem and progenitor cells with human arylsulfatase cDNA treatment has resulted in sustained and clinically important benefits in children with early onset disease. Cognitive function has been preserved, as has motor development in preliminary trials.

The diagnosis of MLD should be suspected in patients with the clinical features of leukodystrophy. Decreased nerve con¬duction velocities, increased cerebrospinal fluid protein, metachromatic deposits in sampled segments of the sural nerve, and metachromatic granules in urinary sediment are all suggestive of MLD. Confirmation of the diagnosis is based on the demonstration of pathogenic variants in *ARSA* or reduced activity of ASA in leukocytes or cultured skin fibroblasts. Sphingolipid activator protein deficiency is diagnosed by genetic testing of *PSAP* or by measuring the concentration of SAP1 in cultured fibroblasts using a specific antibody to the protein. Carrier detection and prenatal diagnosis are available for all forms of the disorder.

MULTIPLE SULFATASE DEFICIENCY

This is an autosomal recessive disorder that results from the enzymatic deficiency of at least nine sulfatases including arylsulfatases A, B, and C and iduronate-2-sulfatase. The specific defect has been shown to be an enzyme in the C-α-formylglycine generating system encoded by the gene *SUMF1,* which introduces a common posttranslational modification in all of the affected sulfatases and explains the occurrence of these multiple enzyme defects. Because of the deficiency of these enzymes, sulfatides, mucopolysaccharides, steroid sulfates, and gangliosides accumulate in the cerebral cortex and visceral tissues, resulting in a clinical phenotype with features of leukodystrophy as well as those of the mucopolysaccharidoses. Severe ichthyosis may also occur. Carrier testing and prenatal diagnosis by measurement of the enzymatic activities can be performed. There is no specific treatment for multiple sulfatase deficiency other than supportive care.

KRABBE DISEASE

This condition, also called *globoid cell leukodystrophy,* is an autosomal recessive fatal disorder of infancy. It results from the deficiency of the enzymatic activity of galactocerebrosidase encoded by the *GALC* gene, leading to white matter accumulation of galactosylceramide, which is normally found almost exclusively in the myelin sheath. Both peripheral and central myelin are affected, resulting in spasticity and cognitive impairment coupled with deceptively normal or even absent deep tendon reflexes. Specific disease-causing pathogenic variants are known. The infantile form of Krabbe disease is rapidly progressive, and patients present in early infancy with irritability, seizures, and hypertonia (see Table 106.16). Optic atrophy is evident in the first years of life, and cognitive development is severely impaired. As the disease progresses, optic atrophy and severe developmental delay become apparent; affected children exhibit opisthotonos and typically die before 3 years of age. A second, late infantile form of Krabbe disease also exists, and patients present after the age of 2 years. Affected individuals, however, have a disease course similar to that of the early infantile form.

The diagnosis of Krabbe disease relies on the demonstration of the specific pathogenic variants or by enzymatic deficiency in white blood cells or cultured skin fibroblasts. Carrier identification and prenatal diagnosis are available. The development of methods to measure GALC activity on dried blood spots has led to the inclusion of Krabbe disease in the newborn screening programs of some states. Treatment of infants with Krabbe disease with umbilical cord blood cell transplantation has been reported in prenatally identified asymptomatic newborns and symptomatic infants. The long-term outcome of umbilical cord blood cell transplantation is being evaluated; transplanted infants develop neurologic manifestations at a slower rate but succumb to a neurologic demise.

FARBER DISEASE

This is a rare autosomal recessive disorder that results from the deficiency of the lysosomal enzyme acid ceramidase and the accumulation of ceramide in various tissues, especially the joints. Symptoms can begin as early as the first year of life with painful joint swelling and nodule formation (Fig. 106.21), which is sometimes diagnosed as rheumatoid arthritis. As the disease progresses, nodule or granulomatous formation on the vocal cords can lead to hoarseness and breathing difficulties; failure to thrive is common. In some patients, moderate CNS dysfunction is present (see Table 106.16). Patients may die of recurrent pneumonias in their teens; there is currently no specific therapy. The diagnosis of this disorder should be suspected in patients who have nodule formation over the joints but no other findings of rheumatoid arthritis. In such patients, ceramidase activity should be determined in cultured skin fibroblasts or peripheral leukocytes. Various disease-causing pathogenic variants have been identified in the gene encoding acid ceramidase *(ASAH1).* Carrier detection and prenatal diagnosis are

Fig. 106.21 Forearm of an 18-month old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

available. There is no specific treatment, but a recombinant human acid ceramidase is under development.

WOLMAN DISEASE AND CHOLESTEROL ESTER STORAGE DISEASE (CESD)

These are autosomal recessive lysosomal storage diseases that result from the deficiency of lysosomal acid lipase and the accumulation of cholesterol esters and triglycerides in histiocytic foam cells of most visceral organs. Wolman disease is the more severe clinical phenotype and is a fatal disorder of infancy. Clinical features become apparent in the first weeks of life and include failure to thrive, relentless vomiting, abdominal distention, steatorrhea, and hepatosplenomegaly (see Table 106.15). There usually is hyperlipidemia. Hepatic dysfunction and fibrosis may occur. Calcification of the adrenal glands is pathognomonic for the disorder. Death usually occurs within 6 months.

CESD is a less severe disorder that may not be diagnosed until adulthood. Hepatomegaly can be the only detectable abnormality, but affected individuals are at significant risk for premature atherosclerosis. Adrenal calcification is not a feature.

Lysosomal acid lipase is encoded by the *LIPA* gene. Diagnosis and carrier identification can be performed by genetic testing or by measuring acid lipase activity in peripheral leukocytes or cultured skin fibroblasts. Prenatal diagnosis can use pathogenic variants or enzyme levels in cultured chorionic villi or amniocytes. Pharmacologic agents to suppress cholesterol synthesis, in combination with cholestyramine and diet modification, have been used in patients with CESD (see Chapter 106.3). Sebelipase alfa (Kanuma) is a commercially available recombinant human lysosomal acid lipase that is approved in the European Union (EU), the United States, and Japan as a long-term ERT for patients diagnosed with LAL deficiency.

106.5 Mucolipidoses

Margaret M. McGovern and Robert J. Desnick

I-cell disease (mucolipidosis II [ML-II]) and pseudo-Hurler polydystrophy (mucolipidosis III [ML-III]) are rare autosomal recessive disorders that share some clinical features with Hurler syndrome (see Chapter 109). These diseases result from the abnormal transport of newly synthesized lysosomal enzymes that are normally targeted to the lysosome by the presence of mannose-6-phosphate residues and recognized by specific lysosomal membrane receptors. These mannose-6-phosphate recognition markers are synthesized in a two-step reaction that occurs in the Golgi apparatus and is mediated by two enzymatic activities. The enzyme that catalyzes the first step, the UDP-N-acetylglucosamine:lysosomal enzyme *N*-acetylglucosamine-1-phosphotransferase, is defective in both ML-II and ML-III, which are allelic disorders resulting from pathogenic variants in the GlcNAc-phosphotransferase alpha/beta-subunits precursor gene *(GNPTAB)*. This enzyme deficiency results in the lack of mannose-6-phosphate tagging of lysosomal enzymes to result in disrupted targeting to the lysosome, and they are consequently secreted into the extracellular matrix. Because the lysosomal enzymes require the acidic medium of the lysosome to function, patients with this defect accumulate a variety of different substrates because of the intracellular deficiency of all lysosomal enzymes. The diagnosis of ML-II and ML-III can be made by genetic testing of the *GNPTAB* gene, determination of the serum lysosomal enzymatic activities, which are elevated, or by the demonstration of reduced enzymatic activity levels in cultured skin fibroblasts. Direct measurement of the phosphotransferase activity is possible as well. Prenatal diagnosis is available for both disorders using familial pathogenic variants or by measurement of lysosomal enzymatic activities in amniocytes or chorionic villus cells; carrier identification studies are available for both disorders using cultured skin fibroblasts. Neonatal screening by tandem mass spectroscopy may detect I-cell disease.

I-CELL DISEASE

This disorder shares many of the clinical manifestations of Hurler syndrome (see Chapter 109), although there is no mucopolysaccharidurria and the presentation is earlier (see Table 106.16). Some patients have clinical features evident at birth, including coarse facial features, craniofacial abnormalities, restricted joint movement, and hypotonia. Nonimmune hydrops may be present prenatally. The remainder of patients present in the first year with severe psychomotor retardation, coarse facial features, and skeletal manifestations that include kyphoscoliosis and a lumbar gibbus. Patients may also have congenital dislocation of the hips, inguinal hernias, and gingival hypertrophy. Progressive, severe intellectual disability leads to death in early childhood. No treatment is available.

PSEUDO-HURLER POLYDYSTROPHY

Pseudo-Hurler polydystrophy is a less severe disorder than I-cell disease, with later onset and survival to adulthood reported. Affected children may present around the age of 4 or 5 years of age with joint stiffness and short stature. Progressive destruction of the hip joints and moderate dysostosis multiplex are evident. Radiographic evidence of low iliac wings, flattening of the proximal femoral epiphyses with valgus deformity of the femoral head, and hypoplasia of the anterior third of the lumbar vertebrae are characteristic findings. Ophthalmic findings include corneal clouding, retinopathy, and astigmatism; visual complaints are uncommon (see Tables 106.15 and 106.16). Some patients have learning disabilities or mental retardation. Treatment, which should include orthopedic care, is symptomatic.

Chapter 107

Defects in Metabolism of Carbohydrates

Ghada Hijazi and Priya S. Kishnani

Carbohydrate synthesis and degradation provide the energy required for most metabolic processes. The important carbohydrates include three monosaccharides—glucose, galactose, and fructose—and a polysaccharide, glycogen. Figure 107.1 shows the relevant biochemical pathways of these carbohydrates. **Glucose** is the principal substrate of energy metabolism, continuously available through dietary intake, glycogenolysis (breakdown of glycogen), and gluconeogenesis (glucose made de novo from amino acids, primarily alanine). Metabolism of glucose generates adenosine triphosphate (ATP) via glycolysis (conversion of glucose or glycogen to pyruvate), mitochondrial oxidative phosphorylation (conversion of pyruvate to carbon dioxide and water), or both. Dietary sources of glucose come from polysaccharides, primarily starch, and the disaccharides lactose, maltose, and sucrose. However, oral intake of glucose is intermittent and unreliable. Hepatic glycogenolysis provides the rapid release of glucose and is the most significant factor in maintaining euglycemia (normal levels of glucose in the blood). **Glycogen** is also the primary stored energy source in muscle, providing glucose for muscle activity during exercise. Gluconeogenesis contributes to maintaining euglycemia but is less immediate. Galactose and fructose are monosaccharides that provide fuel for cellular metabolism, though their role is less significant than that of glucose. **Galactose** is derived from lactose (galactose + glucose), which is found in milk and milk products. Galactose is an important energy source in infants. Galactose (exogenous or endogenously synthesized from glucose) is also an important component of certain glycolipids, glycoproteins, and glycosaminoglycans. The dietary sources of **fructose** are fruits, vegetables, and honey. It is also found in the disaccharide sucrose (fructose + glucose) and the sugar alcohol sorbitol.

Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues, thus the name **glycogen storage disease** (Table 107.1). Defects in gluconeogenesis or the glycolytic pathway, including galactose and fructose metabolism, do not result in an accumulation of glycogen (see Table 107.1). The defects in pyruvate metabolism in the pathway of the conversion of pyruvate to carbon dioxide and water via mitochondrial oxidative phosphorylation are more often associated with **lactic acidosis**.

107.1 Glycogen Storage Diseases

Ghada Hijazi and Priya S. Kishnani

The disorders of glycogen metabolism, the glycogen storage diseases (GSDs), result from deficiencies of enzymes or transport proteins in the pathways of glycogen metabolism (see Fig. 107.1). Glycogen found in these disorders is abnormal in quantity, quality, or both. GSDs are categorized by numerical type in accordance with the chronological order in which these enzymatic defects were identified. This numerical classification is still widely used, at least up to number VII. The GSDs can also be classified by organ involvement into liver and muscle glycogenoses (see Table 107.1).

There are more than 15 forms of GSDs. Glucose-6-phosphatase deficiency (type I), lysosomal acid α-glucosidase deficiency (type II), debrancher deficiency (type III), branching enzyme deficiency (type IV), liver phosphorylase deficiency (type VI), and liver phosphorylase kinase deficiency (type IX) are the most common of those that typically present in early childhood. Myophosphorylase deficiency (type V, McArdle disease) is the most common in adolescents and adults. The cumulative frequency of all forms of GSD is approximately 1 in 10,000-25,000 live births.

LIVER GLYCOGENOSES

The GSDs that principally affect the liver include glucose-6-phosphatase deficiency **(type I)**, debranching enzyme deficiency **(type III)**, branching enzyme deficiency **(type IV)**, liver phosphorylase deficiency **(type VI)**, phosphorylase kinase deficiency (**type IX**), glycogen synthase deficiency **(type 0)**, and glucose transporter-2 (GLUT2) defect (Fanconi-Bickel syndrome). Because hepatic carbohydrate metabolism is responsible for plasma glucose homeostasis, this group of disorders typically causes fasting hypoglycemia and hepatomegaly. Some GSDs (types III, IV, VI, IX) can be associated with liver fibrosis and cirrhosis. Other organs can also be involved and may manifest as renal dysfunction in type I; myopathy (skeletal and/or cardiomyopathy) in types III, IV, and some rare forms of phosphorylase kinase deficiency; and neurologic involvement in types III (peripheral nerves) and IV (diffuse central and peripheral nervous system dysfunction).

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, von Gierke Disease)

Type I GSD is caused by the absence or deficiency of **glucose-6-phosphatase activity** in the liver, kidney, and intestinal mucosa. It has two subtypes: **type Ia**, in which the defective enzyme is glucose-6-phosphatase, and **type Ib**, in which the defective enzyme is a **translocase** that transports glucose-6-phosphate across the microsomal membrane. Deficiency of the enzymes in both types Ia and Ib lead to inadequate hepatic conversion of glucose-6-phosphate to glucose through normal glycogenolysis and gluconeogenesis, resulting in fasting hypoglycemia.

Type I GSD is an autosomal recessive disorder. The gene for subtype Ia is *G6PC*, and the gene for subtype Ib is *SLC37A4*. Common pathogenic variants have been identified in different ancestral populations. Carrier detection and prenatal diagnosis are possible with DNA-based methodologies.

Clinical Manifestations

Patients with type I GSD may present in the neonatal period with hypoglycemia and lactic acidosis, but more often present at 3-4 months of age because of increased intervals between feeds and at time of weaning. Infants can present with hepatomegaly, hypoglycemic seizures, or both. Affected children are often described as having **"doll-like" faces** with full cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is a consequence of massive hepatomegaly. The kidneys are also enlarged, whereas the spleen and heart are not involved.

Intermittent diarrhea may occur in GSD I. In patients with GSD Ib, diarrhea appears to be caused by the loss of mucosal barrier function via inflammation, which is likely related to glycogen-mediated impairment of neutrophil function. Easy bruising and epistaxis are common and are associated with a **prolonged bleeding time** as a result of impaired platelet aggregation and adhesion. A von Willebrand factor–like deficiency and/or dysfunction has also been found in GSD Ia patients.

The biochemical characteristics of type I GSD are hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Hypoglycemia and lactic acidosis can develop even after short fasts. Hyperuricemia is present in young children and rarely progresses to symptomatic gout before puberty. Despite marked hepatomegaly, the liver transaminase levels are usually normal or only slightly elevated. The plasma may be "milky" in appearance due to strikingly elevated triglyceride levels. Cholesterol and phospholipids are also elevated, albeit less prominently. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very low-density lipoprotein, low-density lipoprotein, and a unique apolipoprotein profile consisting of increased levels of apolipoproteins B, C, and E, with relatively normal or reduced levels of apolipoproteins A and D. The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and

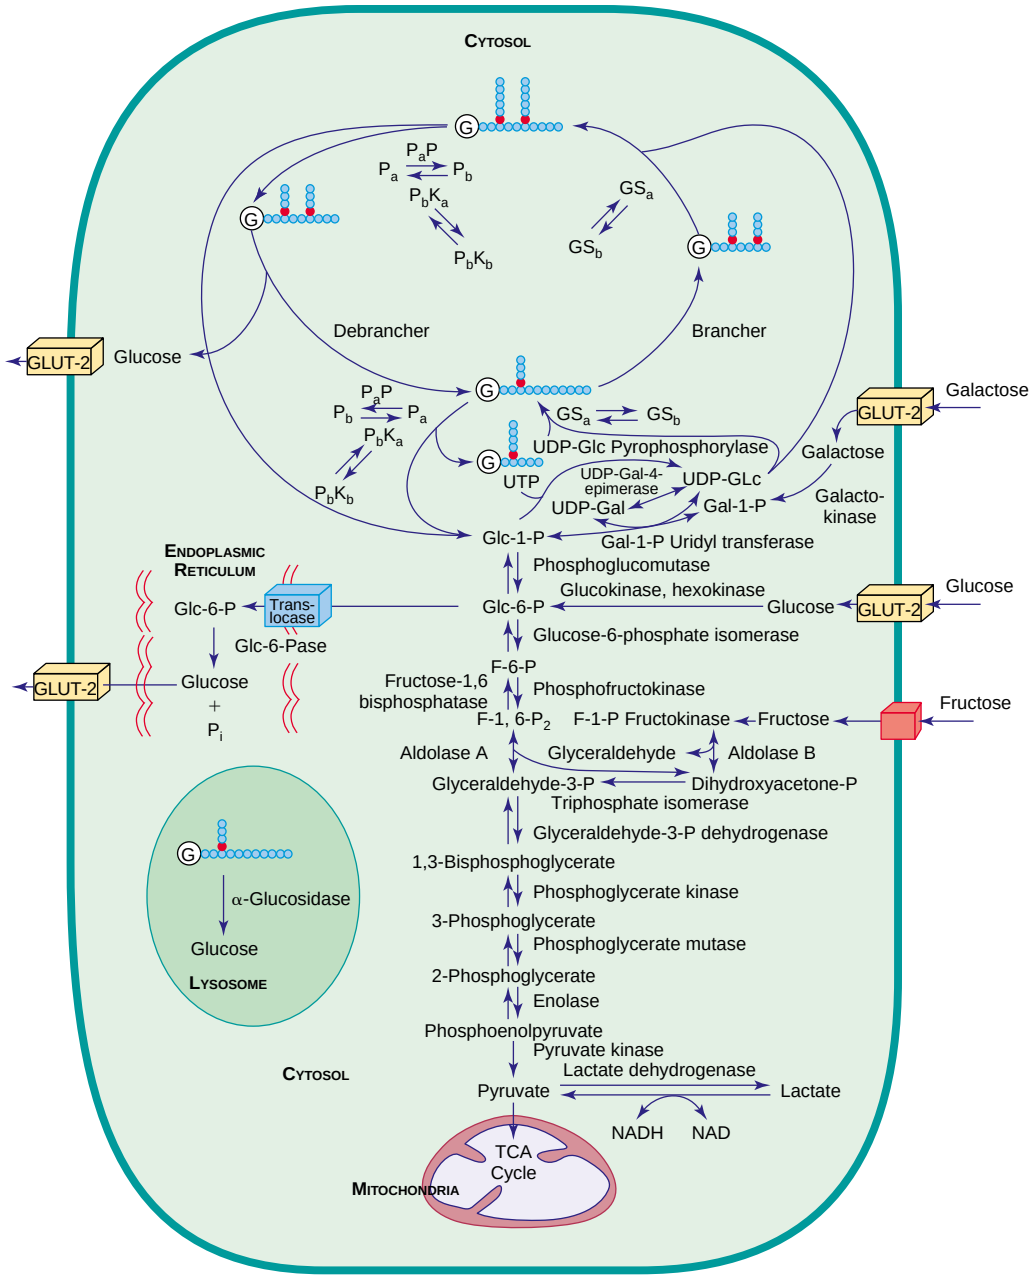

Fig. 107.1 Pathway related to glycogen storage diseases and galactose and fructose disorders. G, Glycogenin, the primer for glycogen synthesis; GLUT-2, glucose transporter 2; GSa, active glycogen synthase; GSb, inactive glycogen synthase; NAD/NADH, nicotinamide adenine dinucleotide; Pa, active phosphorylase; PaP, phosphorylase a phosphatase; Pb, inactive phosphorylase; PbKa, active phosphorylase b kinase; PbKb, inactive phosphorylase b kinase; UDP, uridine diphosphate. *(Adapted from Beaudet AR. Glycogen storage disease. In: Harrison TR, Isselbacher KJ, eds. Harrison's Principles of Internal Medicine, 13th ed. New York: McGraw-Hill; 1994.)*

fat. The lipid vacuoles are particularly large and prominent, and there is no associated liver fibrosis.

Although type I GSD affects mainly the liver, multiple organ systems are involved. **Delayed puberty** is often seen. Females can have ultrasound findings consistent with **polycystic ovaries**, even though other features of polycystic ovary syndrome (acne, hirsutism) are not seen. Nonetheless, fertility appears to be normal, as evidenced in several reports of successful pregnancy in women with GSD I. Increased bleeding during menstrual cycles, including life-threatening menorrhagia, has been reported and could be related to the impaired platelet aggregation. Symptoms of gout usually start around puberty from long-term hyperuricemia. There is an increased risk of **pancreatitis**, secondary to the lipid abnormalities. The dyslipidemia, together with elevated erythrocyte aggregation, could predispose these patients to atherosclerosis, but premature atherosclerosis has not yet been clearly documented except in rare cases. Impaired platelet aggregation and increased antioxidative defense to prevent lipid peroxidation may function as protective mechanisms to help reduce the risk of atherosclerosis. Frequent fractures and radiographic evidence of **osteopenia** are common, and bone mineral content is reduced, even in prepubertal patients.

By the second or third decade of life, some patients with type I GSD develop **hepatic adenomas** that can hemorrhage and become malignant in some cases. **Pulmonary hypertension** has been seen in some long-term survivors of the disease. Iron-refractory anemia and an increased prevalence of thyroid autoimmunity are also being recognized.

Renal disease is another late complication, and most patients with type I GSD over 20 years of age have proteinuria. Glomerular

Table 107.1 Features of the Disorders of Carbohydrate Metabolism

DISORDERS	BASIC DEFECTS	CLINICAL PRESENTATION	COMMENTS
LIVER GLYCOGENOSES			
Type/Common Name			
Ia/von Gierke	Glucose-6-phosphatase complex	Growth retardation, hepatomegaly, hypoglycemia; elevated blood lactate, cholesterol, triglyceride, and uric acid levels	Common, severe hypoglycemia. Adulthood: hepatic adenomas and risk for carcinoma, osteoporosis, pulmonary hypertension, and renal failure
Ib	Glucose-6-phosphate translocase	Same as type Ia, with additional findings of neutropenia, periodontal disease, inflammatory bowel disease, and increased risk of autoimmune hypothyroidism	10% of type I
IIIa/Cori or Forbes	Liver and muscle debrancher deficiency	Childhood: hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated transaminase levels, hepatic fibrosis, left ventricular hypertrophy. Later childhood to adulthood: muscle atrophy and weakness, liver cirrhosis and failure, risk for hepatocellular carcinoma, cardiac hypertrophy and fibrosis, life-threatening arrhythmia at any age.	Common, intermediate severity of hypoglycemia. Muscle weakness may progress to the point that ambulation assistance such as wheelchair use is required.
IIIb	Liver debrancher deficiency; normal muscle enzyme activity	Liver symptoms same as in type IIIa; no muscle or heart symptoms	15% of type III
IV/Andersen/adult polyglucosan body disease	Branching enzyme	Infancy/childhood failure to thrive, hypotonia, hepatomegaly, splenomegaly, cirrhosis progressing to liver failure (death usually before fifth year), elevated transaminase levels; a subset does not have overt progression to liver failure. Risk for extrahepatic manifestations, such as myopathy and cardiomyopathy. Perinatal: decreased fetal movements, polyhydramnios, fetal hydrops; arthrogryposis, hypotonia, muscle atrophy at birth, death in the perinatal period. Congenital: neonatal hypotonia, respiratory failure, dilated cardiomyopathy, early infantile death. Childhood: neuromuscular manifestations, cardiomyopathy. Adult form, adult polyglucosan body disease (APBD): progressive muscle weakness, neuropathic bladder, gait spasticity, central and peripheral nervous system involvement.	A continuum of disease severity, related to residual enzyme activity; multisystem involvement
VI/Hers	Liver phosphorylase	Hepatomegaly, hypoglycemia, hyperlipidemia, elevated liver enzyme levels, and ketosis	Often underdiagnosed; severe presentation also known
IX/phosphorylase kinase (PhK) deficiency			Common, X-linked GSD IX α2, typically less severe than autosomal form GSD IX γ2; clinical variability within and between subtypes; severe cases being recognized across different subtypes
IX α2 (*PHKA2* variant)	Liver PhK	Hypoglycemia, hyperketosis, hepatomegaly, chronic liver disease, liver fibrosis, hyperlipidemia, elevated liver enzymes, growth retardation	X-linked
IX β (*PHKB* variant)	Liver and muscle PhK	Hepatomegaly, growth retardation, mild or absent muscle disease.	Autosomal recessive
IX γ2 (*PHKG2* variant)	Liver PhK	More severe than IX α2; marked hepatomegaly, recurrent hypoglycemia, hyperlipidemia, markedly elevated liver enzymes, liver fibrosis/cirrhosis	Autosomal recessive
0a/Liver glycogen synthase deficiency	Liver glycogen synthase	Early morning drowsiness and fatigue, fasting hypoglycemia and ketosis, no hepatomegaly	Decreased liver glycogen stores
XI/Fanconi-Bickel syndrome	Glucose transporter 2 (GLUT-2)	Failure to thrive, rickets, hepatomegaly, renomegaly, proximal renal tubular dysfunction, impaired glucose and galactose use	GLUT-2 expressed in liver, kidney, pancreas, and intestine
MUSCLE GLYCOGENOSES			
Type/Common Name			
II/infantile Pompe	Acid α-glucosidase	Cardiomegaly, hypotonia, hepatomegaly; onset at birth to age 6 mo	Common, cardiorespiratory failure leading to death by age 1-2 yr; minimal to no residual enzyme activity
II/late-onset Pompe (juvenile and adult)	Acid α-glucosidase	Myopathy (proximal limb girdle), variable cardiomyopathy, respiratory insufficiency; onset from infancy and early childhood to adulthood	Residual enzyme activity
Danon disease	Lysosome-associated membrane protein 2 (LAMP2)	Hypertrophic cardiomyopathy, heart failure, retinopathy, mild cognitive dysfunction	Rare, X-linked

Table 107.1 Features of the Disorders of Carbohydrate Metabolism—cont'd

DISORDERS	BASIC DEFECTS	CLINICAL PRESENTATION	COMMENTS
PRKAG2 syndrome	Adenosine monophosphate (AMP)–activated protein kinase γ	Hypertrophic cardiomyopathy, arrhythmias, myopathy, myalgia, seizures; congenital fetal form is rapidly fatal	Autosomal dominant
0b/muscle glycogen synthase deficiency	Muscle glycogen synthase	Muscle weakness, hypertrophic cardiomyopathy, abnormal heart rate, sudden cardiac arrest	Rare, few cases reported
XV/Polyglucosan body myopathy 2	Glycogenin-1	Juvenile- or adult-onset proximal muscle weakness, nervous system involvement uncommon	Rare, autosomal recessive
V/McArdle	Myophosphorylase	Exercise intolerance, muscle cramps, myoglobinuria, "second-wind" phenomenon, muscle weakness	Common, male predominance
VII/Tarui	Phosphofructokinase	Exercise intolerance, muscle cramps, compensatory hemolytic anemia, myoglobinuria, "out-of-wind" phenomenon	Prevalent in Japanese and Ashkenazi Jewish populations
IX α1 (*PHKA1* variant)	Muscle PhK	Exercise intolerance, cramps, myalgia, increased CK, myoglobinuria in some; no hepatomegaly	X-linked
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	As with type V	Rare, X-linked
X/Phosphoglycerate mutase deficiency	M subunit of phosphoglycerate mutase	As with type V	Rare, majority of patients are Black
XI/Lactate dehydrogenase deficiency	M subunit of lactate dehydrogenase	As with type V	Rare
GALACTOSE DISORDERS			
Galactosemia with transferase deficiency	Galactose-1-phosphate uridyltransferase	Vomiting, feeding difficulties, liver failure/dysfunction/ hepatomegaly, cataracts, failure to thrive, *E. coli* sepsis, generalized aminoaciduria	Black patients tend to have milder symptoms
Galactokinase deficiency	Galactokinase	Cataracts	Benign
Generalized uridine diphosphate galactose-4-epimerase deficiency	Uridine diphosphate galactose-4-epimerase	Similar to transferase deficiency with additional findings of hypotonia and nerve deafness	Benign and intermediate variants also exist
Galactose mutarotase deficiency	Galactose mutarotase	Cataract	Benign
FRUCTOSE DISORDERS			
Essential fructosuria	Fructokinase	Urine-reducing substance	Benign
Hereditary fructose intolerance	Fructose-1-phosphate aldolase (aldolase-B)	Acute; vomiting, hypoglycemia, sweating, lethargy, acute liver failure/liver dysfunction Chronic; failure to thrive, hepatic failure	Prognosis good with fructose restriction
DISORDERS OF GLUCONEOGENESIS			
Fructose-1,6-bisphosphatase deficiency	Fructose-1,6-diphosphatase	Episodic hypoglycemia, lactic acidosis, liver failure/ dysfunction	Good prognosis, avoid fasting
Phosphoenolpyruvate carboxykinase deficiency	Phosphoenolpyruvate carboxykinase	Hypoglycemia, hepatomegaly, hypotonia, failure to thrive	Rare
DISORDERS OF PYRUVATE METABOLISM			
Pyruvate dehydrogenase complex defect	Pyruvate dehydrogenase	Severe fatal neonatal to mild late onset, lactic acidosis, psychomotor retardation, failure to thrive, features overlapping fetal alcohol syndrome, MRI findings suggestive of Leigh syndrome, ataxia	Most commonly caused by $E_{1\alpha}$ subunit defect, X-linked
Pyruvate carboxylase deficiency	Pyruvate carboxylase	Type B: neonatal severe lactic acidosis, hyperammonemia, hypercitrullinemia, hyperlysinemia, and hypoglycemia. Type A: late-onset mild to moderate lactic acidosis and developmental delay. Type C: recurrent episodes of lactic acidosis, ketoacidosis, and mild neurologic deficits.	Rare, autosomal recessive
Respiratory chain defects (oxidative phosphorylation disease)	Complexes I-V, many mitochondrial and nuclear DNA variants	Heterogeneous with multisystem involvement (see Table 107.3 and Table 107.5)	Mitochondrial, autosomal recessive, dominant, and X-linked inheritance
DISORDERS IN PENTOSE METABOLISM			
Pentosuria	l-Xylulose reductase	Urine-reducing substance	Benign
Transaldolase deficiency	Transaldolase	Intrauterine growth restriction, oligohydramnios, dysmorphism, cardiovascular anomalies, anemia, thrombocytopenia, hepatosplenomegaly, endocrine abnormalities, cutis laxa	Autosomal recessive, milder form exists
Ribose-5-phosphate isomerase deficiency	Ribose-5-phosphate isomerase	Progressive leukoencephalopathy and peripheral neuropathy	Four cases reported

hyperfiltration, increased renal plasma flow, and microalbuminuria are often found in the early stages of renal dysfunction and can occur before the onset of proteinuria. In younger patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. Many also have hypertension, renal stones, nephrocalcinosis, proteinuria, renal tubular acidosis (proximal and distal renal acidification defects), and altered creatinine clearance. With the advancement of renal disease, focal segmental glomerulosclerosis and interstitial fibrosis become evident. In some patients, renal function has deteriorated and progressed to failure, requiring dialysis and transplantation. Other renal abnormalities include amyloidosis, a Fanconi-like syndrome, hypocitraturia, hypercalciuria, and a distal renal tubular acidification defect. Patients with *GSD Ib* can have additional features of recurrent bacterial infections from **neutropenia** and impaired neutrophil function. Oral involvement, including recurrent mucosal ulceration, gingivitis, and rapidly progressive periodontal disease, may occur in type Ib. Intestinal mucosa ulceration culminating in GSD enterocolitis is also common. Type 1b is also associated with a chronic inflammatory bowel disease (IBD)–like picture involving the colon that may be associated with neutropenia and/or neutrophil dysfunction and can resemble ulcerative colitis or Crohn disease.

Diagnosis

The clinical presentation and laboratory findings of hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia lead to a suspected diagnosis of type I GSD. Neutropenia is noted in *GSD Ib* patients, although neutrophil counts may be normal initially. Neutropenia has also been noted in some patients with GSD Ia, especially those with the p.G188A variant. Administration of glucagon or epinephrine leads to a negligible increase, if any, in blood glucose levels, but the lactate level rises significantly. Before the availability of genetic testing, a definitive diagnosis required enzyme testing via liver biopsy. Gene-based variant analysis using single-gene sequencing or multigene panel testing provides a noninvasive way to diagnose most patients with GSD types Ia and Ib and has become the primary recommended method of diagnosis.

Treatment

Treatment focuses on maintaining normal blood glucose levels and is achieved by continuous nasogastric (NG) infusion of glucose or administration of uncooked cornstarch. In infancy, overnight NG drip feeding may be needed to maintain normoglycemia. NG feedings can consist of a sucrose- and lactose-free enteral formula or only glucose or a glucose polymer to provide sufficient glucose to maintain euglycemia. During the day, frequent feedings with high-complex carbohydrate content are typically sufficient.

Uncooked cornstarch acts as a slow-release form of glucose and can be introduced at a dose of 1.6 g/kg every 4 hours for children less than 2 years of age. The response of young children is variable. For older children, the cornstarch regimen can be changed to every 4-6 hours at a dose of 1.6-2.5 g/kg body weight and can be given orally mixed with water or a sucrose-, fructose-, and lactose-free beverage. Cornstarch dosing may also be calculated based on hepatic glucose production rate and can be administered more frequently in smaller amounts to improve metabolic control. Other starch products, such as extended-release waxy maize starch with a high amylopectin content, are shown to be beneficial in extending time between overnight feedings in some individuals with hepatic GSD. Because fructose and galactose cannot be converted directly to glucose in GSD type I, these sugars should be restricted in the diet. Sucrose (table sugar, cane sugar, other ingredients), fructose (fruit, juice, high-fructose corn syrup), lactose (dairy foods), and sorbitol should be avoided or limited. As a result of these dietary restrictions, vitamins and minerals such as calcium and vitamin D may be deficient, and supplementation is required to prevent nutritional deficiencies.

Maintaining normoglycemia and avoiding hypoglycemia necessitate frequent blood glucose measurements in patients with hepatic GSDs. This can be accomplished by self-monitoring blood glucose (SMBG) using a finger prick before and after meals, before physical activity, and overnight. Continuous glucose monitoring systems (CGMSs) are a newer technique that allow for 24-hour glucose monitoring. CGMSs have been shown to be safe and effective tools for monitoring glucose levels in patients with hepatic GSDs (GSD I, GSD III, GSD VI, GSD IX) at all hours of the day. Furthermore, when accompanied with the necessary dietary changes, CGMSs aid in metabolic control, improving disease parameters, avoidance of hospitalizations, and blood glucose stability in these patients.

Dietary therapy improves hyperuricemia, hyperlipidemia, and renal function, as well as slowing the development of renal failure. Blood uric acid and lipid levels may, however, be elevated in some individuals, despite good dietary compliance, especially after puberty. The control of hyperuricemia can be further augmented by the use of allopurinol, a xanthine oxidase inhibitor. Hyperlipidemia can be reduced with lipid-lowering drugs, such as β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and fibrate (see Chapter 106). **Microalbuminuria**, an early indicator of renal dysfunction in type I disease, is treated with angiotensin-converting enzyme (ACE) inhibitors. Citrate supplements can be beneficial for patients with hypocitraturia by preventing or ameliorating nephrocalcinosis and development of urinary calculi. Products containing citric acid reduce the effectiveness of cornstarch and should not be taken concurrently. Thiazide diuretics increase renal reabsorption of filtered calcium and decrease urinary calcium excretion, thereby preventing hypercalciuria and nephrocalcinosis. Growth hormone (GH) should be used with extreme caution and limited to only those with a documented GH deficiency. Even in those patients, there should be close monitoring of metabolic parameters and for the presence of adenomas. Kidney transplantation may be performed to treat end-stage renal disease (ESRD). As needed, combined liver and kidney transplantation is sometimes recommended.

In patients with **type Ib GSD**, granulocyte colony-stimulating factor is successful in correcting neutropenia, decreasing the number and severity of bacterial infections, and improving chronic IBD; the minimum effective dose should be used, given noted side effects with this agent, including splenomegaly, hypersplenism, and bone pain, with this agent. Vitamin E administration has been shown to improve neutrophil count and function and to reduce the frequency and severity of infections in GSD1b patients. The use of sodium glucose cotransporter-2 (SGLT2) inhibitors (empagliflozin) to improve neutrophil function and reduce neutropenia and IBD symptoms in GSDIb is showing promising results. Bone marrow transplantation has been reported to correct neutropenia in type Ib GSD.

Orthotopic liver transplantation is a potential cure for type I GSD, especially for patients with liver malignancy, multiple liver adenomas, metabolic derangements refractory to medical management, and liver failure; however, because of the paucity of available organ donors, this can be challenging. Large adenomas (>2 cm) that are rapidly increasing in size and/or number may necessitate partial hepatic resection. Smaller adenomas (<2 cm) may be treated with percutaneous ethanol injection or transcatheter arterial embolization. Recurrence of liver adenomas is a challenge and may potentiate malignant transformation in these patients, ultimately requiring a liver transplant. Before any surgical procedure, the bleeding status must be evaluated and good metabolic control established. Prolonged bleeding times can be normalized with intensive intravenous (IV) glucose infusion for 24-48 hours before surgery. Treatment with DDAVP (1-deamino-8-d-arginine vasopressin) can reduce bleeding complications, but it should be used with caution because of the risk of fluid overload and hyponatremia when administered as an IV infusion. Lactated Ringer solution should be avoided because it contains lactate and no glucose. Glucose levels should be maintained in the normal range throughout surgery with the use of 10% dextrose. Overall, metabolic control is assessed by growth, improvement, and correction of the metabolic abnormalities such as elevated lactate, glucose, triglyceride, cholesterol, and uric acid levels.

GSD I is a promising target for gene therapy because it is caused by pathogenic variants in a single gene. An active phase 3 clinical trial (NCT05139316) is being conducted to determine the efficacy and safety of adeno-associated virus serotype 8 (AAV8)–mediated G6P gene replacement in patients ages 8 years and older with GSD type Ia.

Prognosis

Inadequate metabolic control during childhood can lead to long-term complications in adults. Clinical outcomes have improved dramatically with early diagnosis and effective treatment. However, serious complications such as renal disease and formation of hepatic adenomas with potential risk for malignant transformation persist. The ability to identify transformation of liver adenomas to hepatocellular carcinoma remains a challenge as α-fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels often remain normal in the setting of hepatocellular carcinoma.

Type III Glycogen Storage Disease (Cori Disease, Forbes Disease, Debrancher Deficiency, Limit Dextrinosis)

Type III GSD is caused by deficient activity of the **glycogen debranching enzyme**. This enzyme, together with phosphorylase and phosphorylase kinase, are responsible for complete degradation of glycogen. When debranching enzyme is defective, glycogen breakdown is incomplete, resulting in the accumulation of an abnormal glycogen with short outer-branch chains that resemble *limit dextrin*. GSD **type IIIa** is the most common type and usually involves both liver and muscle; GSD **type IIIb**, seen in approximately 15% of patients, appears to involve only the liver.

Type III GSD is an autosomal recessive disease that has been reported in many different ethnic groups. The frequency is relatively high in the Sephardic Jewish population from North Africa, inhabitants of the Faroe Islands, and the Inuit population. The gene for debranching enzyme *(AGL)* has been noted, with more than 260 different pathogenic variants. At least two pathogenic variants in exon 2, c.18_19del (p.Gln6fs) and c.16C>T (p.Gln6Ter), are specifically associated with GSD type IIIb. Carrier detection and prenatal diagnosis are possible using DNA-based testing.

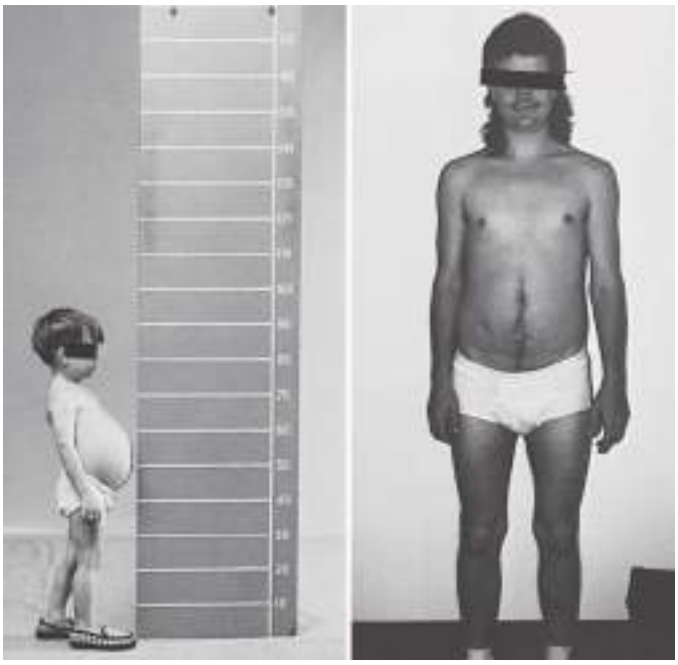

Fig. 107.2 Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in the liver but normal activity in muscle. As a child, he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He had no muscle weakness or atrophy; this is in contrast to patients with type IIIa, in whom a progressive myopathy is seen in adulthood.

Clinical Manifestations

In infancy and childhood, type III GSD may be indistinguishable from type I because of overlapping features such as hepatomegaly, hypoglycemia, hyperlipidemia, and growth stunting (Fig. 107.2). Hepatomegaly in most patients with type III GSD decreases with age; however, liver fibrosis and/or cirrhosis progressing to liver failure are noted in many in late adulthood. Some patients develop hepatocellular carcinoma. Hepatic adenomas with transformation to carcinomas occur less frequently in individuals with GSD III than in those with GSD I. Alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels are not good predictors of malignant transformation.

In patients with GSD type IIIa, the **muscle weakness** is slowly progressive and associated with muscle wasting. The weakness can present in early childhood but can become severe after the third or fourth decade of life. Myopathy does not follow a particular pattern of involvement, and both proximal and distal muscles are involved. Electromyography (EMG) reveals a widespread myopathy, and nerve conduction studies may be abnormal.

Although overt cardiac dysfunction is rare, ventricular hypertrophy is a frequent finding. **Cardiac pathology** has shown diffuse involvement of various cardiac structures, including vacuolation of myocytes, fibrosis, glycogen accumulation in the conduction system, and hyperplasia of smooth muscles. Life-threatening arrhythmia and the need for heart transplant have been reported in some patients with GSD IIIa. Hepatic symptoms in some patients may be mild and the diagnosis is not made until adulthood, when patients show symptoms and signs of neuromuscular disease.

The initial presentation can be confused with Charcot-Marie-Tooth disease (see Chapter 653.1). Polycystic ovaries are noted; some patients can develop hirsutism, irregular menstrual cycles, and other features of polycystic ovarian syndrome. Fertility does not appear to be affected; successful pregnancies have been reported. Low bone mineral density and myopathy in patients with GSD IIIa put them at an increased risk of potential fractures.

Hypoglycemia and hyperlipidemia are common. In contrast to type I GSD, elevation of liver transaminase levels and fasting ketosis are prominent, but blood lactate and uric acid concentrations are usually normal. Glucagon administration 2 hours after a carbohydrate meal provokes a normal increase in blood glucose. However, after an overnight fast, glucagon may provoke no change in blood glucose level. Serum creatine kinase levels can be useful to identify patients with muscle involvement, although normal levels do not rule out muscle enzyme deficiency.

Diagnosis

The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III glycogenosis from type I. The fibrosis, which ranges from minimal periportal fibrosis to micronodular cirrhosis, appears in most cases to be progressive. Overt cirrhosis has been seen in some patients with GSD III.

Patients with myopathy and liver symptoms have a generalized enzyme defect (type IIIa). The deficient enzyme activity can be demonstrated not only in liver and muscle but also in other tissues such as heart, erythrocytes, and cultured fibroblasts. Patients with hepatic symptoms without clinical or laboratory evidence of myopathy have debranching enzyme deficiency only in the liver, with enzyme activity retained in the muscle (type IIIb). Before the availability of genetic testing, a definitive diagnosis required enzyme assay in liver, muscle, or both. Gene sequencing allows for diagnosis and subtype assignment in the majority of patients.

Treatment

The mainstay of treatment of GSD III is dietary management, as in GSD I, although it is less demanding. Patients do not need to restrict dietary intake of fructose and galactose, although simple sugars should be avoided to prevent sudden spikes in blood glucose levels. Hypoglycemia can be prevented by small frequent meals rich in complex carbohydrates, such as cornstarch supplements or nocturnal gastric drip feedings. Additionally, a high-protein diet during the daytime as well as overnight protein enteral infusion is effective in preventing hypoglycemia. The exogenous protein can be used as a substrate for gluconeogenesis, which helps to meet energy needs and prevent endogenous

protein breakdown. Protein in the diet also reduces the overall starch requirement. Overtreatment with cornstarch should be avoided, as it can result in excessive glycogen buildup, which is detrimental and can lead to excessive weight gain. Medium-chain triglyceride (MCT) supplementation and a high-fat diet are being considered as alternative sources of energy. There is no satisfactory treatment for the progressive myopathy other than recommending a high-protein diet, physical therapy, and high-fat diet in some patients. Close monitoring with abdominal MRI is needed to detect progression of liver fibrosis to cirrhosis and hepatocellular carcinoma (HCC). Additional imaging techniques, such as hepatic elastography, are being developed. Liver transplantation has been performed in GSD III patients with progressive cirrhosis and/or HCC. There are reports of cardiac transplant in GSD III patients with end-stage cardiac disease.

Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, Polyglucosan Disease, Andersen Disease, Adult Polyglucosan Body Disease)

Type IV GSD is caused by the deficiency of **branching enzyme activity**, which results in the accumulation of an abnormal glycogen with poor solubility. The disease is also known as *amylopectinosis* because the abnormal glycogen has fewer α-1,6 branch points, more α-1,4 linked glucose units, and longer outer chains, resulting in a structure resembling amylopectin. These excessively long peripheral glucan chains form polyglucosan bodies, which are positive on periodic acid–Schiff (PAS) and resistant to diastase digestion. Polyglucosan body accumulation is seen in all affected patients but to different degrees and in different tissues.

Type IV GSD is an autosomal recessive disorder. The glycogen branching enzyme *(GBE1)* gene has been noted, with more than 128 pathogenic variants responsible for type IV GSD, and their characterization in individual patients can be useful in predicting clinical outcome. The nearly complete absence of glycogen branching enzyme (GBE) activity with null alleles has been associated with perinatal death and fatal neonatal hypotonia. Residual GBE activity results in a continuum of disease manifestations ranging from progressive hepatic cirrhosis, slowly progressive or nonprogressive liver disease, cardiomyopathy, myopathy, peripheral neuropathy, motor neuron disease, and leukodystrophy.

Clinical Manifestations

A high degree of clinical variability is associated with type IV GSD. The most common and classic form is characterized by **hepatic** involvement with progressive cirrhosis of the liver and manifests in the first 18 months of life as hepatosplenomegaly and failure to thrive. Cirrhosis may present with portal hypertension, ascites, and esophageal varices and may progress to liver failure, usually leading to death by 5 years of age. Some patients survive without progression of liver disease, and they are considered to have a milder hepatic form and do not require liver transplant. Extrahepatic involvement in some patients with GSD IV consists of musculoskeletal involvement, particularly cardiac and skeletal muscles, as well as central nervous system (CNS) and peripheral nervous system (PNS) involvement.

Neuromuscular forms of type IV GSD have been reported, with four main subtypes recognized based on age at presentation. The **perinatal** form is characterized by a *fetal akinesia deformation sequence* (FADS) and death in the perinatal period. The **congenital** form presents at birth with severe hypotonia, muscle atrophy, and neuronal involvement, with death in the neonatal period; some patients have cardiomyopathy. The **childhood** form presents primarily with myopathy or cardiomyopathy. The **adult** form, *adult polyglucosan body disease* (APBD), presents with PNS dysfunction and diffuse CNS involvement, accompanied by accumulation of polyglucosan material in the nervous system. Symptoms of neuronal involvement include progressive muscle weakness; gait spasticity; peripheral neuropathy; neuropathic bladder; and, in many cases, leukodystrophy, mood disturbances, and cognitive decline. APBD is often misdiagnosed as multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), or cerebral small-vessel disease (CSVD).

Diagnosis

Deposition of amylopectin-like materials varies and can be demonstrated in the liver, heart, muscle, skin, intestine, brain, brainstem, spinal cord, and peripheral nerves (i.e., sural nerve) in type IV GSD. For patients with hepatic involvement, liver histology shows micronodular cirrhosis and faintly stained basophilic inclusions in hepatocytes. The inclusions are composed of coarsely clumped, stored material that is PAS positive and partially resistant to diastase digestion. Electron microscopy (EM) shows, in addition to the conventional α and β glycogen particles, the accumulation of fibrillar aggregations that are typical of amylopectin. Similar nonmembrane-bound cytoplasmic inclusions (PAS positive, diastase resistant) are observed in the cardiomyocytes and skeletal muscle fibers, and polyglucosan bodies may be present in the muscle biopsy from those with neuromuscular manifestations. In APBD, a peripheral nerve biopsy reveals intra-axonal polyglucosan bodies, and histologic examination of brain tissue shows polyglucosan bodies often visualized in the astrocytes and neurons. The distinct staining properties of the inclusions, as well as EM findings, could be diagnostic. However, polysaccharides with histologic features reminiscent of type IV disease but without enzymatic correlation have been observed. The diagnosis is confirmed by either identification of two pathogenic variants in *GBE1* or a reduction of GBE activity in leukocytes or fibroblasts. Prenatal diagnosis is possible by measuring enzyme activity in cultured amniocytes or chorionic villi or by DNA-based methodologies.

Treatment

There is no specific treatment for type IV GSD. Nervous system involvement, such as gait problems and bladder involvement, requires supportive, symptomatic management. Unlike patients with other liver GSDs (I, III, VI, IX), those with GSD IV do not typically have hypoglycemia. Liver transplantation has been performed for patients with progressive liver disease, but patients must be carefully selected because this is a multisystem disease and, in some patients, extrahepatic involvement may manifest or worsen after transplant. Liver transplantation corrects the hepatic phenotype of the disease but has no effects on the extrahepatic manifestations such as myopathy and cardiomyopathy. Individuals with significant diffuse reticuloendothelial involvement may have greater risk of morbidity and mortality, which may affect the success rate for liver transplant. Patients with symptomatic cardiomyopathy and skeletal myopathy may benefit from heart transplantation and physical therapy, respectively.

Type VI Glycogen Storage Disease (Liver Phosphorylase Deficiency, Hers Disease)

Type VI GSD is caused by deficiency of **liver glycogen phosphorylase**. Patients usually present with hepatomegaly and growth stunting in infancy or early childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are of variable severity. Ketotic hypoglycemia may present after overnight or prolonged fasting. Lactic acid and uric acid levels are normal. Type VI GSD presents within a broad spectrum of involvement, some with a more severe clinical presentation. Patients with severe hepatomegaly, recurrent severe hypoglycemia and hyperketosis have been reported. Focal nodular hyperplasia of liver, hepatocellular adenoma with transformation into carcinoma, hepatic fibrosis, and cirrhosis have been reported in some patients.

Diagnosis

GSD VI is an autosomal recessive disease. Diagnosis can be confirmed through molecular testing of the liver phosphorylase gene *(PYGL)*. Many pathogenic variants are known in this gene, and a splice-site variant in intron 13 has been identified in the Mennonite population. A liver biopsy showing elevated glycogen content and decreased hepatic phosphorylase enzyme activity can also be used to make a diagnosis, especially in cases with inconclusive genetic results. However, with the availability of DNA analysis and next-generation sequencing (NGS) panels, liver biopsies are usually unnecessary.

Treatment

Treatment is symptomatic and aimed at preventing hypoglycemia while ensuring adequate nutrition. A low-carbohydrate (45–50% of total calories), high-protein (2–3 g protein/kg body weight or 20–25% of total calories) diet and frequent feeding are effective in preventing hypoglycemia. Blood glucose and ketones should be monitored routinely, especially during periods of increased activity/illness. Long-term follow-up of these patients is needed to monitor and manage the complications and to expand the understanding of the natural history of this disorder.

Type IX Glycogen Storage Disease (Phosphorylase Kinase Deficiency)

Type IX GSD represents a heterogeneous group of glycogenoses resulting from deficiency of the enzyme **phosphorylase kinase** (PhK), which is involved in the rate-limiting step of glycogenolysis. This enzyme has four subunits (α, β, γ, δ), each encoded by different genes differentially expressed in various tissues. Pathogenic variants in the *PHKA1* gene cause muscle PhK deficiency; pathogenic variants in the *PHKA2* and *PHKG2* genes cause liver PhK deficiency, and pathogenic variants in the *PHKB* gene cause PhK deficiency in liver and muscle. Pathogenic variants in the *PHKG1* gene have not been identified.

Clinical manifestations of liver PhK deficiency are usually recognizable within the first 2 years of life and include short stature and abdominal distention from moderate to marked hepatomegaly. The clinical severity of liver PhK deficiency varies considerably. Hyperketotic hypoglycemia, if present, can be mild but may be severe in some cases. Ketosis may occur even when glucose levels are normal. Some children may have mild delays in gross motor development and hypotonia. It is becoming increasingly clear that GSD IX is not a benign condition. Severe phenotypes are reported, with liver fibrosis progressing to cirrhosis and HCC, particularly in patients with *PHKG2* variants and also in some patients with *PHKA2* variants. Progressive splenomegaly and portal hypertension are reported secondary to cirrhosis. Interventricular septal hypertrophy has been reported in a patient with GSD IX β (*PHKB* variant). Cognitive and speech delays have been reported in a few individuals, but it is not clear whether these delays are caused by PhK deficiency or are coincidental. Renal tubular acidosis has been reported in rare cases. Unlike in GSD I, lactic acidosis, bleeding tendency, and loose bowel movements are not characteristic. Although growth is retarded during childhood, normal height and complete sexual development are eventually achieved. As with debrancher deficiency, abdominal distention and hepatomegaly usually decrease with age. Some adults with liver PhK deficiency are reportedly asymptomatic, although patients at the other end of the spectrum develop cirrhosis and liver failure. Further studies are needed to fully assess and understand the natural history of this disorder in adults.

Phenotypic variability within each subtype is being uncovered with the availability of molecular testing. The incidence of all subtypes of PhK deficiency is approximately 1:100,000 live births.

Type IX α2 Glycogen Storage Disease (X-Linked Liver Phosphorylase Kinase Deficiency, PHKA2 Variant)

Glycogen storage disease IX α2 is one of the most common forms of liver glycogenosis in males. A typical presentation for this condition includes a young male (age 1-5 years) with growth stunting, incidental finding of hepatomegaly, and mild delays in motor development. In addition to the liver, enzyme activity can also be deficient in erythrocytes, leukocytes, and fibroblasts, with normal enzyme activity in muscle. Cholesterol, triglycerides, and liver enzymes are elevated. Ketosis may occur after fasting. Lactate and uric acid levels are normal. Hypoglycemia can range from mild to severe. The response in blood glucose to glucagon is normal. Although hepatomegaly and liver enzymes might gradually reduce and normalize with age in some patients, other groups exhibit an increase in these disease parameters comparable to those observed in patients with GSD IX γ 2. Most adults achieve a normal final height. It is increasingly recognized that this disorder is not benign, as previously thought, and there are patients with severe disease and long-term hepatic sequelae. In some cases, liver fibrosis can occur and progress to cirrhosis. Liver histology shows glycogen-distended hepatocytes, steatosis, fibrosis, and/or cirrhosis. Fibrous septal formation and low-grade inflammatory changes may be seen. Adenomas have been also reported.

The gene for the common liver isoform of the PhK α subunit, *PHKA2,* is located on the X chromosome (Xp22.2). Pathogenic variants in the *PHKA2* gene account for 75% of all PhK cases. X-linked liver PhK deficiency is further subdivided into two biochemical subtypes: XLG1, with measurable deficiency of PhK activity in both blood cells and liver, and XLG2, with normal in vitro PhK activity in blood cells and variable activity in the liver. The mechanism through which XLG2 exhibits normal or increased in vitro PhK activity is unknown. Because of X-inactivation leading to variable expression of the mutant allele, some female carriers may develop symptoms ranging from mild hepatomegaly to more severe symptoms.

Type IX β Glycogen Storage Disease (Autosomal Liver and Muscle Phosphorylase Kinase Deficiency, PHKB Variant)

PhK deficiency in liver and blood cells with an autosomal recessive mode of inheritance has been reported. Similar to the X-linked form, chief symptoms in early childhood include hepatomegaly and growth retardation. Some patients also exhibit muscle hypotonia. In a few cases where enzyme activity has been measured, reduced PhK activity has been demonstrated in muscle. Pathogenic variants are found in PHKB (chromosome 16q12-q13), which encodes the β subunit, and result in liver and muscle PhK deficiency (GSD IX β). Several nonsense and missense variants, a single-base insertion, splice-site pathogenic variants, and a large intragenic pathogenic variant have been identified.

Type IX γ2 Glycogen Storage Disease (Autosomal Liver Phosphorylase Kinase Deficiency, PHKG2 Variant)

This form of PhK deficiency is caused by pathogenic variants in the testis/liver isoform (TL) of the γ2 subunit of the *PHKG2* gene. In contrast to GSD IX α2, patients with GSD IX γ2 typically have more severe phenotypes, with recurrent hypoglycemia, prominent hepatomegaly, significant liver fibrosis, and progressive cirrhosis. Hepatic adenomas have been observed in several patients. Liver involvement occasionally presents with cholestasis, bile duct proliferation, esophageal varices, and splenomegaly. The spectrum of involvement continues to evolve as more cases are recognized. Many pathogenic variants in the *PHKG2* gene have been identified.

Diagnosis

Individuals with liver PhK deficiency usually have ketotic hypoglycemia, elevated transaminases, elevated triglycerides and cholesterol, normal uric acid and lactic acid concentrations, and normal glucagon response. PhK deficiency may be diagnosed by demonstration of the enzymatic defect in affected tissues. Hepatic PhK activity can be measured in liver, leukocytes, and erythrocytes. The interpretation of PhK activity results is complicated by the possibility of both false-positive and false-negative results. False-positive findings are possible, owing to the labile nature of PhK, which is extremely sensitive to handling circumstances and temperature exposure. As a result, extreme caution is required when storing and transporting such diagnostic specimens. Because the PhK enzyme has several isozymes, the diagnosis can easily be missed without the tissue where it is deficient (liver, muscle, or cardiac studies).

Molecular genetic testing is preferable to enzyme assay for diagnosis, as liver biopsy is an invasive procedure. Gene sequencing is used for diagnostic confirmation and subtyping of GSD IX. The *PHKA2* gene encoding the α subunit is most frequently involved, followed by the *PHKB* and *PHKG2* genes encoding the β and γ subunits, respectively.

Treatment and Prognosis

The treatment for liver PhK deficiency is symptomatic and includes a high-protein (2-3 g protein/kg body weight or 20–25% of total calories) diet with complex carbohydrates (45–50% of total calories) and small, frequent feedings to prevent hypoglycemia. Cornstarch can be administered, with symptom-dependent dosage and timing (0.6-2.5 g/kg every 6 hours). Hypoglycemia should be treated with oral glucose, if tolerated; if not, IV glucose should be given.

Patients with pathogenic variants in the γ subunit typically have a more severe clinical course with progressive liver disease. In liver biopsy samples, hepatic fibrosis/cirrhosis was detected in 50% and 95% of patients with *PHKA2* and *PHKG2* pathogenic variants, respectively. Two patients with GSD IX γ2 received liver transplantation, one for liver failure secondary to cirrhosis and the other for HCC. Liver involvement needs to be monitored in all patients with GSD IX by periodic imaging (abdominal ultrasound or MRI every 6-12 months) and serial hepatic function tests.

Type 0a Glycogen Storage Disease (Liver Glycogen Synthase Deficiency)

Liver glycogen synthase deficiency type 0a **(GSD 0a)** is caused by deficiency of **hepatic glycogen synthase** activity, leading to a marked decrease of glycogen stored in the liver. It is caused by pathogenic variants in *GYS2*. The disease appears to be rare in humans and, in the true sense, is not a type of GSD because the enzyme deficiency leads to decreased glycogen stores. Patients present in infancy with early-morning (pre-breakfast) drowsiness, pallor, emesis, and fatigue, and occasional convulsions associated with hypoglycemia and hyperketonemia. Blood lactate and alanine levels are low, and there is no hyperlipidemia or hepatomegaly. **Hyperglycemia**, glycosuria, lactic acidosis, and hyperalaninemia, with normal insulin levels after administration of glucose or a meal, suggest a deficiency of glycogen synthase. ***Diagnosis*** may be through molecular testing that identifies pathogenic variants in *GYS2* or by liver biopsy to measure the enzyme activity.

Treatment consists of frequent meals rich in protein and nighttime supplementation with uncooked cornstarch to prevent hypoglycemia and hyperketonemia. Most children with GSD 0a are cognitively and developmentally age appropriate. Short stature and osteopenia are common features. The ***prognosis*** seems good for patients who survive to adulthood, with a decrease in the frequency and severity of hypoglycemia. Long-term natural history studies are required to have a better understanding of the disease's outcomes and the impact of dietary therapy.

Hepatic Glycogenosis with Renal Fanconi Syndrome (Fanconi-Bickel Syndrome)

Fanconi-Bickel syndrome is a rare autosomal recessive disorder caused by defects in the facilitative GLUT2, which transports glucose in and out of hepatocytes, pancreatic β cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in the liver and kidney.

The affected child typically presents in the first year of life with failure to thrive, rickets, and a protuberant abdomen from hepatomegaly and nephromegaly. The disease may be confused with GSD I because a Fanconi-like syndrome can also develop in that patient population. Adult patients have short stature as a result of hypophosphatemic rickets. Patients are more susceptible to fractures because of early-onset generalized osteopenia. In addition, intestinal malabsorption and diarrhea may occur, and HCC has been seen. Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and radiologic findings of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminase, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show intolerance, which could be explained by the functional loss of GLUT2 preventing liver uptake of these sugars. Tissue biopsy results show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably from the altered glucose transport out of these organs. Diffuse glomerular mesangial expansion, along with glomerular hyperfiltration and microalbuminuria similar to nephropathy in GSD Ia, and diabetes have been reported.

This condition is rare, and 70% of patients with Fanconi-Bickel syndrome have consanguineous parents. Most patients have homozygous pathogenic variants; some patients are compound heterozygotes. Several types of pathogenic variants in the *SLC2A2* gene have been described, including missense, nonsense, insertion/deletion, and intronic variants.

There is no specific treatment. Symptom-dependent treatment with phosphate, bicarbonate, and uncooked cornstarch can result in growth improvement. Growth may also improve with symptomatic replacement of water, electrolytes, and vitamin D and restriction of galactose intake; a diet similar to that used for diabetes mellitus, with small, frequent meals using complex carbohydrates and adequate caloric intake, is recommended.

MUSCLE GLYCOGENOSES

The role of glycogen in muscle is to provide substrates for the generation of ATP for muscle contraction. The muscle GSDs are broadly divided into two groups. The first group is characterized by hypertrophic cardiomyopathy, progressive skeletal muscle weakness and atrophy, or both and includes deficiencies of acid α-glucosidase, a lysosomal glycogen-degrading enzyme (**type II** GSD); lysosomal-associated membrane protein 2 **(LAMP2/Danon disease)**; AMP-activated protein kinase γ2 **(PRKAG2/PRKAG2 syndrome)**; and muscle glycogen synthase **(type 0b)**. Glycogenin-1 deficiency **(GYG1/polyglucosan body myopathy 2)** may manifest as muscle weakness and exercise intolerance to exercise in the absence of cardiomyopathy.

The second group comprises muscle energy disorders characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes myophosphorylase deficiency (McArdle disease, **type V** GSD) and deficiencies of phosphofructokinase **(type VII)**, phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase (LDH), and muscle-specific phosphorylase kinase (**type IX** α1). Some of these latter enzyme deficiencies can also be associated with *compensated hemolysis,* suggesting a more generalized defect in glucose metabolism.

Type II Glycogen Storage Disease (Lysosomal Acid α-1,4-Glucosidase Deficiency, Pompe Disease)

Pompe disease, also referred to as *GSD type II* or **acid maltase deficiency**, is caused by a deficiency of acid α-1,4-glucosidase, an enzyme responsible for the degradation of glycogen in lysosomes. This enzyme defect results in lysosomal glycogen accumulation in multiple tissues and cell types, predominantly affecting cardiac, skeletal, and smooth muscle cells and the nervous system. In Pompe disease, glycogen typically accumulates within lysosomes, as opposed to its accumulation in cytoplasm in the other glycogenoses. However, as the disease progresses, lysosomal rupture and leakage lead to the presence of cytoplasmic glycogen as well.

Pompe disease is an autosomal recessive disorder. The incidence was previously reported to be approximately 1 in 40,000 live births in Whites and 1 in 18,000 live births in the Han Chinese population. Newborn screening for Pompe disease in the United States suggests that the prevalence is much higher than previously thought (between 1 in 10,000 and 1 in 25,000). More than 600 pathogenic variants have been identified in the gene for acid α-glucosidase *(GAA)* and are helpful in delineating the phenotypes. A splice-site variant (c.-32-13 T > G, formerly called IVS1-13 T > G) is commonly seen in White patients with late-onset disease.

Clinical Manifestations

Pompe disease is broadly classified into infantile and late-onset forms. The infantile presentation is a continuum and is further divided into two categories: classic and nonclassic. Classic **infantile Pompe disease** (IPD) is uniformly lethal *without* enzyme replacement therapy (ERT) with *alglucosidase alfa*. Affected infants present in the first days to weeks of life with hypotonia, generalized muscle weakness with a hypotonic *floppy infant* appearance, hypertrophic cardiomyopathy

with or without left ventricular outflow obstruction, feeding difficulties, macroglossia, and hepatomegaly; if untreated, the condition leads to death from cardiorespiratory failure or respiratory infection by 1 year of age. Nonclassic IPD has a slower disease course and a less severe cardiac phenotype at initial presentation.

Late-onset Pompe disease (LOPD; juvenile-, childhood-, and adult-onset disease) is characterized by proximal limb girdle muscle weakness and early involvement of respiratory muscles, especially the diaphragm. The distinguishing feature between IPD and LOPD is absence of cardiomyopathy in the first year of life in patients with LOPD. Symptoms related to progressive dysfunction of skeletal muscles can start within the first year of life to as late as the sixth decade. The clinical picture is dominated by slowly progressive proximal muscle weakness, with truncal involvement and greater involvement of the lower limbs than the upper limbs. The pelvic girdle, paraspinal muscles, and diaphragm are the muscle groups most seriously affected in patients with LOPD. Cardiac involvement can occur and ranges from cardiac rhythm disturbances to cardiomyopathy. Other symptoms may include lingual weakness, ptosis, and dilation of blood vessels (e.g., basilar artery, ascending aorta). With disease progression, patients become confined to a wheelchair and require artificial ventilation. The initial symptoms in some patients may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea, which eventually lead to sleep-disordered breathing and respiratory failure. Respiratory failure is the cause of significant morbidity and mortality in LOPD. Basilar artery aneurysms with rupture also contribute to mortality in some cases. Small-fiber neuropathy presenting as painful paresthesia has been identified in some LOPD patients. Gastrointestinal disturbances such as postprandial bloating, dysphagia, early satiety, diarrhea, chronic constipation, and IBD have been reported. Genitourinary tract involvement is not uncommon and may present as bladder and bowel incontinence, weak urine stream, or dribbling. If untreated, the age of death varies from early childhood to late adulthood, depending on the rate of disease progression and the extent of respiratory muscle involvement. With the advent of ERT, a new natural history is emerging for survivors of both IPD and LOPD.

Laboratory Findings

Pertinent laboratory findings include elevated levels of serum creatine kinase (CK), aspartate transaminase (AST), alanine transaminase (ALT), and LDH. Urine glucose tetrasaccharide (Glc4), a glycogen breakdown metabolite, is a reliable biomarker for gauging disease severity and progression, as well as treatment response. Levels of Glc4 are extremely elevated in patients with IPD. In the infantile form, a chest x-ray film showing massive cardiomegaly is frequently the first symptom detected. **Electrocardiographic findings** include a high-voltage QRS complex, Wolff-Parkinson-White (WPW) syndrome, and a *shortened* PR interval. **Echocardiography** reveals thickening of both ventricles and/or the intraventricular septum and/or left ventricular outflow tract obstruction. Dilated cardiomyopathy and a low ejection fraction have also been reported. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen; acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. EM reveals glycogen accumulation within a membranous sac and with disease progression also in the cytoplasm. EMG reveals myopathic features with excessive electrical irritability of muscle fibers and pseudomyotonic discharges. Serum CK is not always elevated in adult patients. Depending on the muscle sampled or tested, the muscle histologic appearance and electromyography may not be abnormal. Some patients with infantile Pompe disease who had peripheral nerve biopsies demonstrated glycogen accumulation in the neurons and Schwann cells.

Diagnosis

A diagnosis of Pompe disease can be made by either enzyme assay in dried blood spots, leukocytes, blood mononuclear cells, muscle, or cultured skin fibroblasts demonstrating deficient acid α-glucosidase activity or gene sequencing showing two pathogenic variants in the *GAA* gene. The enzyme assay should be done in a laboratory with experience using maltose, glycogen, or 4-methylumbelliferyl-α-d-glucopyranoside (4MUG) as a substrate. In fibroblast enzyme assays, the infantile form has a more severe enzyme deficiency (less than 1% of that in normal controls) than the late-onset forms (between 1% and 30% of that in normal controls). Blood-based assays, especially dried blood spots, have the advantage of being quick and noninvasive and are increasingly being used as the first-line sample to make a diagnosis. The presence of the neutral α-glucosidase isoenzyme, which interferes with acid glucosidase, was formerly considered to be a disadvantage in blood-based assays. However, the addition of an inhibitor to this isozyme, acarbose, improves the assay's reliability by blocking isoenzyme activity. A muscle biopsy is often done with suspected muscle disease and a broad diagnostic differential, as it yields faster results and provides additional information about glycogen content and site of glycogen storage within and outside the lysosomes of muscle cells. However, a normal muscle biopsy, especially in patients with LOPD, *does not* exclude a diagnosis of Pompe disease. Late-onset patients show variability in glycogen accumulation in different muscles and within muscle fibers, and muscle histology and glycogen content can vary depending on the site of muscle biopsy. Because of the high risk of complications, anesthesia in infantile cases with significant cardiomyopathy should be reserved for situations where it is necessary. Availability of NGS panels and whole exome or genome sequencing allow for identification of additional patients with Pompe disease, especially when the diagnosis is ambiguous. *GAA* enzyme activity can be measured in chorionic villi or amniocytes for prenatal diagnosis; however, if the familial pathogenic variants are known, molecular genetic testing is the recommended approach.

Treatment

ERT with recombinant human acid α-glucosidase (alglucosidase alfa and avalgluco) is available for treatment of Pompe disease. Recombinant acid α-glucosidase can prevent deterioration or reversing abnormal cardiac and skeletal muscle functions (Fig. 107.3). ERT should be initiated as soon as possible across the disease spectrum, especially for infants with the infantile form, because the disease is rapidly progressive. Infants who are negative for cross-reacting immunologic material (CRIM) (i.e., infants that have no detectable GAA on a Western blot), develop a high-titer antibody against the infused enzyme and respond to ERT less favorably. A subset of CRIM-positive patients (presence of some protein on a Western blot) can also develop high and sustained antibody titers to ERT. Treatment using immunomodulating agents such as methotrexate, rituximab, and intravenous immunoglobulin (IVIG) have demonstrated efficacy in preventing the development of an immune response to ERT and immune tolerance. Nocturnal ventilatory support, when indicated, should be used. It has been shown to improve the quality of life and is particularly beneficial during a period of respiratory decompensation. In addition to ERT, other **adjunctive therapies** have demonstrated benefit in patients with Pompe disease. For patients with late-onset disease, a high-protein, low-carbohydrate diet may be beneficial. Respiratory muscle strength training has demonstrated improvements in respiratory parameters when combined with ERT. Submaximal aerobic exercise regimens are beneficial in improving muscle strength, pain, and fatigue.

A second-generation ERT, **avalglucosidase alfa** (NeoGAA), has been recently approved by the Food and Drug Administration (FDA) for the treatment of individuals with LOPD older than 1 year of age. Mannose-6-phosphate (M6P) is more abundant in NeoGAA than in alglucosidase alfa, which improves enzyme uptake into cells. Improvements in respiratory function (forced vital capacity [FVC]) and 6-minute walk test (6MWT) in patients with LOPD have been shown by phase 1/2 and 3 trials.

There are other therapies in development for Pompe disease, including intravenous **cipaglucosidase alfa** (a novel recombinant human GAA with high bis-M6P content; functions as substrate reduction therapy), **miglustat** (an oral chaperone; functions as enzyme stabilizer), small-molecule therapy, and gene therapy.

Early diagnosis and treatment are necessary for optimal outcomes. Newborn screening using blood-based assays in Taiwan and 28 U.S. states has resulted in early identification of Pompe cases, and thus improved disease outcomes, through the early initiation of ERT.

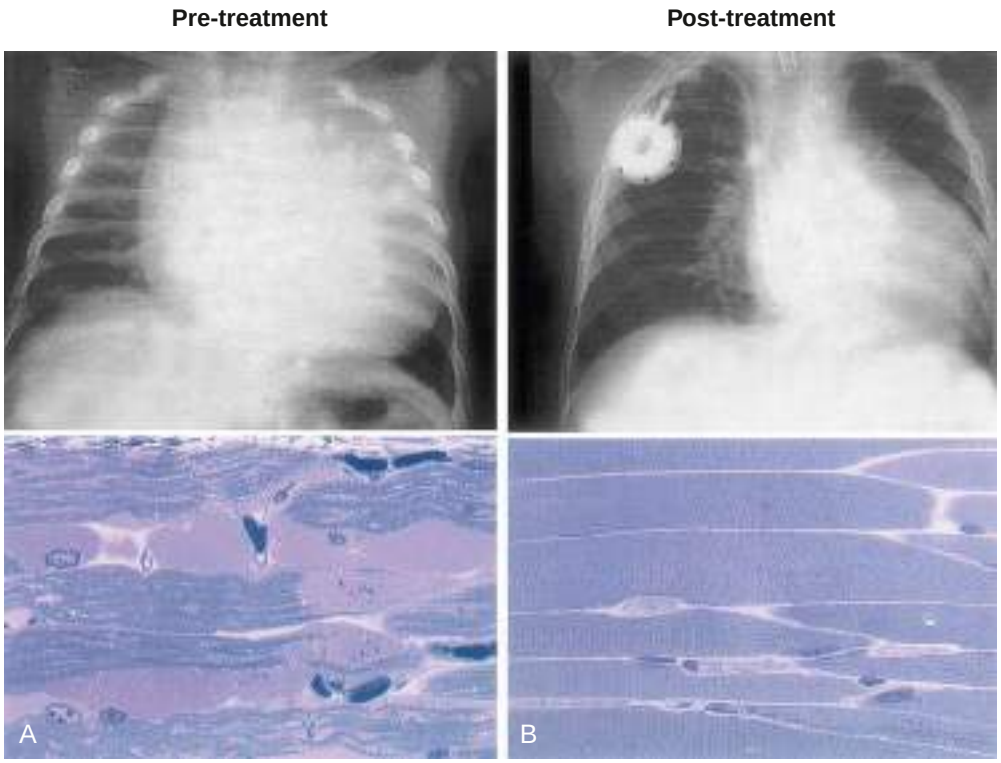

Fig. 107.3 Chest radiograph and muscle histology findings of an infantile-onset Pompe disease patient before (A) and after (B) enzyme replacement therapy. Note the decrease in heart size and muscle glycogen with therapy. *(Modified from Amalfitano A, Bengur AR, Morse RP, et al. Recombinant human acid alpha-glucosidase enzyme therapy for infantile glycogen storage disease type II: results of a phase I/II clinical trial. Genet Med. 2001;3:132–138.)*

Danon Disease

Danon disease is caused by pathogenic variants in the *LAMP2* gene, which leads to a deficiency of **lysosomal-associated membrane protein 2** (LAMP2). This disorder is inherited in an X-linked dominant pattern. Defects in LAMP2 lead to accumulation of glycogen in the heart and skeletal muscle, presenting primarily as hypertrophic cardiomyopathy and skeletal muscle weakness. Danon disease can be distinguished from the usual causes of hypertrophic cardiomyopathy (defects in sarcomere-protein genes) by the electrophysiologic abnormalities, particularly ventricular preexcitation and conduction defects. Patients present with cardiac symptoms, including chest pain, palpitations, syncope, and cardiac arrest, usually between ages 8 and 15 years. Other clinical manifestations include peripheral pigmentary retinopathy, lenticular changes, abnormal electroretinogram, and mild cognitive dysfunction. ***Diagnosis*** can be established by molecular testing of the *LAMP2* gene. The prognosis for LAMP2 deficiency is poor, with progressive end-stage heart failure early in adulthood. ***Treatment*** is directed toward management of symptoms in affected individuals, including management of cardiomyopathy, correction of arrhythmias, and physical therapy for muscle weakness. Cardiac transplantation has been successful in some patients. In male patients with Danon disease, a nonrandomized open-label phase 1 study (NCT03882437) is currently being conducted to assess the safety of gene therapy using recombinant adeno-associated virus serotype 9 (AAV9) containing the human lysosome-associated membrane protein 2 isoform B (LAMP2B) transgene.

PRKAG2 Syndrome (Adenosine Monophosphate [AMP]–Activated Protein Kinase γ2 Deficiency)

PRKAG2 syndrome is caused by pathogenic variants in the *PRKAG2* gene that is required for the synthesis of the enzyme AMP-activated protein kinase (AMPK), which regulates cellular pathways involved in ATP metabolism. PRKAG2 syndrome has an autosomal dominant pattern of inheritance. Common presentations include hypertrophic cardiomyopathy and electrophysiologic abnormalities such as WPW syndrome, atrial fibrillation, and progressive atrioventricular block. Cardiac involvement is variable and includes supraventricular tachycardia, sinus bradycardia, left ventricular dysfunction, and sudden cardiac death in some cases. In addition to cardiac involvement, there is a broad spectrum of phenotypic presentations including myalgia, myopathy, and seizures. Cardiomyopathy caused by *PRKAG2* variants usually allows for long-term survival, although a rare congenital form presenting in early infancy is associated with a rapidly fatal course. Cardiomyopathy in PRKAG2 syndrome often mimics that in other conditions, especially Pompe disease, and should be considered as a differential diagnosis in infants presenting with severe hypertrophic cardiomyopathy. ***Treatment*** is primarily symptomatic, including management of cardiac failure and correction of conduction defects. Patients with PRKAG2 deficiency are at risk for sudden cardiac death and require close monitoring.

Type 0b Glycogen Storage Disease (Muscle Glycogen Synthase Deficiency)

Muscle glycogen synthase deficiency (GSD 0b) results from biallelic loss-of-function pathogenic variants in the gene *GYS1*. In the true sense, this is not a type of GSD because the enzyme deficiency leads to decreased glycogen stores in skeletal and cardiac muscles. The disease is extremely rare and has only been reported in five cases. Muscle biopsies showed lack of glycogen, predominantly oxidative fibers, and mitochondrial proliferation. Glucose tolerance testing was normal. The phenotype was variable and ranged from sudden cardiac arrest, muscle fatigability, hypertrophic cardiomyopathy, abnormal heart rate, and hypotension while exercising to mildly impaired cardiac function at rest.

Type XV Glycogen Storage Disease (Glycogenin-1 Deficiency, Polyglucosan Body Myopathy 2, GYG1 Variant)

Polyglucosan body myopathy 2 is an autosomal recessive, slowly progressive skeletal myopathy caused by pathogenic variants in the *GYG1*

gene disrupting **glycogenin-1** biosynthesis. There is a reduced or complete absence of glyogenin-1, which is a precursor necessary for glycogen formation. Polyglucosan accumulation in skeletal muscles causes juvenile- or adult-onset proximal muscle weakness, prominently affecting the hip and shoulder girdles. Some patients were noted to have a cardiac phenotype. Exertion-induced chest pain, palpitations, and shortness of breath are common early symptoms. Changes in electrophysiological (ECG) parameters and impairment of left ventricular function were reported. Heart transplantation may be necessary in some cases. The missense variant c.304G>C (p. Asp102His) has been observed in homozygosity in the majority of these patients. Compared with GSD IV–APBD, nervous system involvement is uncommon, although polyglucosan deposition is seen in both disorders. Muscle biopsies show PAS-positive, diastase-resistant storage material in 30–40% of muscle fibers. EM reveals the typical polyglucosan structure, consisting of an ovoid form composed of partly filamentous material.

Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease)

GSD type V, the prototype of muscle energy disorders, is one of the most common GSDs with a prevalence of ~1 in 10,000 and is caused by deficiency of **myophosphorylase** activity. Lack of this enzyme limits muscle ATP generation from glycogenolysis, resulting in muscle glycogen accumulation. A deficiency of myophosphorylase impairs the cleavage of glucosyl molecules from the straight chain of glycogen.

Clinical Manifestations

Symptoms usually first develop in late childhood or in the second decade of life. Studies have shown that McArdle disease can manifest in individuals as old as in their seventh decade and in infancy in a fatal, early-onset form characterized by hypotonia, generalized muscle weakness, and respiratory complications. Symptoms are generally characterized by exercise intolerance with muscle cramps and pain and are precipitated by two types of activity: (1) brief, high-intensity exercise, such as sprinting or carrying heavy loads and (2) less intense but sustained activity, such as climbing stairs or walking uphill. Most patients can perform moderate exercise, such as walking on level ground, for long periods. Many patients experience a characteristic *second-wind phenomenon,* with relief of muscle pain and fatigue after a brief period of rest. An increased blood flow of glucose derived from either endogenous liver glycogenolysis or exogenous glucose and free fatty acids, which may be used as an alternative energy source by the exercising muscles, causes the second-wind phenomenon. As a result of the underlying myopathy, these patients may be at risk for **statin-induced myopathy** and rhabdomyolysis. Although patients typically experience episodic muscle pain and cramping from exercise, up to 35% of patients with McArdle disease report permanent pain that has a serious impact on sleep and other activities.

Approximately 50% of patients report burgundy-colored urine after exercise as a result of exercise-induced **myoglobinuria** secondary to **rhabdomyolysis**. Excessive myoglobinuria after intense exercise may precipitate acute renal failure.

Laboratory findings include elevated serum CK levels at rest, which further increase after exercise. Exercise also elevates the levels of blood ammonia, inosine, hypoxanthine, and uric acid, which may be attributed to accelerated recycling of muscle purine nucleotides caused by insufficient ATP production.

Diagnosis

Type V GSD is an autosomal recessive disorder. Testing of the gene for muscle phosphorylase *(PYGM)* helps confirm the diagnosis of GSD V. A common nonsense variant, c.148C>T (p.Arg50Ter) in exon 1, is found in 80% of White patients; deletion of a single codon, c.2128_2130del (p.Phe710del) in exon 17, is found in 61% of patients of Japanese origin. The c.148C>T (p.Arg50Ter) variant represents 55% of alleles in patients of Spanish descent, and the c.2392T>C (p.Trp798Arg) and c.613G>A (p.Gly205Ser) variants represent 10% and 9% of pathogenic alleles in this population. Muscle biopsy can be used to measure glycogen content and enzyme activity in cases where genetic testing results are inconclusive. Lack of an increase in blood lactate levels and exaggerated blood ammonia elevations suggest a defect in the conversion of muscle glycogen or glucose to lactate. An ischemic exercise test offers rapid diagnostic screening for patients suspected to have McArdle disease, though it should be noted that an abnormal response is *not limited* to type V GSD, as other muscle defects in glycogenolysis or glycolysis produce similar results (deficiencies of muscle phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase, or LDH). Additionally, such testing was also associated with severe complications and false-positive results. A nonischemic forearm exercise test with high sensitivity that is easy to perform and is cost-effective has been deemed a more appropriate diagnostic tool; however, it also cannot differentiate abnormal exercise responses due to type V disease from other defects in glycogenolysis or glycolysis.

Treatment

To enhance patients' outcomes and physical activity capacity, a multidisciplinary team approach to care composed of a physician, physiotherapist, psychologist, clinical nurse, and dietitian is advised. Avoidance of strenuous exercise prevents symptoms; regular and moderate exercise is recommended to improve exercise capacity. Patients are advised to take advantage of the second-wind phenomenon by commencing exercise slowly and to slow down or stop if muscle weakness or discomfort, increased heart rate, or increased respiratory effort occurs. This *slow-pause-resume* pattern is intended to be maintained as needed until considerable improvement in physical activity tolerance occurs.

High-dose oral ribose, glucagon, verapamil, vitamin B_6, a high-protein diet, branched-chain amino acid supplementation, dantrolene sodium, high-dose creatine, intravenous gentamicin, and intralipid infusion treatments showed no benefit according to a revised and updated systematic review in the Cochrane Database of nutritional and pharmacologic trials for GSD V. Oral sucrose ingestion before exercise, a carbohydrate-rich diet, ramipril, and low-dose creatine were treatments that showed some promise. There is ongoing research regarding the benefits of a low-carbohydrate ketogenic diet in patients with type V GSD.

Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease)

Type VII GSD is caused by pathogenic variants in the *PFKM* gene, which result in a deficiency of **muscle phosphofructokinase** enzyme. This enzyme is a key regulatory enzyme of glycolysis and is necessary for the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-diphosphate. Phosphofructokinase is composed of three isoenzyme subunits according to the tissue type, encoded by different genes: (*PFKM* [M: muscle], *PFKL* [L: liver], and *PFKP* [P: platelet]). Skeletal muscle has only the M subunit, whereas red blood cells (RBCs) express a combination of L and M forms. In type VII GSD, the M isoenzyme is defective, resulting in complete deficiency of enzyme activity in muscle and a partial deficiency in RBCs.

Type VII GSD is an autosomal recessive disorder with increased prevalence in individuals of Japanese ancestry and Ashkenazi Jewish background. A splicing defect and a nucleotide deletion in *PFKM* account for 95% of pathogenic variants in the Ashkenazi Jewish population. Diagnosis based on molecular testing for the common variants is possible in this population.

Clinical Manifestations

Although the clinical picture is similar to that of type V GSD, the following features of type VII GSD are distinctive:

- Exercise intolerance, which usually commences in childhood, is more severe than in type V disease and may be associated with nausea, vomiting, and severe muscle pain. Vigorous exercise causes severe muscle cramps and myoglobinuria.
- Compensatory hemolysis occurs, as indicated by an increased level of serum bilirubin and an elevated reticulocyte count.
- Hyperuricemia is common and exaggerated by muscle exercise to a greater degree than that observed in type V GSD.

In addition to normal glycogen, GSD VII is characterized by the accumulation of polyglucosan bodies. The accumulation of glucose-6-phosphate caused by PFKM deficiency and the inhibition of glycolysis stimulate the glycogen synthase enzyme, resulting in the formation of polyglucosan bodies.

Exercise intolerance is especially worse after carbohydrate-rich meals because the ingested glucose prevents lipolysis, thereby depriving muscle of fatty acid and ketone substrates. This is called the *out-of-wind phenomenon,* in contrast to patients with type V disease who can metabolize blood-borne glucose derived from either endogenous liver glycogenolysis or exogenous glucose. Indeed, glucose infusion improves exercise tolerance in patients with type V disease.

The *second-wind phenomenon* is absent because of the inability to break down blood glucose.

Several rare type VII presentations have been described. One form presents in infancy with hypotonia and limb weakness and proceeds to a rapidly progressive myopathy that leads to death by 4 years of age. A second type occurs in infancy and results in congenital myopathy and arthrogryposis, with a fatal outcome. A third form presents in infancy with hypotonia, mild developmental delay, and seizures. An additional presentation is *hereditary nonspherocytic hemolytic anemia;* although these patients do not experience muscle symptoms, it remains unclear whether these symptoms will develop later in life. Another group of individuals with asymptomatic partial red cell PFK deficiency has been described. One phenotype presents in adults and is characterized by a slowly progressive, fixed muscle weakness rather than cramps and myoglobinuria. It may also cause mitral valve thickening from glycogen buildup. Myopathy and hemolysis are hallmarks of the classic form.

Diagnosis

To establish a diagnosis, gene sequencing can identify pathogenic variants in the *PFKM* gene. Demonstration of the enzymatic deficiency in muscle may be required in some cases. The absence of the M isoenzyme of phosphofructokinase can also be demonstrated in muscle, blood cells, and fibroblasts.

Treatment

Strenuous exercise should be avoided to prevent acute episodes of muscle cramps, myoglobinuria, acute renal failure, and compartment syndrome. Continuous blood pressure monitoring or compressive devices, as well as the use of tourniquets, are contraindicated in these patients. Patients with GSD VII should follow the same *slow-pause-resume* routine as those with GSD V. Dietary therapy for GSD VII has not been thoroughly investigated. A ketogenic diet has been reported to show clinical improvement in a patient with GSD VII. Carbohydrate meals and glucose infusions have demonstrated worsening symptoms because of the body's inability to use glucose. The administered glucose tends to lower the levels of fatty acids in the blood—a primary source of muscle fuel. *Drugs such as statins should be avoided.* Precautionary measures should be taken to avoid hyperthermia, hypothermia, hypoglycemia, and shivering while undergoing anesthesia in both GSD V and GSD VII.

Type IX α1 Glycogen Storage Disease (Muscle-Specific Phosphorylase Kinase Deficiency, *PHKA1* Variant)

X-linked muscle PhK deficiency (IX α1 GSD) is caused by pathogenic variants in the *PHKA1* gene, which encodes a muscle-specific regulatory subunit (α subunit) of phosphorylase kinase and is located on Xq13.11. The condition is male-predominant, but affected heterozygous females have been reported. Patients generally present with mild to severe exercise intolerance in childhood or adolescence. Most patients have elevated serum CK and, in more involved cases, myoglobulinuria. There is no evidence of hepatic or cardiac disease in these patients. Blood phosphorylase kinase enzymatic activity is normal, and the enzyme activity is decreased to deficient in the muscle. Muscle biopsy reveals subsarcolemmal accumulations of glycogen, and some patients have myopathic changes on EMG. One patient has been described with comorbid muscle PhK deficiency and intellectual disability; although a connection between *PHKA1* and neurodevelopment has not yet been established, patients with the diagnosis should be monitored for developmental concerns.

The gene for the muscle γ subunit *(PHKG1)* is on chromosome 7p11.2, and no pathogenic variants in this gene have been reported to date.

Other Muscle Glycogenoses with Muscle Energy Impairment

Five additional defects in enzymes—phosphoglycerate kinase (PGK), phosphoglycerate mutase (PGAM), LDH, fructose-1,6-bisphosphate aldolase (aldolase A), and β-enolase in the pathway of the terminal glycolysis—cause symptoms and signs of muscle energy impairment similar to those in types V and VII GSD. Deficiency in PGAM, enolase, or LDH causes a myopathic phenotype marked by exercise-induced cramps and myoglobinuria. Patients with aldolase A or PGK deficiencies may present with hemolytic anemia in conjunction with myopathy. The failure of blood lactate to increase in response to exercise is a useful screening test and can be used to differentiate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyltransferase II deficiency and very long-chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels can be normal in the disorders affecting terminal glycolysis, and molecular testing or muscle enzyme activity assay is needed to make a definitive diagnosis. There is no specific treatment (see preceding "Treatment" section).

107.2 Defects in Galactose Metabolism

Ghada Hijazi and Priya S. Kishnani

Milk and dairy products contain **lactose**, the major dietary source of galactose. The metabolism of galactose produces fuel for cellular metabolism through its conversion to glucose-1-phosphate (see Table 107.1). Galactose also plays an important role in the formation of galactosides, which include glycoproteins, glycolipids, and glycosaminoglycans. **Galactosemia** is a term that refers to an abnormally high quantity of galactose in the blood. It can be caused by one of four distinct inborn defects in galactose metabolism involving one of the following enzymes: galactose mutarotase (GALM), galactokinase (GALK), galactose-1-phosphate uridyl transferase (GALT), and uridine diphosphate galactose-4-epimerase (GALE). Among these, the most serious defect is severe GALT deficiency or classic galactosemia, which is frequently referred to as *galactosemia*.

GALACTOSE-1-PHOSPHATE URIDYL TRANSFERASE DEFICIENCY GALACTOSEMIA

Two forms of the deficiency exist: infants with complete or near-complete deficiency of the enzyme (classic galactosemia) and those with partial transferase deficiency. **Classic galactosemia** is a serious disease with onset of symptoms typically by the second half of the first week of life. The incidence is approximately 1 in 60,000 live births. The newborn infant receives high amounts of lactose (up to 40% in breast milk and certain formulas), which consists of equal parts of glucose and galactose. Without the transferase enzyme, the infant is unable to metabolize galactose-1-phosphate, the accumulation of which results in injury to the liver, kidney, and brain. This injury may begin prenatally in the affected fetus by endogenous fetal production of galactose.

Clinical Manifestations

The diagnosis of uridyl transferase deficiency should be considered in newborn or young infants with any of the following features within a few days or weeks after birth: jaundice, hepatomegaly, vomiting, hypoglycemia, seizures, lethargy, irritability, feeding difficulties, poor weight gain or failure to regain birthweight, and aminoaciduria. Untreated children may show nuclear cataracts, vitreous hemorrhage, hepatic failure, cirrhosis, ascites, splenomegaly, or intellectual disability. Patients with galactosemia

are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. Pseudotumor cerebri has been reported in some patients, presenting with failure to thrive and a bulging anterior fontanel. Complete withdrawal of lactose from the diet results in improvement of the acute symptoms. If untreated, death from liver failure and sepsis may follow within days. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain (intellectual disability) becomes increasingly severe and irreversible.

Partial transferase deficiency is classified into two subtypes: clinical variant galactosemia (erythrocyte GALT enzyme activity is ≥1% of controls, but not more than 10–15%) and biochemical (Duarte) variant galactosemia (erythrocyte GALT enzyme activity is ≥25% of controls). Partial transferase deficiency is more common than classic galactosemia and is diagnosed in the newborn screening setting because of moderately elevated blood galactose and/or low transferase activity. Clinical variant galactosemia should be considered in the newborn or young infant who is not thriving or who exhibits any of the classical galactosemia-related symptoms. Generally, biochemical (Duarte) variant galactosemia is asymptomatic. There is no evidence that individuals with biochemical (Duarte) variant galactosemia have an increased risk of neurodevelopmental problems or premature ovarian insufficiency. Additional research is required to properly understand and describe the natural history of this subtype.

Diagnosis

Historically, the detection of a reducing substance in several urine specimens obtained when the patient is on a diet containing human milk, cow's milk, or any other lactose-containing formula was regarded as strongly indicative of galactosemia. The clue was detecting a reducing substance in urine by Clinitest strips (e.g., glucose, galactose) that is negative by Clinistix (which is specific for glucose only). Galactose can also be identified by chromatography or an enzymatic test specific for galactose. Galactose can be detected in urine, provided the milk feeding was within the last few hours and the child is not vomiting excessively. The addition of galactosemia to the newborn screening panel resulted in a considerable reduction in the utility of Clinitest strips for galactosemia screening. Amino acids may be detected in urine (aminoaciduria) because they are excreted together with glucose as a result of proximal renal tubular dysfunction. Because galactose is injurious to persons with galactosemia, diagnostic challenge tests dependent on administering galactose orally or intravenously should not be used. Direct enzyme assay using erythrocytes establishes the diagnosis. The clinician must confirm that the patient did not receive a blood transfusion before the collection of the blood sample for enzyme assay activity in RBCs, because this may lead to a false-negative result, and the diagnosis could be missed. The activity of galactose-1-phosphate uridyl transferase in erythrocytes can be measured in a variety of ways, one of which involves the use of a nonradioactive assay using high-performance liquid chromatography (HPLC) separation and ultraviolet (UV) light detection. Patients with glucose-6-phosphate-dehydrogenase deficiency can have false-positive results. In classic galactosemia, metabolites (urinary galactitol, red cell galactose-1-phosphate, and blood galactose concentration) may be elevated and can be used to confirm the diagnosis and monitor the response to dietary changes and metabolic control.

Genetics

GALT deficiency is an autosomal recessive disorder caused by pathogenic variants in the *GALT* gene. Based on newborn screening in the United States, the frequency of the disease is approximately 1 in 47,000 live births. There are several enzymatic variants of galactosemia. More than 327 pathogenic variants have been associated with GALT deficiency. The most common pathogenic variants that result in classic galactosemia phenotype are c.563A>G (p.Gln188Arg), c.855G>T (p.Lys285Asn), and c.584T>C (p.Leu195Pro). In Whites, the p.Gln188Arg variant is linked to an increased incidence of severe disease, premature ovarian insufficiency, and speech problems in a homozygous state. In Blacks p.Ser135Leu is common, which results in a milder phenotype (clinical variant galactosemia) despite the absence of measurable GALT activity in erythrocytes. These patients retain 10% of enzyme activity in the liver and intestinal mucosa. When treated early, Blacks who are homozygous for this variant are not at risk for neonatal *E. coli* sepsis or chronic complications (i.e., premature ovarian insufficiency and language delay). Four pathogenic variants are unique to the Duarte variant (D2): a four–base pair (bp) deletion in the GALT promoter region (c.-119-116delGTCA), a c.378-27G>C, a c.508-24G>A, and a c.507+62G>A. A fifth variant is a single amino acid substitution (c.940A>G, p.Asn314Asp, also called *N314D*), which has been observed in both the Duarte variant and functionally normal GALT alleles. Individuals heterozygous for Duarte variant galactosemia typically have 25% of normal galactose activity. Symptoms are minimal or absent, metabolites range from elevated to normal, and there is no need for intervention. Carrier testing and prenatal diagnosis can be performed by molecular testing or, less commonly, direct enzyme assay on amniocytes or chorionic villi.

Treatment and Prognosis

Consensus guidelines recommend treating patients with an RBC GALT enzyme activity of ≤10% and erythrocyte galactose-1-phosphate concentration of >10 mg/dL. The decision of whether to treat those with 10–15% RBC residual GALT activity is still a matter of debate. All galactose-containing foods should be removed from the diet on initial suspicion of galactosemia. Various non–lactose-containing milk substitutes are available (casein hydrolysates, soybean-based formula). A galactose-restricted diet, along with adequate calcium and vitamin D supplementation, reverses growth failure and hepatic dysfunction. Cataracts regress, and most patients have no persistent impairment of vision. Early diagnosis and treatment have improved the prognosis of galactosemia. On long-term follow-up, patients still manifest ovarian failure with primary or secondary amenorrhea, decreased bone mineral density, developmental delay, and learning disabilities that increase in severity with age. *Hypergonadotropic hypogonadism* is reported in 80–90+% of female patients with classic galactosemia. Although most females with classic galactosemia are infertile when they reach childbearing age, a small number have given birth. Females with the Duarte variant galactosemia and who are homozygous for p.Ser135Leu do not develop premature ovarian insufficiency. Most patients manifest speech disorders, whereas a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). Strict dietary restriction and relative control of galactose-1-phosphate levels do not always correlate with long-term outcome, leading to the belief that other factors such as elevated galactitol, decreased uridine diphosphate galactose (a donor for galactolipids and proteins), and endogenous galactose production may be responsible.

GALACTOKINASE DEFICIENCY

The deficient enzyme is galactokinase, which normally catalyzes the phosphorylation of galactose. The principal metabolites accumulated are galactose and galactitol. Two genes encode enzymes with galactokinase activity, *GALK1* and *GALK2,* although pathogenic variants have been noted only in *GALK1* that cause autosomal recessive galactokinase deficiency. **Cataract** is the most common manifestation of galactokinase deficiency, and pseudotumor cerebri is a rare complication. The incidence of hypoglycemia and infection is comparable to those found in the general population. There is a higher rate of bleeding diathesis, encephalopathy, and elevated liver transaminases than in the general population during the newborn period. Some patients have intellectual impairment and motor and language delays. Heterozygous carriers may be at risk for presenile cataracts. Laboratory findings include increased concentration of blood galactose levels and urinary galactitol, provided the infant has been fed a lactose-containing formula. The diagnosis is made by demonstrating an absence of galactokinase activity in erythrocytes or fibroblasts. GALT activity is normal. Treatment is dietary restriction of galactose.

URIDINE DIPHOSPHATE GALACTOSE-4-EPIMERASE DEFICIENCY

There are three distinct forms of **epimerase** deficiency based on the level of enzyme activity in different cell types. The first is a **benign** form known as *peripheral epimerase deficiency galactosemia,* diagnosed incidentally through newborn screening programs. Affected individuals are asymptomatic because the enzyme deficiency is limited to

leukocytes and erythrocytes. This form does not require treatment. The second subtype is called **intermediate** form and is caused by epimerase deficiency in RBCs and circulating white blood cells, as well as epimerase activity below 50% of normal in all other cells. Neonates with the intermediate form are typically asymptomatic, even when fed a normal milk diet, and are diagnosed only as a result of newborn screening. The long-term consequences remain unknown. During infancy and early childhood, these individuals are treated with a galactose-/lactose-restricted diet. The third form is rarer and more **severe** as a result of generalized epimerase deficiency. Clinical manifestations resemble GALT transferase deficiency, with additional symptoms of hypotonia and nerve deafness. Clinical symptoms improve with restriction of galactose/lactose in the diet. Although this severe form of epimerase galactosemia is rare, it must be considered in a symptomatic patient with elevated RBC galactose-1-phosphate, urinary galactose, and galactitol levels but with normal GALT transferase activity. The abnormally accumulated metabolites are similar to those in transferase deficiency, with the addition of an increase in cellular uridine diphosphate (UDP) galactose. Biochemical diagnosis is confirmed by the assay of epimerase in erythrocytes demonstrating reduced activity. UDP galactose-4-epimerase is encoded by the *GALE* gene, and pathogenic biallelic variants result in autosomal recessive disease. Carrier detection is possible by measurement of epimerase activity in the erythrocytes. Prenatal diagnosis for the severe form of epimerase deficiency can be done using an enzyme assay of cultured amniotic fluid cells or testing of known familial pathogenic variants.

Patients with the severe form of epimerase deficiency cannot synthesize UDP galactose from UDP glucose and are galactose dependent. Because galactose is an essential component of many nervous system structural proteins, patients are placed on a galactose-*restricted* diet rather than a galactose-*free* diet. Galactose restriction is also indicated for infants and young children with the intermediate form. Additional outcome data are needed to optimize these approaches and develop a better understanding of long-term issues in this patient population. Infants with mild epimerase deficiency have not required treatment.

Galactose Mutarotase Deficiency

GALM catalyzes the first step in the Leloir pathway, the conversion of beta-D-galactose to alpha-D-galactose. There have been a few cases of GALM deficiency reported, with an overall estimated incidence of GALM deficiency in all populations of less than 1 in 200,000, with higher incidences in Black and Japanese populations. Apart from cataracts, individuals with GALM deficiency are often healthy. In some reported cases, elevated blood galactose-1-phosphate (Gal-1-P) and galactose levels were identified during newborn screening. There are no reports of long-term implications of this condition and no formal recommendations regarding optimal dietary intake in this population.

107.3 Defects in Fructose Metabolism

Ghada Hijazi and Priya S. Kishnani

Two inborn errors are known in the specialized pathway of fructose metabolism: benign or essential fructosuria and hereditary fructose intolerance. Fructose-1,6-bisphosphatase deficiency, not formally a defect of the specialized fructose pathway, is discussed in Chapter 107.4.

DEFICIENCY OF FRUCTOKINASE (ESSENTIAL OR BENIGN FRUCTOSURIA)

Deficiency of fructokinase is not associated with clinical manifestations. **Fructosuria** is an incidental finding identified in asymptomatic individuals with reducing substances in urine. No treatment is necessary, and the prognosis is excellent. Inheritance of this autosomal recessive trait is caused by biallelic variants in the *KHK* gene, with an incidence of 1 in 120,000 live births.

Fructokinase catalyzes the first step of metabolism of dietary fructose—conversion of fructose to fructose-1-phosphate (see Fig. 107.1). Without this enzyme, fructose consumption results in a rise in the blood level of fructose, which is partially excreted in the urine, as there is little to no renal threshold for fructose. In adipose tissue and muscle, hexokinase converts the remainder to fructose-6-phosphate, which is considered a slower alternative process. Clinitest results reveal the urinary reducing substance, which can be identified as fructose by chromatography.

DEFICIENCY OF FRUCTOSE-1-PHOSPHATE ALDOLASE (ALDOLASE B, HEREDITARY FRUCTOSE INTOLERANCE)

In comparison to fructokinase, deficiency of fructose-1-phosphate aldolase **(aldolase-B)** is a severe condition in infants resulting from a deficiency of activity in the liver, kidney, and intestine. Fructose-1-phosphate aldolase hydrolyzes fructose-1-phosphate to glyceraldehyde and dihydroxyacetone phosphate. In the glycolytic-gluconeogenic pathway, this enzyme catalyzes the hydrolysis of fructose-1,6-bisphosphate to dihydroxyacetone phosphate and glyceraldehyde phosphate. In the absence of aldolase B activity, there is a rapid accumulation of fructose-1-phosphate and depletion of ATP, which presents with severe symptoms when fructose-containing food is ingested. Accumulation of fructose-1-phosphate also results in inhibition of gluconeogenesis (via inhibition of aldolase A) and glycogenolysis (via inhibition of glycogen phosphorylase A), resulting in decreased glucose production and a rapid decline in blood glucose. Because isozyme fructose-1,6-bisphosphate aldolase (aldolase A) metabolizes fructose-1,6-bisphosphate, glycolysis and gluconeogenesis are not affected in patients with hereditary fructose intolerance in the fasting state.

Epidemiology and Genetics

The incidence of **hereditary fructose intolerance (HFI)** is estimated to be as high as 1 in 26,000 live births. HFI is inherited in an autosomal recessive manner because of biallelic pathogenic variants in the *ALDOB* gene. At least 60 pathogenic variants causing HFI are known. The most common pathogenic variant identified in the Northern European population is p.Ala150Pro. This variant, along with two other missense variants (p.Ala175Asp and p.Asn335Lys), account for 80–85% of HFI cases in Europe and the United States. The diagnosis of HFI can be made by gene sequencing or demonstration of hepatic fructose-1-phosphate aldolase (aldolase B) activity deficiency on liver biopsy (uncommon).

Clinical Manifestations

Affected individuals remain asymptomatic until fructose, sucrose (table sugar), or sorbitol is introduced in the diet (usually from fruit, fruit juice, or sweetened cereal). Signs and symptoms typically manifest in infancy when foods or formulas containing these sugars are introduced. Certain patients are very sensitive to fructose, whereas others can tolerate moderate intake (up to 250 mg/kg/day). Early clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. There may also be a higher incidence of celiac disease in patients with HFI (>10%) compared with the general population (1–3%). With age, affected individuals typically develop an aversion to fructose-containing foods because of associated symptoms of nausea, vomiting, and abdominal pain.

Characteristic laboratory findings include lactic acidosis, hypophosphatemia, hyperuricemia, and hypermagnesemia. A prolonged prothrombin time, hypoalbuminemia, elevation of bilirubin and transaminase levels, and proximal tubular dysfunction are also seen. Acute fructose ingestion produces symptomatic hypoglycemia as a result of impaired gluconeogenesis, with higher intakes causing a more severe clinical picture. Chronic ingestion results in failure to thrive and hepatic disease. If the intake of fructose persists, hypoglycemic episodes recur, leading to progressive renal and hepatic failure and eventually death.

Diagnosis

The presence of a reducing substance in urine during an acute episode raises the possibility of HFI. Oral fructose challenge is no longer considered a diagnostic approach because of the high risk to the patient,

who can become acutely ill after the test. A definitive diagnosis is made by demonstration of two pathogenic variants in *ALDOB* on molecular genetic testing. A common pathogenic variant (p.Ala150Pro) accounts for 53% of HFI alleles worldwide. An alternative approach to diagnosis is to demonstrate deficient hepatic fructose-1-phosphate aldolase (aldolase B) activity on liver biopsy. Carbohydrate-deficient transferrin (CDT) testing (see Chapter 107.7) is generally abnormal in patients with HFI and can be used to monitor fructose, sucrose, and sorbitol consumption in the diet.

Treatment

Acute episodes are managed symptomatically by correcting hypoglycemia with IV glucose (dextrose) administration, providing supportive treatment of hepatic and/or renal insufficiency, and correcting metabolic acidosis. Complete elimination of fructose usually rapidly reverses symptoms and results in normalization of related metabolic disturbances. The cornerstone of long-term treatment is the complete restriction of all sources of fructose, sucrose, and sorbitol from the diet. It may be difficult because these sugars are widely used additives, found even in many medicinal preparations. With treatment, liver and kidney dysfunction improve, and catch-up in growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder even after fructose ingestion, and the long-term prognosis is good. Because of voluntary dietary avoidance of sucrose, affected patients have few dental caries. Care should be taken to avoid fructose-containing IV fluids during hospitalizations. Regular supplementation with a "sugar-free" multivitamin is required to avoid micronutrient deficiencies resulting from reduced fruit and vegetable consumption.

107.4 Defects in Intermediary Carbohydrate Metabolism Associated with Lactic Acidosis

Ghada Hijazi and Priya S. Kishnani

Lactic acidosis **(type B3)** occurs with inborn errors of metabolism, including defects of carbohydrate metabolism, that interfere with the conversion of pyruvate to glucose via the pathway of *gluconeogenesis* or to carbon dioxide and water via the mitochondrial enzymes of the Krebs cycle. Figure 107.4 depicts the relevant metabolic pathways. Type I GSD, fructose-1,6-bis phosphatase deficiency, and phosphoenolpyruvate carboxylase deficiency are disorders of gluconeogenesis associated with lactic acidosis. Other metabolic disorders, including mitochondrial respiratory chain defects, pyruvate dehydrogenase complex deficiency, pyruvate carboxylase deficiency, defects of fatty acid oxidation, organic acidurias (see Chapters 105.6, 105.10, and 106.1), biotin synthesis, and utilization defects also can cause lactic acidosis (Table 107.2). Some of these disorders are easily distinguishable by the presence of an abnormal acylcarnitine profile, amino acids in the blood, and urine organic acids. Blood lactate, pyruvate, acylcarnitine profile, and urine organic acids should be ordered in infants and children with unexplained acidosis, especially if there is an increased anion gap.

Lactic acidosis unrelated to an enzymatic defect occurs in conditions associated with hypoxemia and/or hypoperfusion (**type A** lactic acidosis). In this case, and in defects in the respiratory chain, the serum pyruvate concentration may remain normal (<1.0 mg/dL, with increased lactate to pyruvate ratio), whereas pyruvate is usually increased when lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex (both lactate and pyruvate are increased, and the ratio is normal). Lactate and pyruvate should be measured in the same blood specimen and on multiple blood specimens obtained when the patient is symptomatic because lactic acidosis can be intermittent. Figure 107.5 is an algorithm for the differential diagnosis of lactic acidosis. Lactic acidosis is also noted with various underlying diseases **(type B1)** and drugs or toxins **(type B2)** (see Table 107.2).

DISORDERS OF GLUCONEOGENESIS

Deficiency of Glucose-6-Phosphatase (Type I Glycogen Storage Disease)

Type I GSD is associated with significant fasting lactic acidosis. The chronic metabolic acidosis predisposes these patients to osteopenia; acute lactic acidosis associated with hypoglycemia is a life-threatening condition in GSD I (see Chapter 107.1).

Fructose-1,6-Bisphosphatase Deficiency

Fructose-1,6-bisphosphatase (FBP) deficiency impairs the formation of glucose from all gluconeogenic precursors, including dietary fructose. Hypoglycemia occurs when glycogen reserves are limited or exhausted. The **clinical manifestations** are characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation,

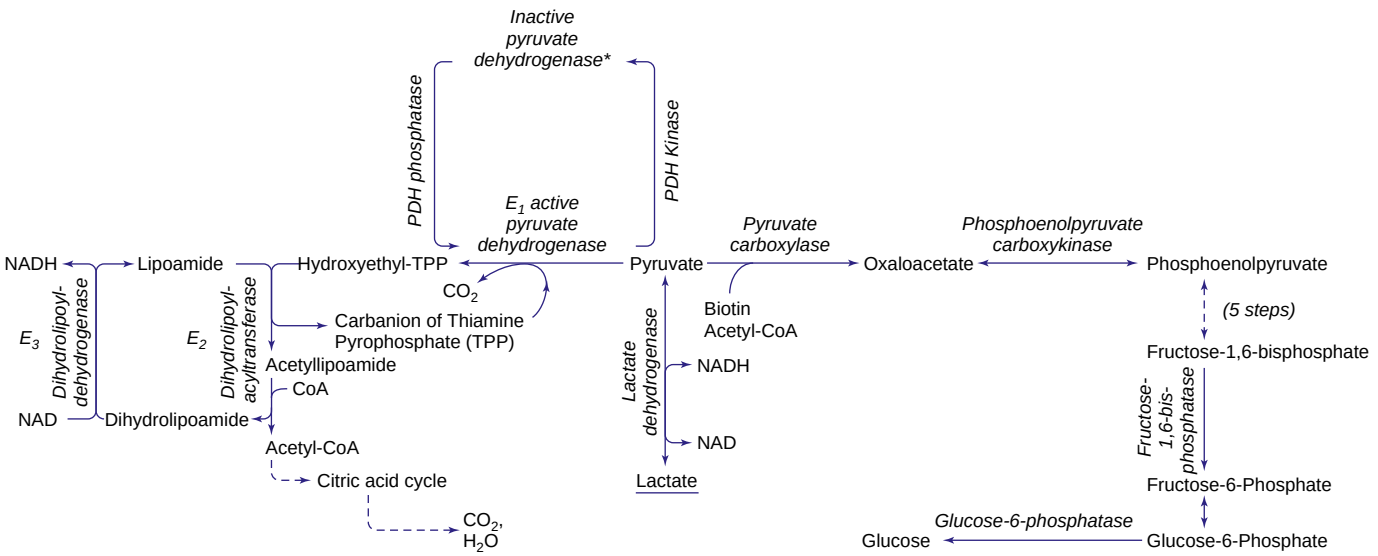

Fig. 107.4 Enzymatic reactions of carbohydrate metabolism, deficiencies of which can give rise to lactic acidosis, pyruvate elevations, or hypoglycemia. The pyruvate dehydrogenase (PDH) complex comprises, in addition to E_1, E_2, and E_3, an E_3-binding protein (not shown), previously called protein X, and PDH kinase and phosphatase. NAD/NADH, nicotinamide adenine dinucleotide.

Table 107.2 Causes of Type B Lactic Acidosis

TYPE B1—UNDERLYING DISEASES
Renal failure
Hepatic failure
Diabetes mellitus
Malignancy
Systemic inflammatory response syndrome
Human immunodeficiency virus

TYPE B2—DRUGS AND TOXINS
Acetaminophen
Alcohols: ethanol, methanol, diethylene glycol, isopropanol, and propylene glycol
Antiretroviral nucleoside analogs—zidovudine, didanosine, and lamivudine
β-Adrenergic agonists: epinephrine, ritodrine, and terbutaline
Biguanides: phenformin and metformin
Cocaine, methamphetamine
Cyanogenic compounds: cyanide, aliphatic nitriles, and nitroprusside
Diethyl ether
Fluorouracil
Halothane
Iron
Isoniazid
Linezolid
Nalidixic acid
Niacin
Propofol
Salicylates
Strychnine
Sugars and sugar alcohols: fructose, sorbitol, and xylitol
Sulfasalazine
Total parenteral nutrition
Valproic acid
Vitamin deficiencies: thiamine and biotin

TYPE B3—INBORN ERRORS OF METABOLISM
Glucose-6-phosphatase deficiency (von Gierke disease)
Fructose-1,6-diphosphatase deficiency
Phosphoenolpyruvate carboxykinase deficiency
Pyruvate carboxylase deficiency
Pyruvate dehydrogenase complex (PDHC) deficiency
Krebs cycle defects
Methylmalonic aciduria and other organic acidemias
Kearns-Sayre syndrome
Pearson syndrome
Barth syndrome
Mitochondrial DNA depletion syndromes
Nuclear DNA respiratory chain defects
Mitochondrial DNA respiratory defects
Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS)
Myoclonic epilepsy with ragged red fibers (MERRF)

Adapted from Vernon C, LeTourneau JL. Lactic acidosis: recognition, kinetics, and associated prognosis. *Crit Care Clin.* 2010;26:255–283, Box 1.

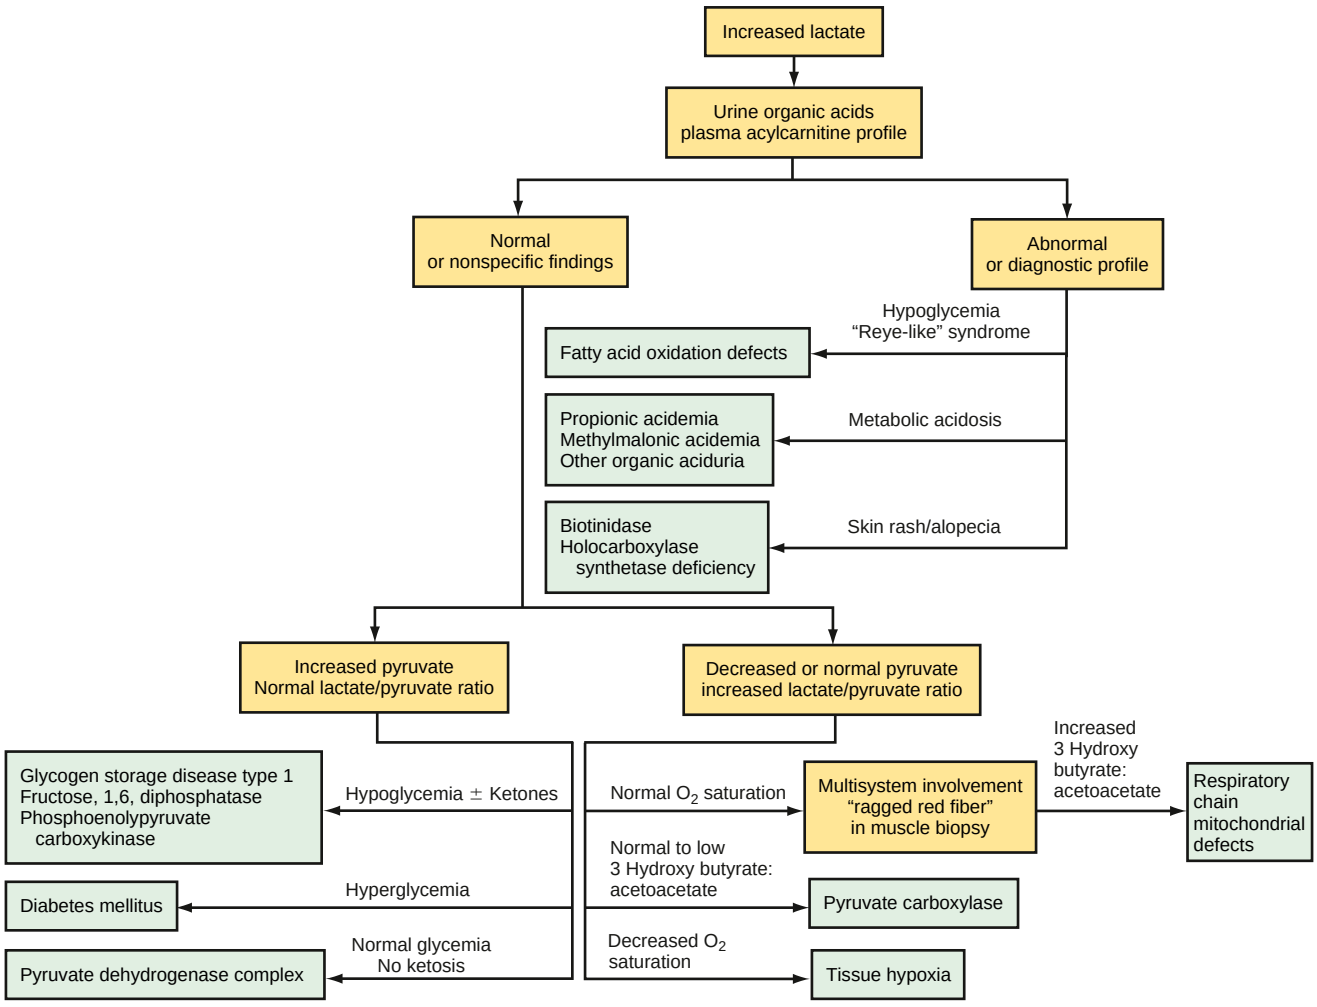

Fig. 107.5 Algorithm of the differential diagnosis of lactic acidosis.

seizures, and coma. In about half of the cases, the deficiency presents in the first week of life. In certain cases, variable degrees of liver impairment (elevated liver tests) and/or failure have been documented, requiring supportive therapy, including intravenous glucose infusion. In infants and small children, hypoglycemia and/or hepatopathy-like episodes are triggered by fasting or missing meals, febrile infections, gastroenteritis, vomiting, and/or poor oral intake. The frequency of these episodes decreases with age. Laboratory findings include low blood glucose, high lactate, glycerol, and uric acid levels and high anion gap metabolic acidosis. Because of the inability of current biochemical assays for plasma triglycerides to differentiate glycerol from triglycerides, FBP deficiency is usually associated with elevated triglyceride levels. This phenomenon is referred to as *pseudo-hypertriglyceridemia* because the plasma has a high concentration of glycerol rather than triglycerides. In contrast to HFI, there is usually no oral aversion to sweets and fruit. Between episodes, renal tubular and liver function may be normal; however, long-term studies are limited.

The **diagnosis** is established by noninvasive molecular genetic testing for pathogenic variants or demonstrating an enzyme deficiency in either liver biopsy or mononuclear white blood cells. The gene coding for fructose-1,6-bisphosphatase is *FBP1,* and pathogenic variants are known, making carrier detection and prenatal diagnosis possible. **Treatment** of acute attacks consists of correction of hypoglycemia and acidosis by IV glucose infusion, and the response is usually rapid. Avoidance of fasting, frequent feedings, aggressive management of infections, and restriction of fructose, sucrose, glycerol, and/or sorbitol from the diet can prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Children remain asymptomatic in between crises, and the majority have normal growth and psychomotor development. A few children have been documented to have suffered brain injury and/or cognitive disabilities, most likely as a result of early and untreated hypoglycemia.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase **(PEPCK)** is a key enzyme in gluconeogenesis. It catalyzes the conversion of oxaloacetate to phosphoenolpyruvate and carbon dioxide (see Fig. 107.4). PEPCK deficiency may occur as a cytosolic or mitochondrial enzyme deficiency, as it is encoded by two distinct genes (*PCK1* and *PCK2,* respectively).

PEPCK deficiency has been reported in only a few cases. The **clinical features** are heterogeneous, with hypoglycemia, lactic acidemia, hepatomegaly, hypotonia, developmental delay, and failure to thrive as the major manifestations. There may be multisystem involvement, with neuromuscular deficits, hepatocellular damage, renal dysfunction, and cardiomyopathy. The **diagnosis** is based on the reduced activity of PEPCK in the liver, fibroblasts, or lymphocytes. Fibroblasts and lymphocytes are not suitable for diagnosing the cytosolic form of PEPCK deficiency because these tissues possess only mitochondrial PEPCK. PEPCK deficiency can also occur as a secondary phenomenon caused by other disease, such as mitochondrial depletion disorders. As a result, molecular testing confirming the presence of two pathogenic variants in either the *PCK1* or *PCK2* gene is the recommended gold standard for diagnosis. To avoid hypoglycemia, patients should receive **treatment** with slow-release carbohydrates such as cornstarch, and fasting should be avoided.

DISORDERS OF PYRUVATE METABOLISM

Pyruvate is formed from glucose and other monosaccharides, from lactate, and from alanine. It is metabolized through four main enzyme systems: LDH, ALT, pyruvate carboxylase, and pyruvate dehydrogenase complex. Deficiency of the M subunit of LDH causes exercise intolerance and myoglobinuria (see Chapter 107.1).

Pyruvate Dehydrogenase Complex Deficiency

After entering the mitochondria, pyruvate is converted into acetyl-CoA by the pyruvate dehydrogenase complex **(PDHC)** and then enters the tricarboxylic acid cycle for ATP production. The complex comprises three functional enzymes: $\mathbf{E_1}$, an α-ketoacid decarboxylase; $\mathbf{E_2}$, a dihydrolipoyl acyltransferase; and $\mathbf{E_3}$, a dihydrolipoyl dehydrogenase. The complex also contains an E_3-binding protein (previously called **protein X**) and PDHC kinase and phosphatase, which regulate the complex's activity via phosphorylation/dephosphorylation. Additionally, it requires thiamine pyrophosphate (TPP), lipoic acid, and flavin adenine dinucleotide (FAD) as cofactors. The E_1 subunit, which is made up of two subunits, $E_{1\alpha}$ and $E_{1\beta}$, catalyzes the first and rate-limiting step in the reaction. The most common disorder is caused by a gene defect in the $E_{1\alpha}$ subunit (see Fig. 107.4).

Deficiency of the PDHC is the most common of the disorders leading to lactic acidemia and CNS anomalies and dysfunction. The CNS dysfunction occurs because the brain obtains its energy primarily from oxidation of glucose through glycolysis. Brain acetyl-CoA is synthesized almost exclusively from pyruvate.

PDHC deficiency is mostly caused by pathogenic variants in the gene coding for the $E_{1\alpha}$ subunit, which is inherited in an X-linked dominant fashion; therefore both males and females with a pathogenic variant exhibit features.

Clinical Manifestations

PDHC deficiency has a wide spectrum of presentations, from the most severe neonatal presentation to a mild late-onset form. The **neonatal onset** is associated with lethal lactic acidosis, white matter cystic lesions, agenesis of the corpus callosum, and severe enzyme deficiency. **Infantile/childhood onset** can be lethal or associated with psychomotor delay and chronic lactic acidosis, cystic lesions in the brainstem and basal ganglia, and features of **Leigh syndrome** (see later and Chapter 638.2). **Late onset** cases, including males, may have less acidosis, greater enzyme activity, and episodic ataxia upon consumption of high-carbohydrate-containing foods. Intelligence in affected males may be normal. Developmental delay, hypotonia, hypertonia, seizures, ataxia, peripheral neuropathy, dystonia, dyskinesia, and/or hemiplegia are among neurologic symptoms of PDHC deficiency. Patients of all ages may have dysmorphic facial features, resembling those seen in fetal alcohol syndrome, as a result of PDHC inhibition and reduction of energy metabolism in the latter. Typically, patients with $\mathbf{E_{1\beta}}$ deficiency are more severely affected.

The $\mathbf{E_2}$ deficiency is rare and results in a milder phenotype with varying brain MRI findings and survival into adolescence and adulthood.

The $\mathbf{E_3}$ **lipoamide dehydrogenase** deficiency leads to reduced activity not only in the PDHC but also in the α-ketoglutarate and branched-chain ketoacid dehydrogenase complexes. This deficiency is more common in the Ashkenazi Jewish population. Individuals deficient in E_3 may present with hypotonia and lactic acidosis during infancy, and affected infants typically die during the first few years of life. Surviving children have been shown to have growth delay and severe neurologic problems. Hepatic disease could be a component of this phenotype or may manifest separately. Only a small number of patients exhibit a myopathic phenotype including muscle weakness and elevated CK. In urine organic acid analysis, α-ketoglutarate and branched-chain ketoacids can be detected, and plasma amino acid analysis may reveal elevated levels of leucine, isoleucine, valine, and allo-isoleucine. These findings depend greatly on the phenotype of the disease. The $\mathbf{E_3}$ **binding protein deficiency** can present with either neonatal lactic acidosis, severe psychomotor retardation, or seizure, as well as abnormalities on brain MRI. **Pyruvate dehydrogenase phosphatase** and kinase deficiencies have also been reported. These other PDHC defects have clinical manifestations within the variable spectrum associated with PDHC deficiency caused by $E_{1\alpha}$ deficiency.

Treatment

The general prognosis is poor, except in rare patients whose variants are associated with altered affinity for thiamine pyrophosphate because they may respond to thiamine supplementation. Because carbohydrates can aggravate lactic acidosis, a ketogenic diet is recommended. The ketogenic diet has been found to decrease blood lactate levels and to reduce seizures and improve ataxia and sleep habits. Modified ketogenic diets (a 1:1 fat-to-carbohydrate and protein ratio) have also been

helpful in patients who cannot tolerate a strict ketogenic diet. Infusions of glucose, lactated Ringer, or other drugs known to increase the risk of lactic acidosis, such as metformin, are contraindicated. A potential treatment strategy is to maintain any residual PDHC in its active form by oral administration of dichloroacetate, an inhibitor of E_1 kinase. Beneficial effects of controlling postprandial lactic acidosis have been shown in some patients. Young children generally tolerate **dichloroacetate** well, but continued exposure is associated with peripheral neuropathy, a condition that could be attributable to the drug or the disease. In vitro studies have demonstrated that **phenylbutyrate** increases PDC enzyme activity, especially in those with pathogenic variants linked to residual enzyme activity. In patients with E_3 deficiency, **branched-chain amino acid** restriction and **riboflavin** supplementation are recommended.

Deficiency of Pyruvate Carboxylase

Pyruvate carboxylase is a mitochondrial, biotin-containing enzyme essential in the process of gluconeogenesis; it catalyzes the conversion of pyruvate to oxaloacetate. The enzyme is also essential for Krebs cycle function as a provider of oxaloacetate and is involved in lipogenesis and formation of nonessential amino acids. **Clinical manifestations** of this deficiency have varied from neonatal severe lactic acidosis accompanied by hyperammonemia, hypercitrullinemia, hyperlysinemia, and hypoglycemia **(type B)** to late-onset mild to moderate lactic acidosis and developmental delay **(type A)**. In both types, patients who survive usually have severe psychomotor retardation with seizures, spasticity, and microcephaly. Some patients have pathologic changes in the brainstem and basal ganglia that resemble **Leigh syndrome**. The clinical severity appears to correlate with the level of the residual enzyme activity. A "benign" form of pyruvate carboxylase deficiency has also been described, characterized by recurrent attacks of lactic acidosis and ketoacidosis, as well as mild neurologic deficits **(type C)**. Laboratory findings include elevated levels of blood lactate, pyruvate, and alanine and ketonuria. In type B, the lactate-to-pyruvate ratio is increased; this ratio is normal in types A and C. Additionally, in type B, blood ammonia, citrulline, and lysine levels are elevated with low glutamine, which might suggest a primary anaplerotic defect involving the urea cycle. The mechanism is likely the result of depletion of oxaloacetate, which leads to reduced levels of aspartate, a substrate for argininosuccinate synthase in the urea cycle (see Chapter 105.12). The gene for pyruvate carboxylase is *PC,* and many pathogenic variants have been identified.

Diagnosis of pyruvate carboxylase deficiency is made by the measurement of enzyme activity in cultured skin fibroblasts or lymphoblasts and must be differentiated from holocarboxylase synthase (HCS) or biotinidase deficiency. Molecular genetic testing is presently the preferred approach for diagnosis. **Treatment** consists of avoidance of fasting and modifying the diet to include high amounts of carbohydrate and protein. During acute episodes of lactic acidosis, patients should receive continuous IV glucose. Metabolic abnormalities have been reduced with the use of anaplerotic compounds such as citrate, aspartate, or more recently, triheptanoin, but no improvement has been shown in neurologic symptoms or increased life span. Although liver transplantation has been shown to correct biochemical abnormalities in two patients, the long-term benefits of this procedure are still unknown. Biotin is a cofactor used for this condition, but most patients do not respond to biotin. Lactated Ringer solution is contraindicated in this condition because of the theoretical risk of worsening lactic acidosis in these patients.

Deficiency of Pyruvate Carboxylase Secondary to Deficiency of Holocarboxylase Synthase or Biotinidase

Deficiency of either **HCS** or biotinidase, enzymes involved in biotin metabolism and recycling, respectively, results in multiple-carboxylase deficiency (pyruvate carboxylase, acetyl-CoA carboxylase, 3-methyl-crotonyl-CoA carboxylase, and propionyl-CoA carboxylase) and in **clinical manifestations** associated with the respective deficiencies, including rash, lactic acidosis, and alopecia (see Chapter 103.6). Both enzyme deficiencies are autosomal recessive disorders. The incidence of HCS and biotinidase deficiency is approximately 1 in 87,000 and 1 in 80,000 live births, respectively. Ancestry-specific pathogenic variants in the HCS and biotinidase (BTD) genes have been described. Two common pathogenic variants (c.98_104delinsTCC; p.Cys33PhefsTer36 and c.1612C>T; p.Arg538Cys) in the BTD account for 52% of all pathogenic alleles in symptomatic patients with biotinidase deficiency.

The course of HCS may be more protracted and less responsive to therapy than BTD deficiency. Lack of treatment may be associated with intermittent exacerbations on top of chronic lactic acidosis, failure to thrive, seizures, and hypotonia leading to spasticity, lethargy, coma, and death. Auditory and optic nerve dysfunction can lead to deafness and blindness, respectively. The course of BTD deficiency may be severe if left untreated. Late-onset milder forms have also been reported. Laboratory findings include an anion gap metabolic acidosis, lactic acidosis, and abnormal urine organic acids. Lactate, 3-methylcrotonylglycine, 3-hydroxypropionate, 3-hydroxisovalerate, and methyl citrate may accumulate in urine organic acid chromatography (OAC), though the concentrations of metabolites differ according to the severity of the enzyme deficiency. Blood and/or urine biotin levels can be used to evaluate treatment adherence, but they do not contribute to diagnosis. Biotin concentrations in plasma and urine are normal in patients with HCS deficiency and are often decreased in patients with BTD deficiency, particularly when the assay used does not detect biocytin.

Diagnosis of HCS deficiency and biotinidase deficiency can be detected through newborn screening tandem mass spectroscopy, which enables early treatment and improves outcomes. Molecular genetic testing is required to confirm the diagnosis, which involves the detection of two pathogenic variants. BTD deficiency can be diagnosed by reduced enzyme activity in the patient's serum or plasma, which helps to classify the deficiency into two categories: profound deficiency (biotinidase activity less than 10% of mean normal serum BTD activity) and partial deficiency (BTD activity between 10% and 30% of mean normal serum BTD activity). HCS activity in skin fibroblasts or lymphocytes can be assessed when HCS deficiency is suspected but genetic testing is equivocal.

Treatment

Treatment consists of biotin supplementation 5-20 mg/day and is generally effective if started early before the onset of symptoms or development of brain damage. Newborn screening has facilitated early treatment for patients with partial or profound BTD deficiency, who respond well to 5-10 mg of biotin; some patients may require higher doses during acute illness. Patients identified through newborn screening and treated with biotin have remained asymptomatic.

Mitochondrial Respiratory Chain Defects (Oxidative Phosphorylation Disease)

The mitochondrial respiratory chain catalyzes the oxidation of fuel molecules and transfers the electrons to molecular oxygen, with concomitant energy transduction into ATP **(oxidative phosphorylation)** (see Chapter 108). The respiratory chain produces ATP from adenosine diphosphate and inorganic phosphate, using the energy from electrons transferred from nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide, and includes five specific complexes (I: NADH–coenzyme Q reductase; II: succinate–coenzyme Q reductase; III: coenzyme QH2 cytochrome-c reductase; IV: cytochrome-c oxidase; V: ATP synthase). Each complex is composed of 4-35 individual proteins that are encoded by nuclear or maternally inherited mitochondrial DNA, with the exception of complex II, which is encoded solely by nuclear genes. Alterations of these complexes or assembly systems produce chronic lactic acidosis, presumably because of a change in the reduction-oxidation state with increased concentrations of NADH (Table 107.3).

In contrast to PDHC or pyruvate carboxylase deficiency, skeletal muscle and the heart are usually involved in the respiratory chain disorders. On muscle biopsy, **ragged red fibers** indicating mitochondrial proliferation are suggestive of mitochondrial involvement when present, especially when observed in young patients with symptoms (see

*Characteristic constellations of symptoms and signs are in **bold**.

+, Presence of a symptom, sign, or finding; −, absence of a symptom, sign, or finding; ±, possible presence of a symptom, sign, or finding; AID, aminoglycoside-induced deafness; KSS, Kearns-Sayre syndrome; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PS, Pearson syndrome, RTA, renal tubular acidosis.

Modified from DiMauro S, Schon EA. Mitochondrial respiratory-chain diseases. *N Engl J Med.* 2003;348:2656–2668.

Fig. 107.5). Because of the ubiquitous nature of oxidative phosphorylation, a defect of the mitochondrial respiratory chain accounts for a vast array of clinical manifestations and should be considered in patients of all ages presenting with multisystem involvement. Some deficiencies resemble **Leigh syndrome** with lactic acidosis, whereas others present with strokelike episodes, myopathies, or ataxia including **MELAS** (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes), **MERRF** (myoclonic epilepsy and ragged red fibers), and **Kearns-Sayre syndrome** (external ophthalmoplegia, ptosis, metabolic acidosis, retinal degeneration, heart block, myopathy, and high cerebrospinal fluid protein) (see Table 107.3) (see Chapters 638.2 and 651.4). There is a higher incidence of neuropsychiatric disorders in adults with a primary oxidative phosphorylation disease than in the general population.

Diagnosis requires identification of pathogenic variants in mitochondrial DNA or nuclear genes encoding mitochondrial proteins or demonstrating functional abnormalities of oxidative phosphorylation enzyme complex activities in tissues (e.g., skin, muscle, or liver). In

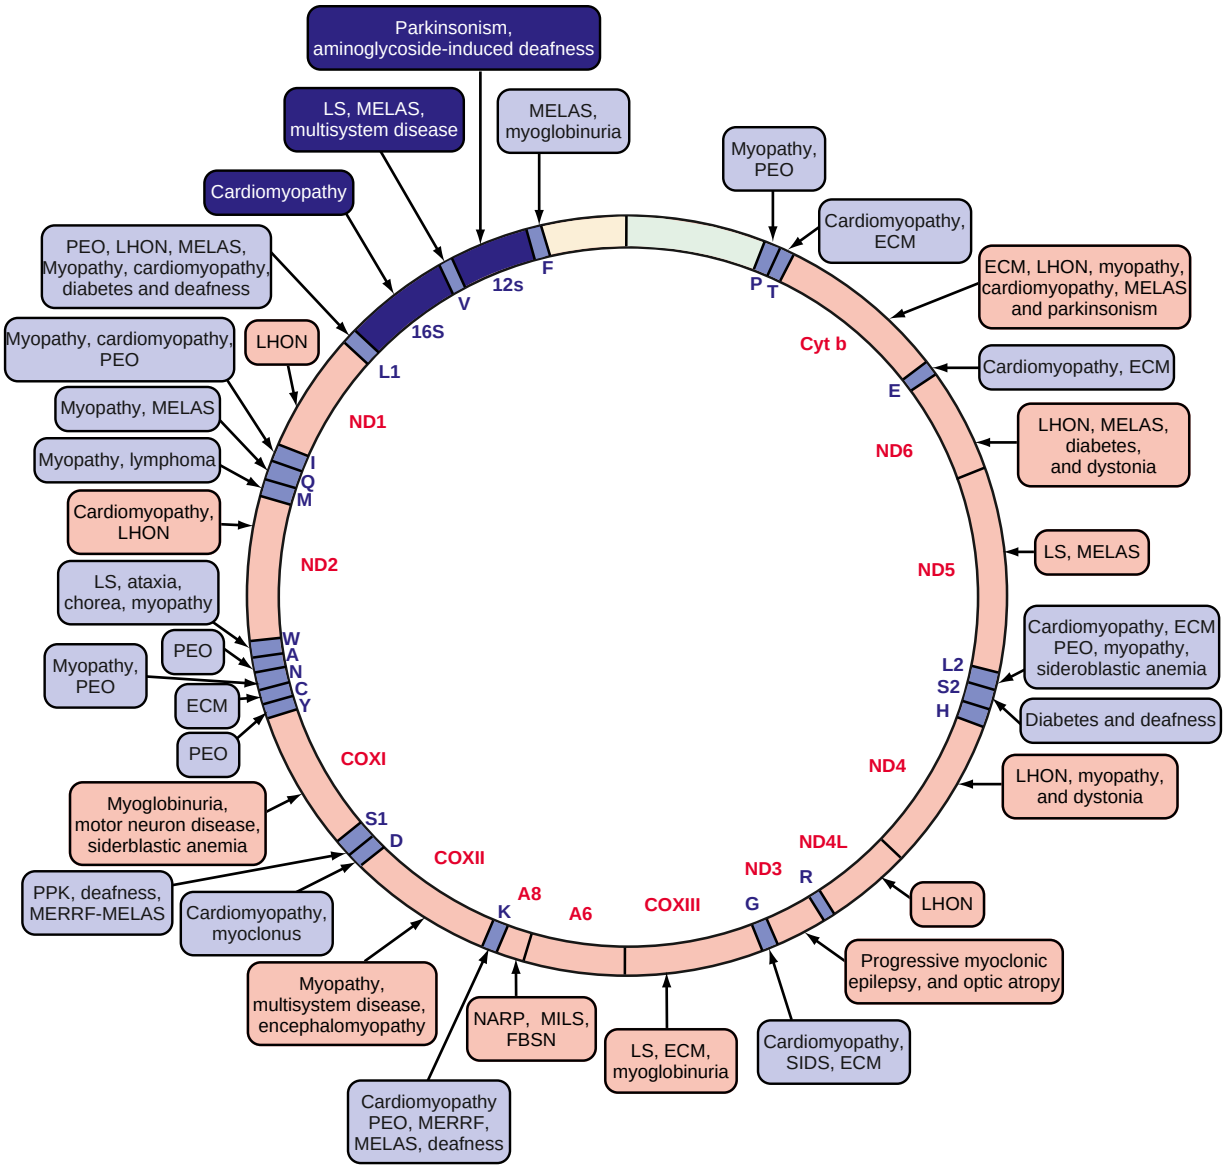

Fig. 107.6 Pathogenic variants in the human mitochondrial genome that are known to cause disease. Disorders that are frequently or prominently associated with pathogenic variants in a particular gene are shown in bold. Diseases caused by pathogenic variants that impair mitochondrial protein synthesis are shown in blue. Diseases caused by pathogenic variants in protein-coding genes are shown in red. ECM, Encephalomyopathy; FBSN, familial bilateral striatal necrosis; LHON, Leber hereditary optic neuropathy; LS, Leigh syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; SIDS, sudden infant death syndrome. *(From DiMauro S, Schon EA. Mitochondrial respiratory-chain diseases. N Engl J Med. 2003;348:2656–2668.)*

some instances, combined molecular and functional testing may be needed (Fig. 107.6). *NGS of single or combined mitochondrial DNA and nuclear gene panels is the preferred method of testing.* Whole exome sequencing with analysis of the mitochondrial genome or whole genome sequencing may be considered if NGS panel testing is nondiagnostic. Biopsy and genetic analysis of clinically affected tissues, with or without biochemical testing, is indicated when genetic testing of blood is negative or inconclusive and there is clinical suspicion of mitochondrial disease. Muscle biopsy was considered the most reliable procedure for diagnosing mitochondrial diseases prior to the availability of molecular genetic testing. Muscle histology, including EM, can detect ragged red fibers and other abnormalities typical of mitochondrial myopathies. Analysis of oxidative phosphorylation complexes I-IV from intact mitochondria isolated from fresh skeletal muscle can be helpful for the diagnosis of mitochondrial disorders; however, electron transport chain testing of flash-frozen muscle provides an alternative approach when fresh muscle testing is not available. The presence of normal muscle biochemistry and histology does not rule out the possibility of mitochondrial disease. Several disorders, such as defects in mitochondrial maintenance, fusion/fission, translation, transcription, or abnormalities in mitochondrial membrane integrity or transport, may not manifest with substantial oxidative phosphorylation deficiency and may have normal muscle biochemistry and histology. Specific criteria may assist in making a clinical diagnosis (Table 107.4). One study conducted to reevaluate the clinical utility of mitochondrial disease criteria (MDC) determined that the criteria are still beneficial and can aid in directing the diagnostic workup and in interpreting results and deciding on muscle biopsy in certain instances. Additionally, the study demonstrated that whole exome sequencing might be used to diagnose patients with lower MDC scores as having primary mitochondrial disorders. Table 107.5 lists clues to the diagnosis of mitochondrial diseases.

Numerous nuclear genes involved in mitochondrial function and causative for the majority of mitochondrial disorders are included in

Table 107.4 Mitochondrial Disease Criteria (Simplified Version for Bedside Use)*

I. CLINICAL SIGNS AND SYMPTOMS, 1 POINT/SYMPTOM (max. 4 points)				
A. MUSCULAR PRESENTATION (max. 2 points)	**B. CNS PRESENTATION (max. 2 points)**	**C. MULTISYSTEM DISEASE (max. 3 points)**	**II. METABOLIC/IMAGING STUDIES (max. 4 points)**	**III. MORPHOLOGY (max. 4 points)**
Ophthalmoplegia†	Developmental delay	Hematology	Elevated lactate†	Ragged red/blue fibers‡
Facies myopathica	Loss of skills	GI tract	Elevated L/P ratio	COX-negative fibers‡
Exercise intolerance	Stroke-like episode	Endocrine/growth	Elevated alanine†	Reduced COX staining‡
Muscle weakness	Migraine	Heart	Elevated CSF lactate†	Reduced SDH staining
Rhabdomyolysis	Seizures	Kidney	Elevated CSF protein	SDH positive blood vessels†
Abnormal EMG	Myoclonus	Vision	Elevated CSF alanine†	Abnormal mitochondria/EM†
	Cortical blindness	Hearing	Urinary TA excretion†	
	Pyramidal signs	Neuropathy	Ethylmalonic aciduria	
	Extrapyramidal signs	Recurrent/familial	Strokelike picture/MRI	
	Brainstem involvement		Leigh syndrome/MRI†	
			Elevated lactate/MRS	

*Score 1: unlikely mitochondrial disorder; score 2-4: possible mitochondrial disorder; score 5-7: probable mitochondrial disorder; score ≥8: definite mitochondrial disorder.
†This specific symptom scores 2 points.
‡This symptom in a higher percentage scores 4 points.
GI, Gastrointestinal; L/P, lactate/pyruvate; COX, cytochrome C oxidase; SDH, succinate dehydrogenase; EM, electron microscopy; EMG, electromyography; TA, tricarbon acid.

clinical testing panels that are used to diagnose mitochondrial disorders. An important consideration is that many genetic and multifactorial conditions have been associated with defects in one or more of the four complexes assayed in mitochondrial oxidative phosphorylation testing; these latter conditions feature so-called secondary mitochondrial dysfunction because the conditions are not considered to be causative for primary mitochondrial dysfunction.

Treatment remains largely symptomatic and nonspecific and does not cure or significantly alter the outcome of disease. Mitochondrial drugs are mainly medicinal/nutritional supplements designed to sustain and boost the mitochondrial residual oxidative phosphorylation function, while also reducing oxidative stress. Although there is no consensus on which vitamins and cofactors should be used to treat mitochondrial disease, the main supplementations used are CoQ10, L-carnitine, creatine, alpha-lipoic acid (ALA), and B vitamins. Additional medications/supplements are indicated based on the genetic diagnosis and clinical symptoms of the patient. For example, arginine (IV, oral) can be prescribed in patients with MELAS for treatment and prevention of metabolic strokes. Citrulline and taurine have also been used with some success in ongoing clinical trials and case reports demonstrating promising results. Patients with mitochondrial disease should be encouraged to exercise regularly. Patients with mitochondrial disorders are at a greater risk of developing anesthesia-related complications. Avoiding prolonged fasting and receiving dextrose-containing IV fluids before, during, and after procedures and operations are critical for avoiding catabolism. There are an increasing number of clinical studies evaluating various therapeutic approaches, including mitochondrial augmentation therapy in pediatric children with Pearson syndrome (NCT03384420) and AAV gene therapy in individuals with Leber hereditary optic neuropathy (LHON) (NCT02161380).

Leigh Syndrome (Subacute Necrotizing Encephalomyelopathy)

Leigh syndrome is a heterogeneous neurologic disease historically diagnosed based on neuropathologic findings of demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain regions (see Chapter 638.2). Leigh syndrome is characterized by decompensation (neurodevelopmental regression and lactic acidosis) initiated by viral infection or other metabolic stress. Patients frequently present with feeding and swallowing problems, failure to thrive, and developmental delay. The presentation is highly variable and may include seizures, altered consciousness, movement disorders, nystagmus, ophthalmoplegia, cerebellar ataxia, and peripheral neuropathy. Extraneurologic manifestations may include pericardial effusion, cardiomyopathy, renal tubulopathy, liver involvement, hypertrichosis, and muscle weakness. **Diagnosis** is usually confirmed by radiologic evidence of symmetric lesions affecting the basal ganglia, brainstem, and subthalamic nuclei. Patients with Leigh syndrome have defects in several enzyme complexes. Dysfunction in cytochrome-c oxidase (complex IV) is the most commonly reported defect, followed by NADH–coenzyme Q reductase (complex I), PDHC, and pyruvate carboxylase (see Chapter 108). Pathogenic variants in the nuclear *SURF1* gene, which encodes an assembly factor involved in the biogenesis of cytochrome-c oxidase, and mitochondrial DNA variants in the adenosine triphosphatase 6 (MT-ATP6) coding region have been reported in patients with Leigh syndrome in association with complex IV deficiency. The most common mitochondrial DNA variant in Leigh syndrome is the m.8993T>G variant in MT-ATP6. The **prognosis** for Leigh syndrome is poor. In a study of 14 cases, there were 7 fatalities before age 1.5 years. Pathogenic variants in *MTFMT* had a milder clinical phenotype and disease progression, according to recent research.

Lactic acidosis and encephalopathy have also been reported in patients with thiamine transporter 2 (THTR2) deficiency and with pyridoxine-dependent epilepsy. Thiamine, either alone or in combination with biotin, is required for the treatment of THTR2 deficiency, whereas pyridoxine is used to treat pyridoxine-dependent epilepsy.

107.5 Defects in Pentose Metabolism

Ghada Hijazi and Priya S. Kishnani

Approximately 90% of glucose metabolism in the body is generated via the glycolytic pathway, with the remaining 10% generated via the hexose monophosphate pathway. The hexose monophosphate shunt leads to the formation of pentose and provides NADPH. One of the metabolites of this alternative pathway is ribose-5-phosphate, which is used in the biosynthesis of ribonucleotides and deoxyribonucleotides. Through the transketolase and transaldolase reactions, pentose phosphates can be converted back to fructose-6-phosphate and glucose-6-phosphate.

ESSENTIAL PENTOSURIA

Essential pentosuria is a benign asymptomatic disorder encountered principally in the Ashkenazi Jewish population and is inherited in an

Table 107.5 Clues to the Diagnosis of Mitochondrial Disease

NEUROLOGIC
Cerebral strokelike lesions in a nonvascular pattern
Basal ganglia disease
Encephalopathy, recurrent or with low/moderate dosing of valproate
Neurodegeneration
Epilepsia partialis continua
Myoclonus
Ataxia
MRI findings consistent with Leigh syndrome
Characteristic MRS peaks
Lactate peak at 1.3 ppm TE (time to echo) at 35 and 135
Succinate peak at 2.4 ppm
CARDIOVASCULAR
Hypertrophic cardiomyopathy with rhythm disturbance
Unexplained heart block in a child
Cardiomyopathy with lactic acidosis (>5 mM)
Dilated cardiomyopathy with muscle weakness
Wolff-Parkinson-White arrhythmia
OPHTHALMOLOGIC
Retinal degeneration with signs of night blindness, color vision deficits, decreased visual acuity, or pigmentary retinopathy
Ophthalmoplegia/paresis
Fluctuating, dysconjugate eye movements
Ptosis
Sudden- or insidious-onset optic neuropathy/atrophy
GASTROENTEROLOGIC
Unexplained or valproate-induced liver failure
Severe dysmotility
Pseudoobstructive episodes
OTHER
A newborn, infant, or young child with unexplained hypotonia, weakness, failure to thrive, and a metabolic acidosis (particularly lactic acidosis)
Exercise intolerance that is not in proportion to weakness
Hypersensitivity to general anesthesia
Episodes of acute rhabdomyolysis
Elevated GDF-15 level

MRI, Magnetic resonance imaging, MRS, magnetic resonance spectroscopy; GDF, growth and differentiation factor.
From Haas RH, Parikh S, Falk MJ, et al. Mitochondrial disease: a practical approach for primary care physicians. *Pediatrics*. 2007;120:1326–1333, Table 1.

autosomal recessive fashion. The urine contains **L-xylulose**, which is excreted in increased amounts because of a block in the conversion of L-xylulose to xylitol as a result of **xylitol dehydrogenase deficiency**. The condition is usually discovered incidentally in a urine test for reducing substances. No treatment is required.

TRANSALDOLASE DEFICIENCY

Transaldolase deficiency is a rare autosomal recessive inborn error of the pentose phosphate pathway. It is more common in Middle Eastern countries and can manifest in three distinct phenotypes. Prenatal intrauterine growth restriction (IUGR), oligohydramnios, and/or hydrops fetalis occur with the most severe phenotype. The second is a neonatal phenotype, where patients may have dysmorphic facial features (triangular-shaped face, low-set ears, wide mouth, and thin lips), cardiovascular abnormalities (ventricular and atrial septal defects), anemia, thrombocytopenia, and hepatosplenomegaly noted in the newborn period. In some cases, hepatic dysfunction was described associated with fibrosis and/or cirrhosis, and transplantation of the liver was indicated in a number of patients. Endocrine abnormalities (abnormal genitalia, vitamin D insufficiency, hypergonadotrophic hypogonadism), renal tubulopathy, and skin abnormalities (cutis laxa, wrinkled skin, capillary hemangioma) have been observed. A third, milder phenotype is described as presenting later in life. Biochemical abnormalities reveal elevated levels of the polyols arabitol, ribitol, and erythritol and the seven-carbon sugars sedoheptitol, perseitol, sedoheptulose, mannoheptulose, and sedoheptulose-7P in the urine. The **diagnosis** is established with the detection of biallelic pathogenic variants in the *TALDO1* gene. When genetic testing is inconclusive, low transaldolase activity in lymphoblasts, fibroblasts, and liver tissue can be used to confirm the diagnosis. The available **treatment** is symptomatic. Supportive management of the disease manifestations (e.g., hepatic dysfunction) is needed. Transplantation of the liver may be indicated. Regular follow-up and monitoring for complications such as anemia and thrombocytopenia is required. N-acetylcysteine (NAC) supplementation delayed the progression of disease and restored normal alpha fetoprotein levels in a research trial. Additional long-term studies are required to evaluate the broader effectiveness of NAC supplementation.

RIBOSE-5-PHOSPHATE ISOMERASE DEFICIENCY

Only four cases of ribose-5-phosphatase isomerase deficiency disorder have been reported. Affected patients may present with psychomotor delay or regression, epilepsy, peripheral neuropathy, and leukoencephalopathy. Magnetic resonance spectroscopy (MRS) and urine analysis usually reveal elevated levels of polyols arabitol and ribitol in these patients. Confirmation of diagnosis is established by identification of biallelic *RPIA* pathogenic variants or by enzyme assay in cultured fibroblasts.

107.6 Disorders of Glycoprotein Degradation and Structure

Margaret M. McGovern and Robert J. Desnick

The disorders of glycoprotein degradation and structure include several lysosomal storage diseases that result from defects in glycoprotein degradation and the congenital disorders of glycosylation (see Chapter 107.7). *Glycoproteins* are macromolecules composed of oligosaccharide chains linked to a peptide backbone. They are synthesized by two pathways: the glycosyltransferase pathway, which synthesizes oligosaccharides linked *O*-glycosidically to serine or threonine residues, and the dolichol, lipid-linked pathway, which synthesizes oligosaccharides linked N-glycosidically to asparagine.

The **glycoprotein lysosomal storage diseases** result from the deficiency of the enzymes that normally participate in the degradation of oligosaccharides and include sialidosis, galactosialidosis, aspartylglucosaminuria, and α-mannosidosis. In some instances, the underlying abnormality that leads to glycoprotein accumulation also results in abnormal degradation of other classes of macromolecules that contain similar oligosaccharide linkages, such as certain glycolipids and proteoglycans. In these cases the underlying enzymatic deficiency results in the accumulation of both glycoproteins and *glycolipids*. The classification of these types of disorders as *lipidoses* or *glycoproteinoses* depends on the nature of the predominantly stored substance. In general, the glycoprotein disorders are characterized by autosomal recessive inheritance and a progressive disease course with clinical features that resemble those seen in the mucopolysaccharidoses.

SIALIDOSIS AND GALACTOSIALIDOSIS

Sialidosis is an autosomal recessive disorder that results from the primary deficiency of neuraminidase because of pathogenic variants in the gene *(NEU1)* that encodes this protein. In contrast, **galactosialidosis** is caused by the deficiency of two lysosomal enzymes—neuraminidase and β-galactosidase. The loss of these enzymatic activities results from pathogenic variants in a single gene, *CTSA,* that encodes the

protective protein cathepsin A, which functions to stabilize these enzymatic activities. Neuraminidase normally cleaves terminal sialyl linkages of several oligosaccharides and glycoproteins. Its deficiency results in the accumulation of oligosaccharides and the urinary excretion of sialic acid terminal oligosaccharides and sialylglycopeptides. Examination of tissues from affected individuals reveals pathologic storage of substrate in many tissues, including liver, bone marrow, and brain.

The clinical phenotype associated with neuraminidase deficiency is variable and includes **type I** sialidosis, which usually presents in the second decade of life with myoclonus and cherry-red spots in the macula. These patients typically present secondary to gait disturbances, myoclonus, or visual complaints. In contrast, **type II** sialidosis occurs at several ages of onset (congenital, infantile, and juvenile), depending on the severity of the gene pathogenic variant. The **congenital** and **infantile** forms result from isolated neuraminidase deficiency, whereas the **juvenile** form results from both neuraminidase and β-galactosidase deficiency. The congenital type II disease is characterized by hydrops fetalis, neonatal ascites, hepatosplenomegaly, stippling of the epiphyses, periosteal cloaking, and stillbirth or death in infancy. The type II infantile form presents in the first years of life with dysostosis multiplex, moderate global developmental delays, visceromegaly, corneal clouding, cherry-red maculae, and seizures. The juvenile type II form of sialidosis, which is sometimes designated *galactosialidosis,* has a variable age of onset ranging from infancy to adulthood. In infancy, the phenotype is similar to that of GM1 gangliosidosis, with edema, ascites, skeletal dysplasia, and cherry-red spots. Patients with later-onset disease have dysostosis multiplex, visceromegaly, intellectual disability, dysmorphism, corneal clouding, progressive neurologic deterioration, and cherry-red spots.

No specific therapy exists for any form of the disease, although studies in animal models have demonstrated improvement in the phenotype after bone marrow transplantation. The **diagnosis** of sialidosis and galactosialidosis is achieved by the demonstration of the specific enzymatic deficiency or by pathogenic variants in the responsible gene. **Prenatal diagnosis** using cultured amniotic cells or chorionic villi is available by demonstrating the enzyme defect and/or specific gene pathogenic variants.

ASPARTYLGLUCOSAMINURIA

This is a rare autosomal recessive lysosomal storage disorder, except in Finland, where the carrier frequency is estimated at 1 in 36 adults, the high frequency due to a *founder gene.* The disorder results from the deficient activity of **aspartylglycosaminidase** and the subsequent accumulation of aspartylglycosamine, particularly in the liver, spleen, and thyroid. The gene for the enzyme is *AGA,* and in the Finnish population, a single *AGA* pathogenic variant encoding p.Cys163Ser accounts for most mutant alleles. Outside of Finland, a large number of private pathogenic variants have been described.

Affected individuals with aspartylglucosaminuria typically present in the first year of life with recurrent infections, diarrhea, and umbilical hernias. Coarsening of the facies and short stature usually develop later. Other features include joint laxity, macroglossia, hoarse voice, crystal-like lens opacities, hypotonia, and spasticity. Psychomotor development is usually near normal until age 5 years, when a decline is noted. Behavioral abnormalities are typically seen, and IQ values in affected adults are usually <40 (severe intellectual disability). Survival to adulthood is common, with most early deaths attributable to pneumonia or other pulmonary causes. Definitive **diagnosis** requires demonstration of markedly deficient aspartylglucosaminidase in peripheral blood leukocytes and/or the specific *AGA* pathogenic variant(s). Several patients have undergone allogeneic bone marrow transplants, but this approach has not proved effective, and no specific treatment is available. **Prenatal diagnosis** is available by the determination of aspartylglucosaminidase deficiency and/or the specific *AGA* pathogenic variants in cultured amniocytes or chorionic villi.

α-MANNOSIDOSIS

This autosomal recessive disorder results from the deficient activity of **α-mannosidase** and the accumulation of mannose-rich compounds. The gene *MAN2B1* encodes the enzyme, and to date, >140 gene pathogenic variants have been reported. Affected patients display clinical heterogeneity. There is a severe infantile form, or **type I** disease, and a milder juvenile variant, **type II** disease. All patients have psychomotor retardation, facial coarsening, and dysostosis multiplex. The **infantile** form of the disorder, however, is characterized by more rapid cognitive deterioration, with death occurring between ages 3 and 10 years. Patients with the infantile form also have more severe skeletal involvement and hepatosplenomegaly. The **juvenile** disorder is characterized by onset of symptoms in early childhood or adolescence, with milder somatic features and survival to adulthood. Hearing loss, destructive synovitis, pancytopenia, and spastic paraplegia have been reported in type II patients. The **diagnosis** is made by identification of biallelic pathogenic variants in *MAN2B1* and may be supplemented by the demonstration of the marked deficiency of α-mannosidase activity in white blood cells or cultured fibroblasts. Clinical trials of ERT with recombinant human α-mannosidase are underway. **Prenatal diagnosis** can be made by demonstrating the enzyme defect and/or known pathogenic variants in cultured amniocytes or chorionic villi.

107.7 Congenital Disorders of Glycosylation

Eva Morava and Peter Witters

Glycosylation is the complex multistep metabolic process of adding (oligo)saccharides to macromolecules such as proteins and lipids. The classification of **disorders of hypoglycosylation** is based on biochemical structures: (1) defects in protein *N*-linked glycosylation, (2) defects in protein *O*-linked glycosylation, (3) defects in glycosphingolipid and in glycosylphosphatidylinositol-anchor glycosylation, and (4) defects in multiple glycosylation pathways and in other pathways (Fig. 107.7). No disorders are known to result from abnormal *C*-linked glycosylation. Congenital disorders of glycosylation (CDGs) are labeled based on their genetic defect.

Protein glycosylation is an essential process. Most functional proteins are glycosylated, including serum proteins (e.g., transferrin, ceruloplasmin, thyroxine-binding globulin [TBG]), hormones (e.g., thyroid-stimulating hormone [TSH], follicle-stimulating hormone [FSH], luteinizing hormone [LH], adrenocorticotropic hormone [ACTH], IGFBP3), and clotting and anticoagulation factors (e.g., factors IX and XI, antithrombin). Membrane proteins are also highly glycosylated. Important intracellular glycoproteins include enzymes such as glycosyltransferases or lysosomal enzymes.

***N*-glycans** are linked to the amide group of asparagine. They are synthetized in a complicated process throughout the cytoplasm, endoplasmic reticulum (ER), and Golgi complex, starting with sugar activation and nucleotide sugar synthesis, then oligosaccharide assembly, and finally glycan processing (see Fig. 107.7). Most of the pediatric glycosylation disorders are the result of N-glycosylation defects. ***O*-glycans** are linked to the hydroxyl group of serine or threonine. These diverse glycoproteins are mostly formed in the Golgi complex; their defects can involve xylosylation, fucosylation, mannosylation, or other modifications. An important focus is *O*-mannosylation defects because of their relevance for dystroglycanopathies.

Lipid glycosylation is an essential process for the synthesis of ceramide and ganglioside synthesis. **Glycosylphosphatidylinositols** (GPIs) are very special glycolipids that link various proteins to the plasma membrane, as complex lipid-sugar anchors (GPI anchors, see Fig. 107.7).

CDGs are predominantly multisystem diseases caused by more than 150 different genetic defects in glycoprotein and glycolipid glycan synthesis. Most patients described with CDG have N-glycosylation defects, followed by the fastest-growing groups of CDGs, involving multiple glycosylation pathways and dolicholphosphate synthesis. Smaller groups are *O*-glycosylation disorders and disorders of GPI. The "oldest" and most common CDG is PMM2-CDG, in which the

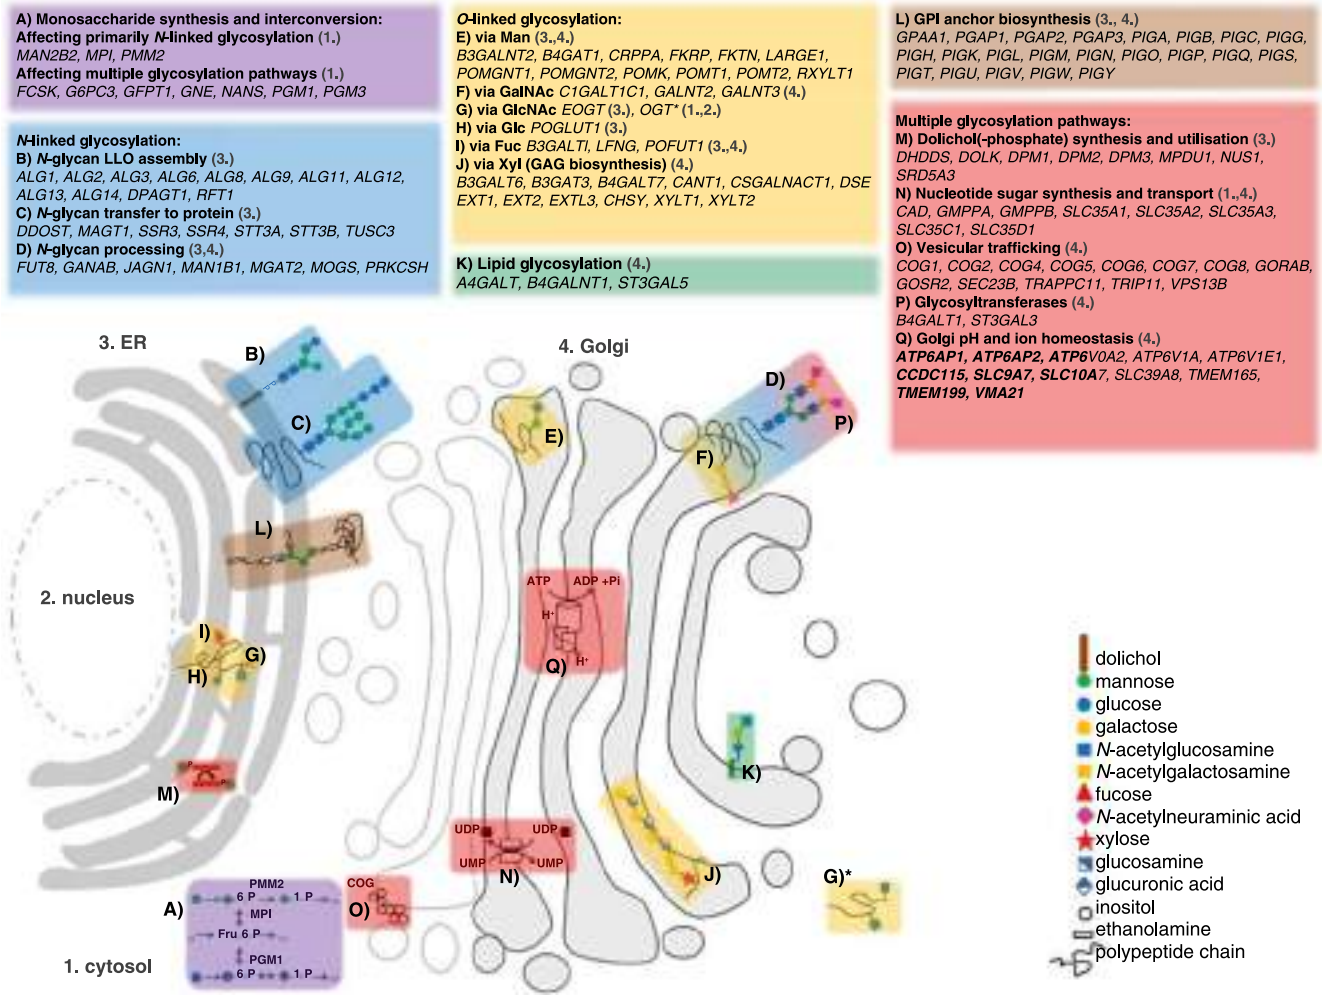

Fig. 107.7 Congenital disorders of glycosylation (CDG): an overview of the currently known subtypes. The picture shows a schematic illustration of the individual 137 CDG subtypes known to date, designated by the symbol of the affected gene, which are categorized according to the nature of the biochemical event impaired within the glycosylation pathway. Glycosylation is a complex metabolic process resulting in the attachment of an oligosaccharide chain of varying length and composition (a glycan) to proteins and lipids. It involves a set of enzyme-catalyzed reactions that take place mainly in the cytosol (1.), endoplasmic reticulum (ER; 3.) and Golgi apparatus (4.), after which the newly formed glycoconjugates are, generally, incorporated into membranes or secreted out of the cell. Depending on how a glycan is linked to the polypeptide backbone, protein glycosylation is classified into *N*-linked (a bond via the amide group of asparagine) or *O*-linked (a bond via the hydroxyl group of serine, threonine, or hydroxylysine). *N*-glycoproteins share a common core structure of the glycan, which is first assembled on a dolichol anchor and then transferred onto the protein in the ER; this is later followed by further modifications of the *N*-glycan, removing and adding different monosaccharides, in the Golgi apparatus. *O*-glycosylation consists of a stepwise addition of individual monosaccharide units in the ER and Golgi apparatus, while six subclasses can be distinguished based on which sugar (Man, GalNac, GlcNAc, Glc, Fuc, or Xyl) is the first one attached to the protein, and thus more varied *O*-glycan structures are produced. Other specific types of glycosylation involve lipid glycosylation and the modification of proteins by the glycosylphosphatidylinositol (GPI) anchor. The substrates for glycosylation in the form of nucleotide-monosaccharides are synthesized predominantly in the cytosol, and because they are used in different glycosylation reactions, their deficiency possibly influences the structure of various glycoconjugates. Similarly, several defects have been described that affect multiple glycosylation pathways, and, often, other cellular processes might be disturbed as well (e.g., because of altered ion homeostasis in the Golgi apparatus). ADP, adenosine diphosphate; ATP, adenosine triphosphate; COG, conserved oligomeric Golgi (complex); ER, endoplasmic reticulum; Fru-6-P, fructose-6-phosphate; Fuc, fucose; GalNAc, N-acetylgalactosamine; Glc, glucose; GlcNAc, N-acetylglucosamine; GPI, glycosylphosphatidylinositol; H+, protons; LLO, lipid-linked oligosaccharides; Man, mannose; MPI, mannose phosphate isomerase; PGM1, phosphoglucomutase 1; PMM2, phosphomannomutase 2; UDP, uridine diphosphate; UMP, uridine monophosphate; Xyl, xylose. *(From Ondruskova N, Cechova A, Hansikova H, et al. Congenital disorders of glycosylation: still "hot" in 2020. Biochim Biophys Acta Gen Subj. 2021;1865[1]:129751, Fig. 1.)*

genetic defect leads to the loss of **phosphomannomutase 2** (PMM2), the enzyme that catalyzes the conversion of mannose-6-phosphate into mannose-1-phosphate. The majority of CDGs have an autosomal recessive inheritance. Only two *N*-linked CDGs are autosomal dominant: GANAB-CDG and PRKCSH-CDG. The dominantly inherited *O*-linked CDGs include EXT1-CDG, H63ST-CDG, and POFUT1-CDG. Some CDGs have both an autosomal dominant and recessive phenotype such as EXT2-CDG, POGLUT1-CDG, GNE-CDG, DHDDS-CDG, NUS1-CDG, COG4-CDG, and SEC23B-CDG. X-linked CDGs include ALG13-CDG, MAGT1-CDG, SSR4-CDG, HS6ST2-CDG, OGT-CDG, PIGA-CDG, SLC35A2-CDG, TRAPPC2-CDG, VMA21-CDG, ATP6AP2-CDG, ATP6AP1-CDG, and SLC9A7-CDG.

CDGs can be lethal, with 20% of PMM2-CDG patients dying in the first 2 years of life. Some patients, however, stabilize throughout

Fig. 107.8 Patients with phosphomannomutase-2 deficiency (PMM2-CDG) and recognizable clinical features. **A,** Inverted nipples. **B** and **C,** Abnormal fat distribution. **D,** Muscle atrophy caused by peripheral neuropathy after puberty. **E,** Characteristic facial features with strabismus, short nose, anteverted nares, long philtrum, and large ears. **F,** T1-weighted sagittal MRI of the brain showing cerebellar vermis hypoplasia *(arrow)* and brain atrophy.

young adulthood. Almost any clinical phenotype can be present in a patient with CDG. It can affect any organ or organ system and most often includes the CNS. The most **common clinical features** include developmental and speech delay, seizures, ataxia, spasticity, peripheral neuropathy, hypotonia, strabismus, abnormal fat distribution, visual loss, cardiomyopathy, feeding difficulties, liver dysfunction, endocrine abnormalities, bleeding diathesis, and thrombosis (Fig. 107.8 and Table 107.6). Single-organ presentations are rare in CDGs, although some do exist, including TUSC3-CDG and ST3GAL3-CDG: brain; DHDDS-CDG: retina; ALG14-CDG: neuromuscular junction; POFUT1-CDG and POGLUT1-CDG: skin; SEC23B-CDG: red cell lineage; EXT1/EXT2-CDG: cartilage; and TMEM199-CDG: liver. Many CDGs are recognizable syndromes. *CDG should be considered in any patient with a developmental disability or an unexplained clinical condition, especially in multisystem disease with neurologic involvement.*

There are also **congenital disorders of deglycosylation**, including known lysosomal disorders and a severe neurologic condition caused by a defective *N*-glycanase function (*NGLY1* defect).

Laboratory evaluations in most *N*-linked CDGs rely on transferrin glycoform analysis in serum or plasma. A common screening method is called serum **transferrin isoelectric focusing (TIEF)**. Transferrin isoforms, which are hyposialylated (missing terminal sialic acid residues), show different cathodal shifts depending on either missing glycan chains or truncated glycans. A **type 1 pattern** suggests an early metabolic defect in the cytosolic-ER–related glycan synthesis and assembly. A **type 2 pattern** suggests Golgi-related glycan-processing defects (Fig. 107.9). **Isoelectric focusing of apolipoprotein C-III (IEF apoC-III)**, a serum mucine type *O*-glycosylated protein, can detect some *O*-glycosylation disorders (combined *N*- and *O*-linked glycosylation defects). **Mass spectrometry of intact (glycosylated) transferrin in serum** is highly sensitive for mild type 1 glycosylation abnormalities and diagnostic in most CDGs affecting N-glycosylation. Mass spectrometry of apoC-III is useful specifically in type II CDG. Glycomics by **matrix-assisted laser desorption/ionization time of flight (MALDI-TOF)** can be diagnostic in specific types of CDG (mostly Golgi related with a type 2 pattern). Dolichol-linked glycan or lipid-linked oligosaccharide (LLO) analysis is a complicated but sensitive method to detect ER-related N-glycan assembly (CDG type 1) defects in patient fibroblasts. GPI-anchor defects can be suspected based on *recurrent elevation of alkaline phosphatase levels* in blood.

Table 107.6 Clinical and Laboratory Features in Common Congenital Disorders of Glycosylation (CDGs), with Clinically Recognizable Phenotype and Abnormal Glycosylation, Detectable by Serum Transferrin Isoform Analysis (TIEF)

DEFECTIVE GENE	MOST FREQUENT CLINICAL FEATURES	SUGGESTIVE FEATURES	LABORATORY ABNORMALITIES	OTHER BIOCHEMICAL ANOMALIES
PMM2	Strabismus, nystagmus, smooth philtrum, large ears, vomiting, diarrhea, FTT, axial hypotonia, cerebellar vermis hypoplasia, ataxia, psychomotor disability, seizures, spasticity, neuropathy, pigmentary retinitis	Inverted nipples and/or abnormal fat pads, strokelike episodes	Elevated serum transaminases; hypoalbuminemia, decreased factor IX, XI, and AT activity; low serum ceruloplasmin and TBG levels	Type 1 serum TIEF, decreased PMM activity in leukocytes and fibroblasts
MPI	Cholestasis, hepatomegaly, feeding difficulties, recurrent vomiting, chronic diarrhea, ascites, recurrent thrombosis, gastrointestinal bleeding	Hyperinsulinism, protein-losing enteropathy Normal intelligence and absence of neurologic features	Elevated transaminases; hypoalbuminemia; hypoglycemia; decreased factor IX, XI, and AT-III activity	Type 1 serum TIEF, decreased PMI activity in leukocytes and fibroblasts
ALG6	Hypotonia, muscle weakness, seizures, ataxia, intellectual disability, behavioral abnormalities	Distal limb malformations	Elevated serum transaminases; hypoalbuminemia; decreased factor IX, XI, and AT activity; low serum IgG level	Type 1 serum TIEF, abnormal LLO results in fibroblasts
DPAGT1	Microcephaly, brain malformations, hypotonia, severe psychomotor disability, seizures, spasticity, proximal weakness, failure to thrive, joint contractures	Congenital myasthenia phenotype In multisystem phenotype: cataract	Decreased AT, protein C, and protein S activity; increased creatine kinase; hypoalbuminemia; normal creatine kinase in myasthenia	Type 1 serum TIEF
SRD5A3	Developmental delay, hypotonia, ataxia, cerebellar vermis hypoplasia, intellectual disability, speech delay, visual loss	Congenital cataract, retinal and iridic coloboma, glaucoma, optic nerve dysplasia, ichthyosis	Low anticoagulation factors (AT, protein C, and protein S activity), increased serum transaminases	Type 1 serum TIEF but reported false-negative TIEF
ATP6V0A2 *ATP6V1A* and *ATP6V1E1*	Generalized cutis laxa, hypotonia, strabismus, characteristic facial features, joint laxity, seizures, motor and language developmental delay, spontaneous improvement of cutis laxa by aging	Cobblestone-like brain dysgenesis Cardiovascular anomalies	Mild coagulation abnormalities, increased serum transaminase levels Mild coagulation abnormalities and increased serum transaminase levels, hypercholesterolemia	Type 2 serum TIEF but reported false-negative TIEF Abnormal apoC-III IEF, characteristic MALDI TOF profile (Note abnormal skin histology)
PGM1	Pierre Robin sequence, cholestasis, short stature, dilated cardiomyopathy	Cleft palate, hyperinsulinism, normal intelligence	Hypoglycemia, increased serum transaminase levels, decreased AT	Mixed type 1/ serum TIEF, decreased fibroblast PGM1 activity
MAN1B1	Developmental delay, speech delay, intellectual disability, muscle weakness	Obesity, autistic features, inverted nipples, characteristic face	Increased serum transaminase levels, low AT	Type 2 serum TIEF, abnormal apoC-III IEF, diagnostic MALDI TOF profile
TMEM199 *CCDC115* *ATP6AP1* and *ATP6AP2*	Cholestasis, hepatomegaly, liver steatosis, liver fibrosis, liver failure, spontaneous bleedings, motor developmental delay	Normal intelligence Hepatomegaly Immune deficiency	Decreased serum ceruloplasmin, increased serum transaminase levels, hypercholesterolemia, high AP	Type 2 serum TIEF, abnormal apoC-III IEF, characteristic MALDI TOF profile
SLC39A8	Seizures, hypsarrhythmia, hypotonia, developmental and speech delay, FTT	Dwarfism, craniosynostosis, rhizomelia, Leigh disease	Decreased serum manganese, high serum transaminases, abnormal coagulation	Type 2 serum TIEF, abnormal apoC-III, characteristic MALDI TOF profile

AP, Alkaline phosphatase; AT, antithrombin; apoC-III: apolipoprotein C-III; FTT, failure to thrive; LLO, lipid-linked oligosaccharides; MALDI-TOF, matrix-assisted laser desorption/ionization time of flight; TBG, thyroxine-binding globulin; TIEF, transferrin isoelectric focusing.

Fluorescence-activated cell sorting (FACS) analysis of the membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially when alkaline phosphatase in the blood is significantly elevated. **Enzyme analysis** in blood is only available for a few, more common CDGs (PMM2-CDG, MPI-CDG, PGM1-CDG); it is more reliable in fibroblasts. Dystroglycanopathies can be confirmed based on abnormal immunohistochemistry in a **muscle biopsy**.

[1]Transferrin; [2]Next-generation sequencing (CDG panel analysis, WES, WGS); [3]Intellectual disability; [4]Cerebellar hypoplasia; [5]Glycosylphosphatidylinositol anchor synthesis defect; [6]Alkaline phosphatase. ID, intellectual disability; WES, whole exome sequencing; WGS, whole genome sequencing. *(From Quelhas D, Martins E, Azevedo L, et al. Congenital disorders of glycosylation in Portugal – two decades of experience. J Pediatr. 2021;231:148–156.)*

With an abnormal TIEF pattern result or clinical suspicion of any type of CDG, most metabolic centers use a direct **CDG gene panel analysis** or **NGS** (whole exome sequencing) (see Fig. 107.9).

CONGENITAL DISORDERS OF PROTEIN N-GLYCOSYLATION

Phosphomannomutase-2 Deficiency (PMM2-CDG)

Clinical Manifestations

PMM2-CDG is the most common and easily recognizable CDG. Over 900 patients have been identified with an estimated incidence of 1:20,000-1:80,000. Most patients have alternating strabismus, characteristic facial features (short nose, long philtrum, large ears) (see Fig. 107.8E), inverted nipples and/or abnormal fat pads (see Fig. 107.8A-C), feeding difficulties, axial hypotonia, and decreased reflexes already in the first few months of life. Nystagmus (caused by pontocerebellar and vermis hypoplasia; see Fig. 107.8F) is also common. Psychomotor disability is present in most patients, but normal intellectual development has been described in a few patients. Most patients develop a **multisystem disease**, and <25% show an isolated neurologic phenotype without other organ involvement, normal endocrine regulation, and no coagulopathy. The **neurologic involvement** is quite diverse, with ataxia, seizures, spasticity, and peripheral neuropathy (see Fig. 107.8D) the most common features. Dystonia, strokelike episodes, and proximal myopathy can also occur. PMM2-CDG is not a progressive disease, but certain features, when present, typically appear at a different age during the disease. From birth, pericardial fluid collection, cardiomyopathy, or chronic vomiting/diarrhea can occur; after the age of 7 years, retinitis pigmentosa and cataracts; and after puberty, scoliosis, neuropathy, and recurrent thrombotic events. Liver function anomalies are mild and usually improve by age, and only a few patients develop cholestasis or liver fibrosis. Most patients have a hypergonadotropic hypogonadism; no successful pregnancies have been reported. Intellectual disability can be mild to severe; speech development is frequently delayed and can even be absent. Autistic behavior is common, although most patients have a cheerful personality. The oldest patient is 72 years old.

Pathophysiology

PMM2 catalyzes the conversion of mannose-6-phosphate to mannose-1-phosphate and is essential for the formation of activated mannose units used in the synthesis of the growing glycan chain in the ER. Hypoglycosylation leads to abnormal function affecting many essential glycoproteins, such as coagulation and anticoagulation factors; endocrine regulation; transport proteins; liver function; and immune, membrane, and receptor proteins.

Diagnosis

The primary screening method for PMM2-CDG is **serum transferrin glycoform analysis**, which is most frequently performed by TIEF or mass spectrometry. Intact transferrin has four negatively charged sialic acid residues (tetrasialotransferrin). Transferrin glycoforms, missing terminal sialic acid residues, show different cathodal shifts, less abundant tetrasialotransferrin, increased disialotransferrin, and some a-sialotransferrin. This is the so-called type 1 pattern, suggestive of a defect in glycan assembly in the cytosol-ER. Transferrin isoforms are detectable by mass spectrometry, which is a more reliable diagnostic method compared with TIEF. Certain other disorders can cause a *false-positive* transferrin isoform pattern, including galactosemia, hereditary fructose intolerance, and excessive alcohol use. PMM enzyme analysis is available in leukocytes and fibroblasts.

The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, or low ceruloplasmin or TBG level is highly suggestive of CDG, including the most common type, PMM2-CDG.

PMM2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most frequent pathogenic variant (c.422G>A; R141H) is present in 75% of White patients. Prenatal diagnosis is only reliable by genetic testing.

Treatment

The therapy in PMM2-CDG relies on supportive treatment. Even with the best treatment, mortality is about 20% in the first 2 years of life, mostly from cardiac or kidney involvement and severe infections. Recommended therapy includes adequate nutrition, diet or tube feeding if needed, cardiac support, hormone supplements, physical and occupational therapy, speech therapy, seizure management, and strabismus surgery. Treatment with acetazolamide (7-17 mg/kg/day) resulted in improvement of ataxia and a decrease in disease severity (measured by the Nijmegen Pediatric CDG rating scale). This is likely mediated by the function of the glycosylated CaV2.1 channel. Possible dehydration, changes in plasma pH, and bicarbonate levels (renal tubular acidosis) need to be monitored throughout therapy.

Therapeutic developments include targeted (liposomal) mannose-phosphate treatment, drug repurposing, and chaperone therapy; these are only in early trial phases.

Mannosephosphoisomerase Deficiency (MPI-CDG)

Clinical Manifestations

MPI deficiency is a recognizable and treatable CDG. Approximately 35 patients have been published. Most patients show early symptoms of **liver disease** (cholestasis, elevated transaminases) and feeding difficulties, with recurrent vomiting and chronic diarrhea, most frequently with **protein-losing enteropathy**. Life-threatening episodes might appear as early as the first few months of life with recurrent thrombosis and severe gastrointestinal bleeding because of severe coagulation abnormalities. Hypoglycemia is usually caused by hyperinsulinism. Hypoalbuminemia can be severe; patients might develop visible abdominal distention from a combination of ascites and hepatomegaly. Patients with MPI-CDG have no other organ involvement, and the CNS is not affected. There are no dysmorphic features. The liver disease frequently progresses to fibrosis or cirrhosis.

Pathophysiology

Mannosephosphoisomerase (MPI) catalyzes the conversion of fructose-6-phosphate to mannose-6-phosphate, one step before PMM2, therefore blocking the formation of activated mannose units (GDP mannose) for oligosaccharide synthesis. Hypoglycosylation leads to abnormal glycoprotein function, the same as in PMM2-CDG, especially coagulation and anticoagulation factors, liver function, and hormone receptors.

Diagnosis

The primary screening method in a suspected MPI-CDG patient is **serum transferrin isoform analysis** by mass spectrometry or screening by TIEF (see Fig. 107.9). MPI deficiency leads to a type 1 pattern, as seen in PMM2 deficiency. MPI enzyme analysis is available in leukocytes and fibroblasts. The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, hyperinsulinism, and nonketotic hypoglycemia are highly suggestive for MPI-CDG.

MPI-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence of MPI-CDG is not known, but it is estimated at 1 in 800,000 in Europe. Prenatal diagnosis is only reliable by genetic testing. Although this is a rare CDG, early diagnosis is imperative because it is treatable.

Treatment

MPI-CDG is the first CDG type treatable by dietary therapy (Table 107.7). Mannose therapy is clinically effective by both IV and oral supplementation. The dose of oral mannose is 150-170 mg/kg/dose for four or five doses per day (maximum dosing 600-1200 mg/kg/day and maximum of six doses per day). IV mannose should be used only in life-threatening conditions when oral intake is not possible. The maximum dose of IV mannose is 1 g/kg/day as a continuous infusion, combined with IV glucose to prevent hypoglycemia. A known side effect is hemolysis. The treatment uses an alternative pathway: mannose can be phosphorylated by hexokinases to mannose 6-phosphate, bypassing the MPI defect. The clinical symptoms improve rapidly, but liver function may further deteriorate. Liver fibrosis and cirrhosis may necessitate liver transplantation, which will resolve the metabolic disease. The oldest patient known with MPI-CDG has survived into their late 30s.

Glucosyltransferase-1 Deficiency (ALG6-CDG)

Clinical Manifestations

ALG6-CDG is the second most common CDG. Most patients have hypotonia, muscle weakness, seizures, and ataxia. No patient with ALG6-CDG has been reported with normal intelligence. Speech delay and nystagmus are common neurologic signs. Brachydactyly, skeletal abnormalities, and transverse limb defects have been observed. Strabismus and characteristic facial dysmorphism are rare (hypertelorism, oval face, short nose). Inverted nipples and/or abnormal fat pads are exceptional in ALG6-CDG.

The most severe ALG6-CDG patients show a multisystem phenotype in the first few months of life, including severe infections, protein-losing enteropathy, hypoalbuminemia, anemia, and failure to thrive. Autistic behavior and mood changes have been observed in several patients. The oldest patient to date is almost 50 years old.

Pathophysiology

The metabolic problem is caused by defective binding of the first of three glucoses to the lipid-linked oligosaccharide in the ER. This glucose binding is essential for attachment of the oligosaccharyltransferase enzyme complex to the newly built oligosaccharide chain and the ability to transfer it to the protein. This leads to protein hypoglycosylation and abnormal glycoprotein function similar to PMM2-CDG and MPI-CDG. Laboratory abnormalities are also similar, including abnormalities in coagulation and anticoagulation factors, liver function, thyroid hormones, and immunoglobulins (IgGs).

Diagnosis

The primary screening method in a suspected ALG6-CDG patient is **serum transferrin glycoform analysis** by mass spectroscopy or TIEF analysis. ALG6 deficiency leads to a type 1 pattern (see Fig. 107.9), as seen in PMM2 and MPI deficiency. There is no available enzyme analysis, although LLOs could be evaluated in patient fibroblasts.

ALG6-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most common pathogenic variants are p.A333V and p.I299Del. Prenatal diagnosis is only reliable by genetic testing. The exact incidence of ALG6-CDG is not known.

Treatment

The current therapy in ALG6-CDG relies on supportive treatment. Mortality is about 10% in the first years of life, mostly from protein-losing enteropathy and severe infections.

UDP-GlcNAc:Dol-P-GlcNAc-P Transferase Deficiency (DPAGT1-CDG)

Clinical Manifestations

DPAGT1 deficiency is a recognizable and potentially treatable CDG. About one third of patients show the **congenital myasthenia**

Table 107.7 Effective Therapies in CDG

CDG	TREATMENT	RECOMMENDED DOSE	CLINICAL EFFECTS	SIDE EFFECTS
MPI-CDG	Mannose	600-1200 mg/kg BW/day in 4-6 oral doses	Improvement of digestive symptoms (13/14), coagulopathy (12/12), and hypoglycemia (9/9); no long-term effect on liver symptoms	Abdominal pain and diarrhea (5/10; responding to dose adjustment)
PGM1-CDG	Galactose	1 g/kg/day (500-2500 mg/kg/day; max 50 g/day), divided in up to 6 oral doses per day	Improvement of hepatopathy (15/18), muscle symptoms (14/14), coagulopathy (10/12), hypoglycemia (10/13), and pubertal delay (2/2); minimal effect on growth (1/8), ID (0/2), and cardiologic symptoms (0/2)	Not reported
SLC35C2-CDG	Galactose	1.5 g/kg/day (up to 3 g/kg/day), divided in up to 5 oral doses per day	Improvement of psychomotor development (5/10), growth (n.s.), gastrointestinal symptoms (n.s.), and seizures (3/5)	Not reported
SLC35C1-CDG	Fucose	400 mg/kg/day (up to 1.2 g/kg/day in severe cases), divided into 2-3 oral doses per day	Normalization of neutrophil count (5/5), decreased incidence of severe infections (3/3), improvement of psychomotor development (1/5), no effect on adult form of the disease (ID, ataxia, epilepsy, autism)	Autoimmune neutropenia and hemolysis (responding to dose adjustment)
CAD-CDG	Uridine	100 mg/kg/day in 4 oral doses	Cessation of pharmacoresistant seizures (3/3), significant developmental progress (3/3), resolution of anemia (2/2), and anisopoikilocytosis (3/3)	Not reported
SLC39A8-CDG	Manganese	15-20 mg $MnSO_4$/kg BW/day in 5 oral doses	Improvement of glycosylation (2/2), motor abilities (2/2), epilepsy (1/1), ataxia (1/1), and hearing (1/1)	Not reported, risk of manganism
	Galactose	500-3750 mg/kg BW/day in 5 oral doses	Improvement of glycosylation (2/2), no clinical improvement reported	Not reported
TMEM165-CDG	Galactose	1000 mg/kg/day orally	Improvement of glycosylation (2/2), hepatopathy (2/2), coagulopathy (2/2), and IGF1 levels (2/2) (clinical improvement not mentioned)	Not reported
GFPT1-CDG	Pyridostigmine (cholinesterase inhibitors)	2.5-15 mg/kg/day in 3 oral doses	Improvement of muscle weakness (52/56)	Muscle twitching, depression, and anxiety (2/56)
ALG2-CDG	Pyridostigmine (cholinesterase inhibitors)	Oral, dose n.s.	Improvement of muscle weakness (1/1)	Not reported
ALG14-CDG	Pyridostigmine (cholinesterase inhibitors)	5-8 mg/kg/day in 2-6 oral doses	Improvement of muscle weakness (4/4, in 1 patient the effect was only temporary)	Not reported
PIGM-CDG	Sodium butyrate	60-90 mg/kg/day in 3 oral doses	Effect on seizures (3/3), developmental delay (2/2), and increase in the expression of GPI-linked blood cell surface markers (2/4)	Not reported
PMM2-CDG	Acetazolamide	7-17 mg/kg/day in 2 oral doses	Effect on cerebellar symptoms (20/23), speech (20/23), anxiety (20/23), some coagulation parameters (20/23), stereotypic movements (5/5), and SLE (1/1). No improvement of ID and non-neurologic symptoms.	Acidosis with significant decrease of serum bicarbonate (9/23), asthenia (4/23), and paresthesia (2/23) responding to dose adjustments; risk of urolithiasis, osteopenia

BW, Body weight; GPI, glycosylphosphatidylinositol; ID, intellectual disability; IGF1, insulin-like growth factor 1; n.s., not specified; SLE, strokelike episodes.
Modified from Ondruskova N, Cechova A, Hansikova H, et al. Congenital disorders of glycosylation: still "hot" in 2020. *Biochim Biophys Acta Gen Subj*. 2021;1865(1):129751, Table 2.

phenotype, indistinguishable from other genetic congenital myasthenias. CK levels are normal. These patients have a relatively good prognosis, especially with early myasthenia therapy. The other patients show a multisystem phenotype with microcephaly, brain malformations, hypotonia, severe psychomotor disability, seizures, spasticity, failure to thrive, joint contractures, and cataracts.

Pathophysiology

The DPAGT1 defect leads to very early arrest of glycan synthesis outside the ER membrane by slowing the addition of the second GlcNAc sugar to the phosphorylated dolichol arm. Abnormal receptor glycosylation in the *neuromuscular junction* leads to myasthenia. Hypoglycosylation in the multisystem type leads to

abnormal glycoprotein function similar to PMM2-CDG, especially involving the anticoagulation factors, and interestingly leading to high serum CK (in contrast to the congenital myasthenia phenotype) and hypoalbuminemia.

Diagnosis

The primary screening method is **serum transferrin glycoform analysis** by mass spectroscopy or TIEF analysis. Most patients show a type 1 pattern (see Fig. 107.9), but patients with the congenital myasthenia phenotype can show normal screening. There is no clinically available enzyme analysis.

DPAGT1-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. Prenatal diagnosis is only reliable by genetic testing. Because of the false-negative TIEF results in several patients with the myasthenic phenotype, congenital myasthenia panel testing is suggested in suspected cases, especially for determining the potential therapy.

Treatment

The congenital myasthenia phenotype is frequently treatable by high-dose pyridostigmine, eventually enhanced with salbutamol and a potassium channel blocker (amifampridine). In the multisystem phenotype of DPAGT1-CDG, treatment is supportive.

CONGENITAL DISORDERS OF PROTEIN *O*-GLYCOSYLATION

Cerebro-Ocular Dysplasia–Muscular Dystrophy and Muscle-Eye-Brain Disease Spectrum (POMT1-CDG, POMT2-CDG, POMGNT1-CDG)

From isolated muscular dystrophy to **Walker Warburg syndrome**, this group of *O*-linked glycosylation disorders presents with severe muscle weakness, congenital eye malformations, and neuronal migration defects. Pachygyria, cobblestone dysgenesis, hydrocephalus, polymicrogyria, heterotopias, and corpus callosum agenesis are variably present. Eye malformations include anophthalmia, microphthalmia, congenital cataract, or colobomas. **Congenital muscular dystrophy** is associated with significant CK elevations. There is severe psychomotor disability.

The underlying metabolic defect is the abnormal synthesis of the *O*-mannosylglycan core, which is essential for the proper glycosylation of α-dystroglycan. The α-dystroglycan is heavily *O*-glycosylated with mannose residues and is expressed in both muscle and brain. Defective mannosylation of α-dystroglycan leads to muscle degeneration and migration defects. Muscle biopsy shows abnormal α-dystroglycan staining on immunohistochemistry.

Transferrin glycoform analysis, including TIEF, is normal in patients with isolated *O*-mannosylation defects. There is also no clinically available enzyme analysis. **Diagnosis** is based on histology (muscle biopsy) and genetic analysis.

POMT1-CDG, POMT2-CDG, and POMGNT1-CDG are the most common autosomal recessive α-dystroglycanopathies. Additional gene defects occur in the pathway; *POMK, FKTN, FKRP, LARGE, B3GALNT2, B4GAT1, DAG1, TMEM5,* and *ISPD* have been described in association with human disease. The exact incidence of α-dystroglycanopathies is not known.

The treatment for α-dystroglycanopathies is supportive.

DEFECTS IN LIPID GLYCOSYLATION AND IN GLYCOSYLPHOSPHATIDYLINOSITOL ANCHOR BIOSYNTHESIS

Hyperphosphatasia–Intellectual Disability Syndromes: PIGA Deficiency (PIGA-CDG)

This clinically recognizable syndrome is an epilepsy syndrome with intellectual disability, hypotonia, dysmorphic facial features, skin anomalies, congenital brain malformations, and behavioral abnormalities, including autism. Other organ malformations, including cardiac and renal defects, have also been reported. *Somatic* pathogenic variants with a *PIGA* defect can also lead to paroxysmal nocturnal hemoglobinuria.

N-acetylglucosamine (GlcNAc) cannot be efficiently transferred to phosphatidylinositol for glycophosphatidylinositol synthesis. Abnormal anchoring of alkaline phosphatase leads to hyperphosphatasemia in the blood and loss of specific surface antigens on blood cells.

Transferrin isoform analysis is normal in GPI-anchor defects. FACS analysis demonstrating reduction of membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially in association with increased levels of serum alkaline phosphatase. Pathogenic variant analysis confirms the defect.

PIGA-CDG is X-linked. The exact incidence is not known. A similar phenotype has been described in *PIGO, PIGV, PIGY, PIG, PGAP2,* and *PGAP3* defects.

In PIGA-CDG the treatment is supportive.

DEFECTS IN MULTIPLE GLYCOSYLATION PATHWAYS AND IN OTHER PATHWAYS, INCLUDING DOLICHOLPHOSPHATE BIOSYNTHESIS DEFECTS

Steroid 5α-Reductase Deficiency (SRD5A3-CDG)

Clinical Manifestations

SRD5A3 deficiency is a clinically recognizable CDG, originally described as a **multiple-congenital malformation syndrome**. About 20 patients have been diagnosed at different ages, including one at 45 years of age. Patients have hypotonia, ataxia, and eye abnormalities, including congenital cataracts, retinal and iridic colobomas, glaucoma, optic nerve dysplasia, and visual loss. Cerebellar vermis hypoplasia can be variable. Intellectual disability has been described in all affected patients thus far. About 30% of patients have severe *congenital ichthyosis*. Hypertrichosis and dysmorphic facial features are common, including squared face, high forehead, large ears, and coarsening. Some children with SRD5A3-CDG have a severe autism spectrum disorder. Skeletal abnormalities (scoliosis) and cardiac malformations are less common.

Pathophysiology

SRD5A3 deficiency leads to abnormal dolichol synthesis affecting early glycan synthesis outside the ER membrane and affects *O*-mannosylation and GPI-anchor synthesis. Hypoglycosylation affects anticoagulation factors and leads to increased serum transaminases.

Diagnosis

The primary screening method in a suspected SRD5A3-CDG patient is **serum transferrin glycoform analysis or mass spectroscopy analysis**. Most patients show a type 1 pattern (see Fig. 107.9), but several false-negative cases have been described. There is no clinically available enzyme analysis.

SRD5A3-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. SRD5A3-CDG treatment is supportive.

Autosomal Recessive Cutis Laxa Type 2 (ARCL-2A or ATP6V0A2-CDG, ATP6V1A-CDG and ATP6V1E1-CDG)

Clinical Manifestations

ATP6V02-CDG is a multiple-malformation syndrome originally described as *cutis laxa syndrome* and recently discovered to be a combined *N*- and *O*-linked glycosylation disorder. Patients show generalized cutis laxa with inelastic, sagging skin at birth, hypotonia, strabismus, myopia, characteristic facial features, and joint laxity. The facial features include hypertelorism, short nose, long philtrum, downslanting palpebral fissures with sagging eyelids, and sagging cheeks. Cardiovascular involvement is rare, and there is variable CNS involvement. Seizures and motor and language

developmental disability are common, but normal intelligence has been described as well. Sensorineural hearing loss is sometimes observed. Some patients have vermis hypoplasia, and several children have been described with cobblestone-like dysgenesis and partial pachygyria on brain MRI. Skeletal abnormalities and short stature are common, as are late-closing fontanels and/or brachydactyly and scoliosis. There is frequently enamel dysplasia. The skin features spontaneously improve with age. **ATP6V1A-CDG** and **ATP6V1E1-CDG** show a highly overlapping phenotype with associated cardiovascular symptoms and hypercholesterolemia.

Pathophysiology

ATP6V0A2 is a membrane subunit of the proton pump of the vesicular adenosine triphosphatase (V-ATPase) complex. Abnormal function of the V-ATPase complex alters the pH gradient in the secretory pathway and affects the maturation and transport of several glycosyltransferases and elastic fibers (e.g., elastin). ATP6V1A and ATP6V1E1 are other complex subunits affecting ATP6V0A2 function and cause secondary ATPase deficiency. Both *N*- and *O*-linked glycosylation are affected. There are mild coagulation abnormalities and high serum transaminase levels in some patients.

Diagnosis

The primary screening method in a suspected ATP6V0A2-CDG patient is **serum transferrin glycoform analysis** by mass spectroscopy or TIEF analysis. Most patients show a type 2 pattern (see Fig. 107.9), but false-negative cases have been described before the age of 6 weeks. **Apolipoprotein III-C** (apoC-III) is a mucin-type secretory glycoprotein that is only *O*-glycosylated. ApoC-III TIEF shows a hypoglycosylation pattern by mass spectroscopy in patients, even when the TIEF is falsely negative. Skin biopsies in patients show classic histologic changes of cutis laxa with diminished, short, abnormal, and fuzzy elastic fibers.

ATP6V0A2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. *ATP6V1A* and *ATP6V1E1* defects have been recently described.

Treatment

In autosomal recessive cutis laxa type 2, the treatment is supportive. Fortunately, there is continuous and spontaneous improvement of skin symptoms throughout the disease course, especially in ATP6V0A2-CDG.

Golgi-$\alpha_{1\text{-}2}$ Mannosidase-1 Deficiency (MAN1B1-CDG)

Clinical Manifestations

The *MAN1B1* defect was originally described as an intellectual disability syndrome in association with dysmorphic features. Additional patients were recognized with psychomotor disability, muscle hypotonia, and inverted nipples in association with truncal obesity. The degree of intellectual disability is quite variable. Autistic behaviors, eating disorders, and aggressive behavior are frequent features. More than 30 patients have been reported.

Pathophysiology

MAN1B1 codes for a Golgi mannosidase, which is essential for the final "trimming" of mannose units during the glycan processing in the Golgi apparatus. Hypermannosylation leads to abnormal, truncated glycans and CDG-II. The glycosylation abnormality in serum is relatively mild. Increased serum transaminases and abnormal coagulation are uncommon.

Diagnosis

Most patients show a mild type 2 pattern by TIEF, but false-negative cases have been described. MALDI-TOF analysis shows characteristic, hybrid glycans in serum. In suspected cases, direct sequence analysis is recommended, even if the TIEF is normal.

MAN1B1-CDG is autosomal recessive. The exact incidence is unknown; several adult patients are known.

Treatment

Only supportive treatment is available.

Phosphoglucomutase-1 Deficiency (PGM1-CDG)

Clinical Manifestations

PGM1-CDG is a disorder presenting with midline malformations (cleft palate, Pierre Robin sequence, bifid uvula), liver dysfunction, hypoglycemia, and short stature in almost all patients. *Hypoglycemia* is usually caused by hyperinsulinism in the first years of life. It can resolve with aging; ketotic hypoglycemia has also been observed. Cholestasis, liver fibrosis, and even cirrhosis have been described in a few patients. About one third of patients also show proximal muscle weakness and dilated cardiomyopathy; the latter led to mortality in at least seven reported cases. Other malformations, including cardiac and skeletal anomalies, have also been described. Wound healing is frequently abnormal, and there is a very high risk for bleeding during surgery. Intelligence is normal.

Pathophysiology

Phosphoglucomutase 1 (PGM1) is an essential enzyme for glycogenolysis and glycolysis. It also provides substrates for the nucleotide sugars needed for normal glycosylation. PGM1 regulates the bidirectional conversion of glucose-1-phosphate and glucose-6-phosphate. During fasting it leads to a glycogenosis-like phenotype (also called GSD XIV, MIM 614921). PGM1-CDG affects both the ER- and Golgi-related glycosylation and causes a mixed type 1/type 2 hypoglycosylation pattern. Abnormal serum proteins include coagulation and anticoagulation factors, insulin-like growth factor–binding protein 3 (IGFBP3), TBG, and TSH, in addition to serum transaminases, hypoglycemia, and elevated CK.

Diagnosis

The primary screening method in a suspected PGM1-CDG patient is **serum transferrin glycoform analysis** or mass spectroscopy analysis. Patients show a mixed type 1/type 2 pattern.

PGM1-CDG is autosomal recessive. It is among the relatively common CDGs; >40 patients have been described. Enzyme testing is possible in blood but is more reliable in fibroblasts. Direct sequencing is available for testing.

Treatment

PGM1-CDG is a treatable CDG (see Table 107.1). D-Galactose replenishes depleted levels of different nucleotide-sugars (galactose-1-phosphate, UDP-galactose, and UDP-glucose). Adding 1 g/kg/day D-galactose (500–2500 mg/kg/day, maximum 50 g/day, divided in up to six doses/day) to the diet improves glycosylation significantly after a few weeks, although the transferrin glycoform pattern does not fully normalize. This treatment improves liver transaminases and antithrombin levels and in some patients the hormonal status. The effect of D-galactose on hypoglycemic episodes, cardiomyopathy, and myopathy is not yet clear.

Disorders of Golgi Homeostasis: TMEM199-CDG, CCDC115-CDG, ATP6AP2-CDG, and ATP6AP1-CDG

Clinical Manifestations

These four disorders are clinically and biochemically indistinguishable. They have been described with liver function anomalies, cholestasis, fibrosis, and cirrhosis with liver failure, necessitating liver transplantation in a few patients. The phenotype resembles **Wilson disease**, especially because of low serum ceruloplasmin and copper levels, but there is no Kayser-Fleischer ring. In CCDC115-CDG there are frequently also neurologic features. The intellectual outcome is variable. Additional abnormalities include hypercholesterolemia

and elevated alkaline phosphatase. In ATP6AP1-CDG there is also immunologic involvement.

Pathophysiology
TMEM199-, CCDC115-, ATP6AP1-CDG, and ATP6AP2-CDG are important for Golgi homeostasis. The exact pathologic mechanism is not yet known, but it is hypothesized that the secondary Golgi dysfunction affects and delays the normal glycosylation process.

Diagnosis
The primary screening method in a patient with one of these suspected CDGs is serum transferrin glycoform analysis by mass spectroscopy or TIEF analysis. Patients show a type 2 pattern (see Fig. 107.9). ApoC-III TIEF is abnormal. Glycomics results by MALDI-TOF analysis are characteristic but cannot discriminate between the three defects. The final diagnosis requires pathogenic variant analysis. TMEM199-CDG and CCDC115-CDG are autosomal recessive, whereas ATP6AP1-CDG and ATP6AP2-CDG are X-linked.

Treatment
Treatment is supportive. Two patients successfully underwent liver transplantation.

Manganese Transporter Defect: SLC39A8-CDG
Clinical Manifestations
This intriguing disorder was originally described as a neurologic disease with hypotonia, seizures (hypsarrhythmia), and developmental disability. Some of the later-described patients had severe skeletal dysplasia with rhizomelic chondrodysplasia, craniosynostosis, and dwarfism. Mitochondrial dysfunction (Leigh disease, cerebral lactic acidemia, dystonia) may also be present.

Pathophysiology
SLC39A8 is a membrane transporter, responsible for manganese (Mn) transmembrane transport. SLC39A8 deficiency affects all Mn-dependent enzymes and therefore different parts of the metabolism. Because several glycosyltransferases (e.g., β-1,4-galactosyltransferase) are Mn dependent, a secondary Golgi glycosylation occurs with a type 2 glycosylation defect. Low serum Mn levels are suggestive but not always present in patients.

Diagnosis
The primary screening method in a suspected patient with SLC39A8-CDG is **serum transferrin glycoform analysis** by mass spectroscopy or TIEF analysis. Patients show a type 2 pattern (see Fig. 107.9). MALDI-TOF analysis is suggestive but not discriminative. Low serum Mn levels are not always present in patients. The final diagnosis requires pathogenic variant analysis. SLC39A8-CDG is an autosomal recessive disease. The exact incidence for this rare disease is unknown.

Treatment
Besides supportive treatment, a few patients have shown biochemical and clinical improvement (better seizure control) with oral D-galactose (1-3.75 g/kg/day) and manganese (II)-sulfate monohydrate (15-20 mg/kg/day) therapy (see Table 107.7).

CONGENITAL DISORDERS OF DEGLYCOSYLATION
N-Glycanase 1 Deficiency (*NGLY1* Defect)
Clinical Manifestations
Patients with NGLY1 deficiency have a glycosylation disorder, but not from the deficient synthesis; rather, it is caused by deficient breakdown of glycoproteins. The phenotype comprises severe CNS involvement, microcephaly, intellectual disability, seizures, neuropathy, movement disorders, and hypotonia. The presence of *alacrimia* or hypolacrimia is highly suggestive for the diagnosis, but not all patients have problems with tearing. Other features include failure to thrive, IUGR, and liver involvement. Some patients have a recognizable oval face with a short nose, flat profile, and hypertelorism. Masklike face also occurs, imitating the phenotype of mitochondrial disorders, especially when serum lactic acid levels are also elevated.

Pathophysiology
N-glycanase is responsible for the deglycosylation of misfolded *N*-linked glycoproteins. The enzyme is essential for cutting off the glycans before the proteins are degraded in the ER. The exact disease pathomechanism, however, is not yet clear. Serum transaminase and α-fetoprotein levels are also frequently increased.

Diagnosis
Serum transferrin isoform analysis shows a normal pattern. In some patients the excretion of a specific urine biomarker (aspartylglucosamine; Neu5Ac1Hex1GlcNAc1-Asn) is present and can be used as screening. The final diagnosis requires genetic analysis.

NGLY1-CDG is an autosomal recessive disease. The most common pathogenic variant is c.1201A>T/p.R401X. The exact incidence of the condition is unknown, but >50 patients have been reported in the few years since the discovery of the disease.

Treatment
Only supportive treatment is available for the patient with NGLY1 deficiency.

THERAPEUTIC SUMMARY (SEE TABLE 107.7)
Most CDGs are treatable only with supportive therapy. The initially discovered oral mannose treatment in MPI-CDG (1 g/kg/day) has proved to be efficient for coagulation problems and protein-losing enteropathy but cannot prevent liver fibrosis in all patients. Liver transplantation in MPI-CDG has been successful in a few patients. Oral D-galactose in PGM1-CDG (1g/kg/day) can improve serum transaminases and coagulation and have a positive effect on endocrine function but cannot restore glycosylation fully. Seizure frequency improved in patients with SLC39A8-CDG receiving oral D-galactose treatment (1 g/kg/day) and oral manganese intake. The congenital myasthenic syndrome in DPAGT1-CDG, GFPT1-CDG, and GMPPB-CDG has been successfully treated with a high dose of cholinesterase inhibitors. Several CDGs have been positively controlled by transplantation, including DOLK-CDG (DK1-CDG; heart transplantation), PGM3-CDG (hematopoietic stem cell transplantation), ATP6AP1-CDG, and CCDC155-CDG (liver transplantation).

Patients with CAD-CDG show significant clinical improvement on receiving oral uridine therapy, especially with seizure control. Two children with SLC35C1-CDG–defective immune function improved on oral fucose therapy. GNE-CDG patients showed significant improvement in muscle strength on *N*-acetylmannosamine therapy.

Chapter 108

Mitochondrial Disease Diagnosis

Elizabeth M. McCormick and Marni J. Falk

See also Chapters 107.4, 638.2.

Mitochondrial diseases are multisystemic energy failure states with extensive clinical and genetic heterogeneity. Their common basis is best understood through recognition that mitochondria function as biologic "fuel cells" or "batteries," producing chemical energy in the form of adenosine triphosphate (ATP) by aerobic metabolism of nutrient-derived reducing equivalents, through the integrated function of the five-complex mitochondrial respiratory chain (RC) (Fig. 108.1). Mitochondria also play other essential roles that can be variably disrupted in disease states, such as regulating calcium homeostasis, diverse aspects of intermediary nutrient metabolism, nucleotide metabolism, and oxidative stress. Primary mitochondrial disease results from deficient RC function, which can be caused by pathogenic variants in genes that encode RC subunits, assembly factors or cofactors, components of mitochondrial DNA (mtDNA) metabolism and maintenance, or a host of other basic metabolic processes ongoing within mitochondria (Table 108.1). Approximately 1,500 proteins exist within the mitochondrial proteome of different tissues, with variants in more than 350 unique genes across both the nuclear and the mitochondrial genomes already implicated as causal in human mitochondrial disease.

Collectively recognized as the most common group of inherited metabolic diseases, **primary** (genetic based) mitochondrial disease has a combined minimal prevalence of 1 in 4,300 individuals across all ages. In addition, **secondary** mitochondrial dysfunction is broadly implicated in the pathogenesis of a host of complex diseases, ranging from metabolic syndrome to ischemia-reperfusion injury after stroke, to neurodegenerative diseases. Failure of high-energy-demand organs in mitochondrial diseases may clinically present as severe neurodevelopmental, cardiac, myopathic, renal, hepatic, endocrine, immune, gastrointestinal (GI), hearing, and vision disabilities, as well as global metabolic instability with lactic acidosis (Fig. 108.2) (see Tables 107.2 and 107.3). In most mitochondrial disorders, the phenotype may vary depending on the patient's age, the specific gene or genetic variant, or tissue affected. Particularly common mitochondrial disease clinical syndromes that present in children

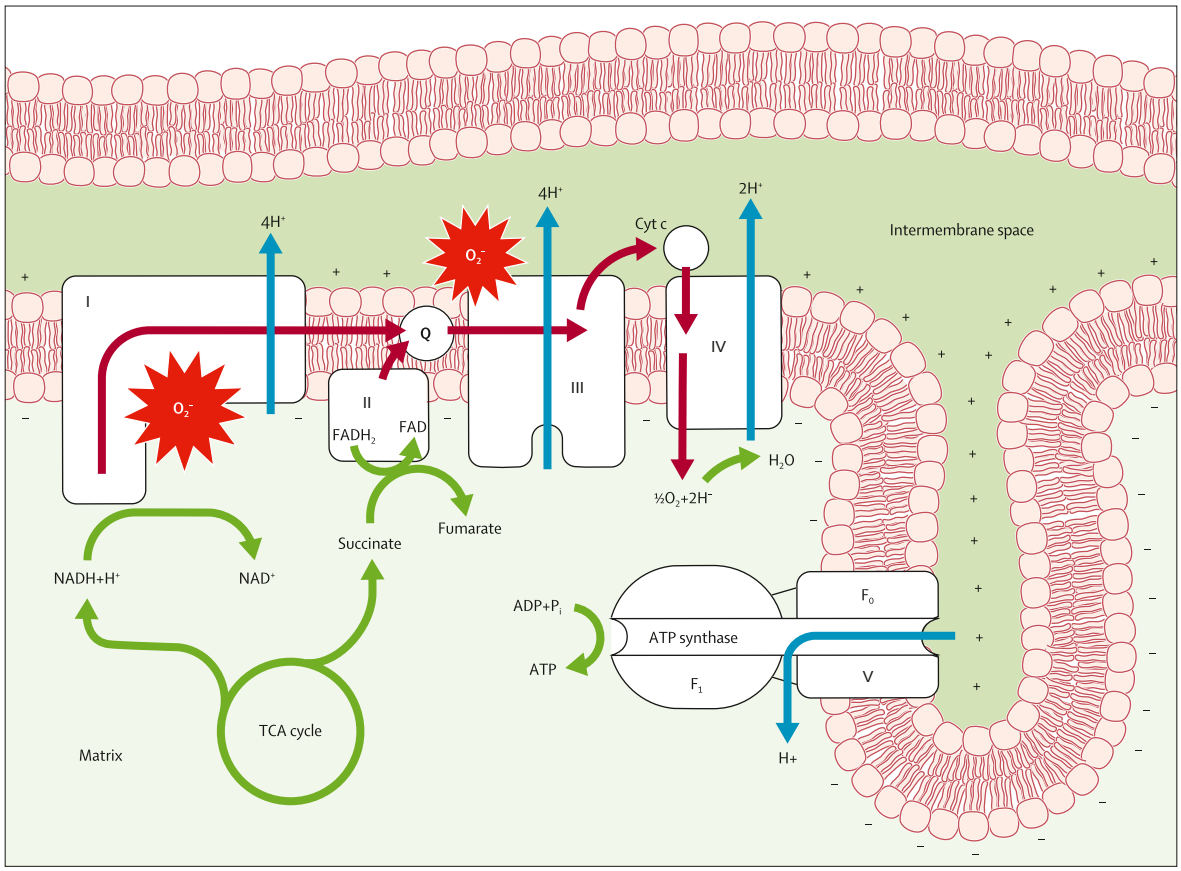

Fig. 108.1 Electron transport chain. The electron transport chain consists of four protein complexes (I-IV) coupled to a fifth (V) unlinked complex, ATP synthase. Together, these five complexes are known as the respiratory chain and are the site where oxidative phosphorylation (OXPHOS) occurs to generate energy. The transport chain accepts electrons from NADH (complex I) or $FADH_2$ (complex II) that have been produced by glycolysis, the formation of acetyl–coenzyme A, and the TCA cycle *(green arrows)*. Electrons flow from one complex to another *(red arrows)* because of the redox potential of each complex and lose a small amount of energy as they move through the chain. Three of the four complexes act as pumps, driven by electron flow, moving H^+ ions from the matrix to the intermembrane space *(blue arrows)*. This pumping builds a concentration gradient and creates an electrochemical force that is used by ATP synthase to produce ATP. Under normal conditions, this machinery provides almost all (90%) of the ATP in a cell. However, a small proportion of electrons escape the electron transport chain even under normal conditions and can react with oxygen and complexes I and III to form superoxide (O_2^-). ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Cyt c, cytochrome *c*; Q, coenzyme Q; NADH, nicotinamide dinucleotide; Pi, inorganic phosphate; TCA, tricarboxylic acid cycle; FADH2, 1,5-dihydro-flavin adenine dinucleotide. Table 108.1 Current Mitochondrial Gene Defects and Pathomechanisms

	GENE(S)
OXIDATIVE PHOSPHORYLATION DEFICIENCY	
Complex I subunits and assembly factors	*NDUFA1, NDUFA2, NDUFA6, NDUFA9, NDUFA10, NDUFA11, NDUFA12, NDUFA13 NDUFB3, NDUFB8, NDUFB9, NDUFB10, NDUFB11, NDUFS1, NDUFS2, NDUFS3, NDUFS4, NDUFS6, NDUFS7, NDUFS8, NDUFV1, NDUFV2, NDUFAF1, NDUFAF2, NDUFAF3, NDUFAF4, NDUFAF5, NDUFAF6, NDUFAF7, NDUFAF8, ACAD9, ECSIT, FOXRED1, NUBPL, TIMMDC1, TMEM126B, MT-ND1, MT-ND2, MT-ND3, MT-ND4, MT-ND4L, MT-ND5, MT-ND6*
Complex II subunits and assembly factors	*SDHA, SDHB, SDHC, SDHD, SDHAF1, SDHAF2*
Complex III subunits and assembly factors	*UQCRB, UQCRC2, UQCRFS1, UQCRQ, CYC1, BCS1L, HCCS, TTC19, LYRM7, UQCC2, UQCC3, MT-CYB*
Complex IV subunits and assembly factors	*COX4I1, COX4I2, COX5A, COX6A1, COX6B1, COX7B, COX8A, NDUFA4, SURF1, SCO1, SCO2, COX10, COX15, COA3, COA5, COA6, COA7, COX14, COX20, FASTKD2, PET100, PET117, CEP89, MT-CO1, MT-CO2, MT-CO3*
Complex V subunits and assembly factors	*ATP5A1, ATP5D, ATP5E, ATPAF2, TMEM70, USMG5, MT-ATP6, MT-ATP8*
DISORDERS OF MITOCHONDRIAL DNA MAINTENANCE	
Nucleotide pool maintenance	*ABAT, AK2, DGUOK, RRM2B, SAMHD1, SUCLA2, SUCLG1, TK2, TYMP*
Replication, maintenance, and transcription of mtDNA	*DNA2, FBXL4, MGME1, MPV17, POLG, POLG2, SSBP1, SLC25A4, TWNK*
MITOCHONDRIAL TRANSLATION DEFECTS	
Mitochondrial tRNAs	*MT-TA, MT-TC, MT-TD, MT-TD, MT-TE, MT-TF, MT-TG, MT-TH, MT-TI, MT-TK, MT-TL1, MT-TL2, MT-TM, MT-TN, MT-TP, MT-TQ, MT-TR, MT-TS, MT-TT, MT-TV, MT-TW, MT-TY*
Mitochondrial aminoacyl-tRNA synthetases	*AARS2, CARS2, DARS, DARS2, EARS2, FARS2, GARS, HARS2, IARS, IARS2, KARS, LARS, LARS2, MARS2, NARS2, PARS2, QARS, RARS2, SARS2, TARS2, VARS2, WARS2, YARS2*
tRNA modification	*ELAC2, MTFMT, NSUN3, PDE12, QRSL1, TRIT1, TRMT5, TRMT10C, TRNT1*
Mitochondrial rRNA	*MT-RNR1, MT-RNR2*
RNA processing	*PNPT1*
Mitoribosome subunits and assembly	*ERAL1, MRPL3, MRPL12, MRPL44, MRPS2, MRPS7, MRPS16, MRPS22, MRPS23, MRPS34, MRM2, RMND1*
Protein synthesis	*C12orf65, GFM1, GFM2, GTPBP3, GUF1, LRPPRC, MTO1, MTPAP, PUS1, TACO1, TRMU, TSFM, TUFM*
MITOCHONDRIAL QUALITY CONTROL DEFECTS	
Mitochondrial membrane phospholipid and import machinery	*AGK, CHKB, DNAJC19, GFER, MIPEP, PAM16, PLA2G6, PMPCA, SERAC1, SLC25A3, SLC25A10, SLC25A12, SLC25A22, TAZ, TIMM8A, TIMM50, XPNPEP3*
Mitochondrial dynamics	*DNM1L, GDAP1, MFF, MFN2, MSTO1, OPA1, STAT2, TRAK1, YME1L1*
MICOS complex	*CHCHD10, QIL1, SLC25A46*
ER-mitochondrial tethering	*EMC1*
Mitochondrial protein quality control	*AFG3L2, ATAD3A, CLPB, CLPP, CLPX, HSPA9, HSPD1, HSPE1, LONP1, PITRM1, SACS, SPG7, TRAP1*
Toxicity	*ECHS1, ETHE1, HIBCH*
Antioxidant defense	*NNT, TXN2*
METABOLIC DEFECTS	
Tricarboxylic acid cycle enzymes	*ACO2, DHTKD1, FH, IDH3A, IDH3B, MDH2, OGDH*
Pyruvate metabolism	*DLAT, DLD, MPC1, PC, PDHA1, PDHB, PDHX, PDK3, PDP1, PDPR*
Fatty acid metabolism	*CRAT, ETFA, ETFB, ETFDH, FA2H, HSD17B10, PYCR1, SLC25A1*
CoA metabolism and transport	*COASY, PANK2, SLC25A42*
VITAMIN AND COFACTOR METABOLISM DEFECTS	
Coenzyme Q_{10} biosynthesis	*COQ2, COQ4, COQ5, COQ6, COQ7, COQ8A, COQ8B, COQ9, PDSS1, PDSS2*
Iron-sulfur cluster protein biosynthesis	*ABCB7, FDXR, FDX1L, FXN, ISCA1, ISCA2, ISCU, LYRM4, NFS1, NFU1*
Lipoic acid biosynthesis	*BOLA3, GLRX5, IBA57, LIAS, LIPT1, LIPT2, MECR*
Cytochrome *c*	*CYCS*
Biotin metabolism	*BTD, HLCS*
Thiamine metabolism and transport	*SLC19A2, SLC19A3, SLC25A19, TPK1*
Mitochondrial one-carbon metabolism	*SLC25A26, SLC25A32*
Heavy metal metabolism	*SLC25A24, SLC33A1, SLC39A8*
Selenoprotein biosynthesis	*SECISBP2, SEPSECS*
NADPH metabolism	*NADK2, NAXD, NAXE*
Riboflavin metabolism and transport	*FLAD1, SLC52A2, SLC52A3*
OTHER CELLULAR DEFECTS ASSOCIATED WITH MITOCHONDRIAL DYSFUNCTION	
Ca^{2+} homeostasis	*ANO10, C19ORF70, CISD2, CYP24A1, MICU1, MICU2, WFS1*
Heme biosynthesis	*ABCB6, ALAS2, SFXN4, SLC25A38*
Apoptosis defects	*AIFM1, APOPT1, DIABLO, HTRA2, PTRH2*
DNA repair	*APTX, XRCC4*
Miscellaneous or unknown function	*ALDH1B1, ALDH18A1, BDH1, CA5A, CTBP1, C1QBP, C19ORF12, DCC, DIAPH1, FHF1, KIF5A, OPA3, PNPLA4, PNPLA8, POP1, PPA2, ROBO3, RTN4IP1, SLC44A1, STXBP1, TANGO2, TMEM65, TMEM126A*

mtDNA, Mitochondrial DNA; MICOS, mitochondrial contact site and cristae organizing system; ER, endoplasmic reticulum.

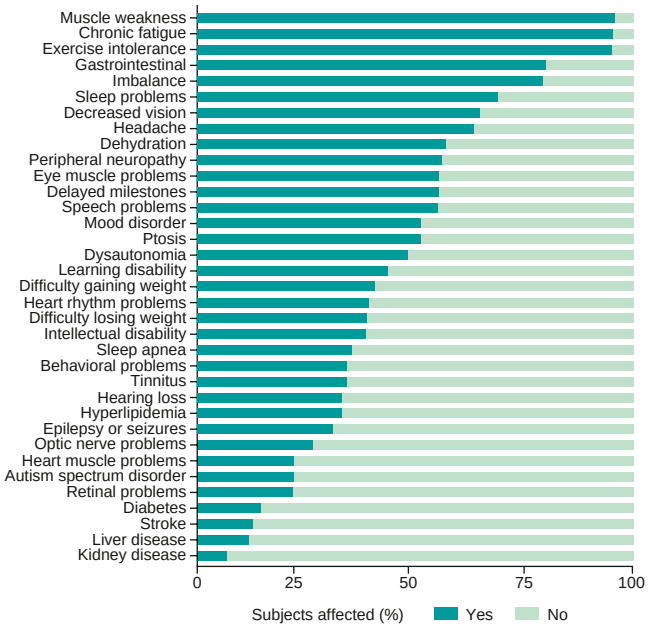

Fig. 108.2 Mitochondrial disease subject cohort experienced symptoms. Frequency of experienced symptoms as reported by the Rare Diseases Clinical Research Network (RDCRN) self-reported cohort revealed muscle weakness, chronic fatigue, exercise intolerance, imbalance, and gastrointestinal problems to be the top five common symptoms. (*Modified from Zolkipli-Cunningham Z, Xiao R, Stoddart A, et al. Mitochondrial disease patient motivations and barriers to participate in clinical trials. PLoS ONE. 2018;13[5]:e0197513. Fig. 2.*)

include **Leigh syndrome** (for which there are more than 110 causal genes; for gene listing visit https://search.clinicalgenome.org/kb/conditions/MONDO:0009723.), **mtDNA depletion syndrome** (MDS, for which there several dozen causal genes), **mtDNA deletion syndromes (Pearson**, **Kearns Sayre)**, primary lactic acidosis, and pyruvate dehydrogenase deficiency. Common clinical features in children present in at least 90% of patients include fatigue, exercise intolerance, weakness, GI and hepatic dysfunction, ataxia, and developmental delay. Thus mitochondrial diseases present to and must be considered by clinicians across every medical specialty.

Reversible infantile respiratory chain deficiency is an unusual mitochondrial disorder that presents in early (≤3 months) infancy with muscle weakness, hypotonia, poor feeding, and lactic acidosis and spontaneously resolves beginning around 1 year of age. Responsible maternal inherited genes include *mt-tRNAGlu (MT-TE)* (in 100%) and possible modifier genes *(EARS2, TRMU)*. Muscle biopsy may show ragged red fibers.

Patients with suspected mitochondrial disease often have an extensive phenotypic heterogeneity without a common biomarker, which presents a challenge to the accurate **clinical diagnosis** of mitochondrial disorders. Lactate and growth differentiation factor 15 (GDF-15) are screening tests that may be elevated in *some* mitochondrial diseases, particularly those involving mtDNA deletions or depletion. In addition, their extensive genetic heterogeneity involving known etiologies in >300 nuclear genes and all 37 mtDNA genes can make the accurate **genetic diagnosis** of an individual patient challenging. The diagnostic uncertainty can be further compounded by poor genotype-phenotype correlations and variable clinical presentations of individual gene disorders, high locus heterogeneity (i.e., multiple different causal disease genes) for similar clinical phenotypes, incomplete penetrance for some gene disorders, variable life stressors or environmental exposures that may exacerbate a given child's disease, and the unique biologic aspects of maternal inheritance for the subset of mitochondrial diseases caused by mtDNA pathogenic variants.

WHEN TO SUSPECT MITOCHONDRIAL DISEASE

Because of failure in the ability to generate cellular energy, mitochondrial diseases can involve any organ system at any age (see Fig. 108.2). Mitochondrial disease should be suspected when classic symptoms are present or if unexplained symptoms occur in three or more apparently unrelated organs. Individuals may present with a vast array of symptoms, including fatigue, muscle weakness, exercise intolerance, metabolic strokes, seizures, cardiomyopathy, arrhythmias, developmental or cognitive disabilities, autism, diabetes mellitus, and other endocrinopathies (adrenal, thyroid), dysautonomia, and autoimmune disorders, as well as impairment of hearing, vision, growth, liver, GI, or kidney function. Although individuals may have just one or a few symptoms and a fluctuating disease course in terms of symptom severity, most patients with primary mitochondrial disease tend to develop *progressive* symptoms over time. A study of patients with mitochondrial diseases showed an average of 16 different clinically significant symptoms per patient, with a range of 7-35. When considering the diagnosis, it is helpful to recognize that most symptoms of mitochondrial disease involve *functional,* rather than structural, problems.

When mitochondrial disease is considered in the differential diagnosis, it is often helpful to obtain several **laboratory screening** studies for common biochemical features of mitochondrial disease and overlapping disorders at baseline and, if unrevealing, during an acute illness or period of decompensation. Blood-based metabolic screening studies include comprehensive chemistry panel, complete blood count with differential, blood lactate and pyruvate, plasma amino acid quantitative analysis, carnitine analysis (total, free, acyl-carnitine profile), ammonia, creatine kinase, and testing for common secondary manifestations of mitochondrial disease (e.g., thyroid screen, lipoprotein profile, hemoglobin A_{1c}). Urine-based metabolic screening studies include urinalysis, urine organic acid quantitative analysis, and urine amino acid quantitative analysis. Consideration should also be given for screening for congenital disorders of glycosylation or vitamin deficiencies, which may have overlapping clinical features in some cases with mitochondrial disease. Lactic acidemia is neither highly sensitive nor specific for primary mitochondrial disease, but laboratory findings suggestive of primary mitochondrial disease include elevations of blood lactate, pyruvate, lactate:pyruvate ratio, alanine, ratios of alanine to lysine (>3) and alanine to the sum of phenylalanine and tyrosine (>4), and anion gap. Biochemical alterations further suggestive of mitochondrial disease may include secondary impairment of fatty acid oxidation with elevation of dicarboxylic acids on acyl-carnitine profile, increased branched-chain amino acids and proline on plasma amino acid analysis, increased tricarboxylic acid cycle intermediates and lactate excretion on urine organic acid analysis, and generalized aminoaciduria on urine amino acid analysis. **GDF-15** may be a useful screening test for mitochondrial depletion-based myopathies.

Similarly, when mitochondrial disease is considered in the differential diagnosis, obtaining additional **clinical evaluations** to carefully phenotype the patient for prevalent or highly morbid and potentially modifiable features of mitochondrial disease is important. Because many individuals with mitochondrial disease develop problems with their *vision* (reduced visual acuity not correctable with glasses, photophobia or nyctalopia with reduced peripheral vision associated with retinal disease or optic atrophy, ophthalmoplegia, ptosis), *hearing* (high-frequency sensorineural hearing loss), and *heart* (arrhythmia, conduction block, cardiomyopathy), carefully evaluating for involvement of these high-energy systems is indicated. **Neurologic** evaluation is essential because many mitochondrial disease patients experience a range of *central* (metabolic stroke in cortical or deep gray matter, including basal ganglia, midbrain, and/or brainstem; white matter changes; seizures; ataxia; movement disorder; migraine; cognitive changes), *peripheral* (axonal sensorimotor neuropathy), or *autonomic* nervous system dysfunction; brain imaging (MRI), spectroscopy (MRS), and, on occasion, electromyogram or nerve conduction velocity (EMG/NCV) studies can be helpful to support the diagnosis. Formal **exercise physiology** evaluation can also be useful to quantify and advise patients on their exercise capacity and safety, with some specific features (e.g., reduced Vo_2 maximal capacity) suggestive of quantifiable mitochondrial dysfunction. A **sleep** study may be useful for individuals with sleep dysfunction because sleep disorders may mimic mitochondrial disease symptoms, and sleep problems are common and potentially treatable in mitochondrial disease. **Gastrointestinal** symptoms are common and underrecognized in mitochondrial disease patients, usually involving dysmotility of any portion of the GI tract with reflux, swallowing dysfunction, delayed gastric emptying,

feeding and/or growth problems, pseudoobstruction, malabsorption, and constipation. **Endocrine** abnormalities are also common but underappreciated in many patients, including pituitary, adrenal, thyroid, and pancreatic dysfunction.

Such careful phenotyping of patients with suspected mitochondrial disease can thus provide reassurance that the common, and potentially treatable, clinical aspects of mitochondrial disease are not present although they may develop over time, or conversely if identified, increase diagnostic suspicion and direct further diagnostic evaluation. A screening tool for mitochondrial diseases is noted in Table 108.2. The differential diagnosis of mitochondrial disorders is extensive (Table 108.3).

MITOCHONDRIAL DISEASE INHERITANCE

Primary mitochondrial disease may result from variants in either nuclear genes or mtDNA genes, which may be inherited from a parent or occur de novo in an affected individual (for a list of genes curated for their association with primary mitochondrial disease, visit https://search.clinicalgenome.org/kb/affiliate/10027). Thus all *mendelian* (autosomal recessive, autosomal dominant, X-linked) or *maternal* (mtDNA) inheritance patterns can be consistent with mitochondrial diseases. Obtaining a detailed, three-generation pedigree is important to potentially highlight the specific inheritance pattern in a family. Individuals with inherited mtDNA disorders may report family members related through their **maternal** lineage (both males and females may be affected, but only affected individuals will be connected through the female germline), with a range of functional problems in different organs, such as migraines, fatigue, exercise intolerance, stroke, diabetes mellitus, thyroid dysfunction, irritable bowel syndrome, mood disorder, or vision and hearing problems (for a list of curated mtDNA variants, visit https://erepo.clinicalgenome.org). Inherited **X-linked** disorders typically present with symptoms only or, more severely, in males related through unaffected or minimally affected females. **Autosomal recessive** disorders are common in pediatric mitochondrial disease, particularly in consanguineous pedigrees, where a rare variant in the general population becomes enriched and passed down through both maternal and paternal lineages to become homozygous in the affected proband and also affect multiple individuals in a given generation without having affected individuals in earlier generations. **Autosomal dominant** variants may occur de novo or are passed on from either parent to their child, although many disorders may have reduced penetrance, which may make the genetic disorder appear to skip a generation. Identifying a likely inheritance pattern through pedigree analysis can inform accurate interpretation of large-scale genetic diagnostic evaluations, such as multigene sequencing and deletion/duplication analysis panels and exome or genome sequencing. Establishing a correct genetic diagnosis for mitochondrial disease in an affected individual is essential to enable reliable recurrence risk counseling and testing options in a given family, whether in a future pregnancy by chorionic villus sampling (CVS, typically performed at 10-12 weeks' gestation) or amniocentesis (typically performed at 16-20 weeks' gestation) or in the in vitro fertilization (IVF) setting with preimplantation genetic testing (PGT) for a specific disease-causing variant. Of note, PGT is readily available to families for known nuclear gene disorders but remains of limited availability in known pathogenic mtDNA variants.

Special mention is warranted to consider the unique aspects of *maternal inheritance* that typify mtDNA disorders. More than 300 disease-causing mtDNA variants have been identified, with extensive variation in disease manifestations and features. Most disease-causing variants are present in only a portion of an individual's mtDNA genomes, a concept known as **heteroplasmy**. For heteroplasmic mtDNA variants, the precise pathogenic variant level (percent) can vary between an individual's different tissues and can change over time, with symptom severity corresponding to different threshold pathogenic variant levels that can be difficult to define and that typically vary between organs. An individual's mtDNA genome background set of fixed sequence variants, known as a **haplogroup**, can also influence the penetrance or severity of an mtDNA disease. When a novel or rare mtDNA variant is identified in a given individual, it may be helpful to use highly sensitive sequencing methods to test the levels of that pathogenic variant (which may be accurate to detect 1% of pathogenic variant levels) in their different tissues (blood, urine, buccal, skin cells, muscle), as well as tissues from their mother or maternal relatives, to accurately determine whether it may be causal of disease in that family. Research-based functional testing may also be necessary to characterize fully the effects of a newly recognized mtDNA variant. When it is not known whether an mtDNA variant is maternally inherited or occurs de novo, the recurrence risk to future offspring of their asymptomatic parent is empirically estimated at 1 in 25 (4%), although the empirical recurrence risk rises to 1 in 2 (50%) when the mother is symptomatic.

Table 108.2 Mitochondrial Disease Criteria

	FEATURES	
Muscular	Myopathy Abnormal EMG Motor developmental delay Exercise intolerance	Maximal score for muscle is 2
Neurologic	Developmental delay or ID Speech delay Dystonia Ataxia Spasticity Neuropathy Seizures or encephalopathy	Maximal score for neurologic is 2
Multisystem	Any gastrointestinal tract disease Growth delay or failure to thrive Endocrine Immune Eye (vision) or hearing Renal tubular acidosis Cardiomyopathy	Maximal score for multisystem is 3
Total clinical		**Total maximal clinical score is 4**
Metabolic	Lactate high at least 2×: (score 2) Alanine high at least 2× Krebs cycle intermediates[a] Ethyl malonic and methyl malonic acid 3 methyl glutaconic acid CSF lactate, alanine	
Imaging/other	Leigh disease (score 2) Strokelike episodes (score 2) Lactate peak on MRS Leukoencephalopathy with brainstem and spinal cord involvement[b] Cavitating leukoencephalopathy[b] Leukoencephalopathy with thalamus involvement[b] Deep cerebral white matter involvement and corpus callosum agenesis[b]	Total metabolic and MRI maximal score is 4
Total MDC score (clinical, metabolic, imaging)		**Total maximal score is 8**

[a]Krebs cycle intermediates: alpha-ketoglutarate, succinate, fumarate.

[b]Numerous MRI patterns characteristic of mitochondrial disease have been described in addition to Leigh syndrome and basal ganglia with brainstem involvement. We include leukoencephalopathy with brainstem and spinal cord involvement *(DARS2)*, cavitating leukoencephalopathy *(LYRM7)*, leukoencephalopathy with thalamus involvement *(EARS2)*, and deep cerebral white matter involvement and corpus callosum agenesis *(NUBPL)*.

Every element scores 1 unless indicated differently. The severity of each finding is not taken into account because of the progressive nature of the disease. A total score of 1 indicates unlikely mitochondrial disorder; score 2–4, possible mitochondrial disorder; score 5–7, probable mitochondrial disorder; and score ≥8, definite mitochondrial disorder.

COX, Cytochrome c oxidase; EMG, electromyography; L/P, lactate/pyruvate; SDH, succinate dehydrogenase.

From Witters P, Saada A, Honzik T, et al. Revisiting mitochondrial diagnostic criteria in the new era of genomics. *Genetics Med.* 2018;20(4):444–451, Table 2.

Table 108.3 Differential Diagnosis of Selected Phenotypes Commonly Associated with Mitochondrial Disease

PHENOTYPE	MITOCHONDRIAL CAUSE	LIMITED DIFFERENTIAL DIAGNOSIS
Dystonia	Leigh syndrome, deafness-dystonia syndrome, other mitochondrial encephalomyopathies	Biotinidase deficiency, thiamine transporter deficiency 2, *ADAR* pathogenic variants (Aicardi-Goutières syndrome 6), organic acidemias (especially glutaric aciduria type I), NBIA, acute (viral) necrotizing encephalopathy, pathogenic variants in *NUP62, RANBP2,* and *PDE8B*, primary genetic dystonias
Epileptic encephalopathy	Alpers-Huttenlocher syndrome, many other mitochondrial disorders	Many genetic epileptic encephalopathies, including Dravet syndrome and *KCNQ2* pathogenic variants, pyridoxine-dependent epilepsies (antiquitin deficiency, PNPO deficiency), viral encephalitis
Progressive myoclonic epilepsy	MERRF	Ramsay Hunt syndrome, Unverricht-Lundborg disease, Lafora body disease, sialidosis, *PRICKLE1* pathogenic variants
Leukoencephalopathy	Complex I deficiency, complex II deficiency, SURF1 deficiency (rarely), disorders of mitochondrial translation and Fe-S cluster assembly	Vanishing white matter disease, lysosomal storage disorders, Canavan disease, Alexander disease, Pelizaeus-Merzbacher(-like), hypo/dysmyelination
Ataxia	*ADCK3* pathogenic variants, ataxia-neuropathy syndromes, for example, SCAE, MIRAS, MERRF, NARP, disorders of coenzyme Q_{10} biosynthesis	Spinocerebellar ataxias, CAPOS syndrome
Demyelination	MNGIE	ADEM, multiple sclerosis
Peripheral neuropathy	Pathogenic variants in *POLG, MPV17, KARS,* and *SURF1*; part of multisystem disease in many mitochondrial disorders, for example, MNGIE	Other nonmitochondrial genetic causes of Charcot-Marie-Tooth syndromes, riboflavin transporter deficiency, toxic neuropathies, critical illness
Ptosis and ophthalmoplegia	PEO, KSS, MNGIE, MELAS	Some congenital myopathies, pseudo-upgaze impairment in *OPMD,* horizontal gaze palsy and scoliosis (*ROBO3* pathogenic variant)
Optic neuropathy	LHON, ADOA, Leigh syndrome	Toxic optic neuropathy (e.g., methanol, cyanide, tobacco)
Hypertrophic cardiomyopathy with lactic acidosis	Complex I deficiency, *TMEM70* pathogenic variants, Sengers syndrome (AGK deficiency), disorders of mitochondrial translation	Viral infection
Dilated cardiomyopathy with lactic acidosis	Barth syndrome, disorders of mitochondrial phospholipid remodeling, other mitochondrial cardiomyopathies	Viral infection
Exocrine pancreatic insufficiency	Pearson syndrome	Cystic fibrosis
Diabetes and deafness	MIDD, other mtDNA pathogenic variants	Type 2 diabetes mellitus with incidental nonsyndromic deafness
Sideroblastic anemia	Pearson syndrome, MLASA, TRNT1 deficiency, *PUS1* or *YARS2* pathogenic variants	Blackfan-Diamond syndrome, Schwachman-Diamond syndrome, X-linked sideroblastic anemia
B-cell immune deficiency	TRNT1 deficiency	Primary immunodeficiency disorder
Liver failure	Mitochondrial DNA (mtDNA) depletion syndromes	NBAS, LARS, and IARS deficiencies, viral infection, lysosomal storage disorders, other syndromic genetic conditions
Renal tubulopathy/failure	Pearson and Kearns-Sayre syndromes, *RMND1*-related disease	Gitelman syndrome, Fanconi Bickel (*SLC2A2* pathogenic variants) syndrome, other syndromic genetic conditions
Myopathy	Part of multisystem disease in many mitochondrial disorders, especially mtDNA depletion syndromes	Congenital muscular dystrophies, myositis, many other disorders
Rhabdomyolysis	Mitochondrial myopathies (e.g., *MTCO1, MTCO2, MTCO3,* and *MTCYB* pathogenic variants)	*LPIN1* pathogenic variants, fatty acid oxidation defects (VLCAD, LCHAD), TANGO deficiency, glycolytic defects, toxic, postexercise
Low copper	Cytochrome oxidase deficiency	Menkes, *SLC33A1* pathogenic variants
Complex multisystem disorders	Many mitochondrial disorders, particularly in childhood	Congenital disorders of glycosylation, peroxisomal disorders, lysosomal storage disorders, other syndromic genetic conditions

ADEM, Acute disseminated encephalomyelitis; ADOA, autosomal dominant optic atrophy; CAPOS, cerebellar ataxia, areflexia, pes cavus, optic atrophy and sensorineural hearing loss; Fe-S, iron-sulfur; KSS, Kearns-Sayre syndrome; LHON, Leber hereditary optic neuropathy; MERRF, myoclonic epilepsy with ragged red fibers; MIDD, maternally inherited diabetes and deafness; MIRAS, mitochondrial recessive ataxia syndrome; MLASA, myopathy, lactic acidosis, sideroblastic anemia; MNGIE, mitochondrial neurogastrointestinal encephalomyopathy; NBIA, neurodegeneration with brain iron accumulation; PEO, progressive external ophthalmoplegia; SCAE, spinocerebellar ataxia with epilepsy.
Modified from Parikh S, Karaa A, Goldstein A, et al. Diagnosis of "possible" mitochondrial disease: an existential crisis. *J Med Genet.* 2019;56(3):123–130, Table 1.

DIAGNOSTIC TESTING FOR MITOCHONDRIAL DISEASE

The diagnosis of mitochondrial disease relies foremost on genetic testing (genomic analysis), with biochemical screens useful in blood or urine and invasive tissue testing often seen as secondary or sometimes not required at all (Fig. 108.3).

When the clinical evaluation—medical history; detailed review of systems; careful physical, neurologic, and dysmorphic examinations; pedigree review; blood- and urine-based biochemical screening studies; and additional phenotyping clinical evaluations—is suggestive of mitochondrial disease, a range of clinical diagnostic testing options can be pursued. Without a known molecular etiology in an affected family member, first-line genetic diagnostic testing should include whole exome sequencing (WES) and mtDNA genome sequencing using methodologies that will detect both single-nucleotide variants and larger-scale gene deletions and duplications. WES is more comprehensive for genes known not only to cause mitochondrial disease but also to cause all human genetic diseases. The rationale for this diagnostic testing approach includes the following factors:

- The mtDNA genome sequence is often included at no extra cost when clinical WES is ordered in blood or buccal samples but may need to be repeated in a symptomatic tissue (e.g., muscle, liver) to detect heteroplasmic mtDNA variants that may not be present in more accessible tissues such as blood or buccal cells.
- The utility of performing concurrent proband and both parental sample sequencing *(trio-based testing)*, as usually pursued with WES but not panel-based testing, thereby allowing concurrent segregation analysis of a suspected pathogenic variants as well as ready identification of de novo dominant variants in the proband.
- The ability to use WES raw data (either on a research basis or for reanalysis at a later date by the clinical diagnostic laboratory) to highlight and/or identify "novel" gene disorders not previously recognized or associated with human disease.

Exome sequencing including mtDNA is estimated to identify the definitive genetic etiology for mitochondrial disease in at least 60% of patients in whom it is strongly suspected. Whole genome sequencing (WGS) is increasingly used when routine molecular testing such as WES with mtDNA sequencing is unrevealing of the genetic etiology. A mitochondrial disease community resource to centrally curate all mitochondrial disease, gene, and variant knowledge across both genomes is publicly accessible at https://mseqdr.org/.

Tissue-based diagnostic testing has decreased in frequency as a front-line test in all patients with suspected mitochondrial disease, although it still has clinical utility. These include (1) in the setting of rapidly deteriorating clinical status when genetic testing results may not be available in a timely fashion; (2) when a variant of uncertain significance identified on genomic testing has unclear biochemical consequences; and (3) when uninformative genomic sequencing in blood in an individual with myopathy or muscle symptoms raises concern for other disease processes that may be evident on histology, electron microscopy, immunohistochemistry, or enzymatic tissue testing. In addition, some mitochondrial diseases are only evident by tissue-based diagnostic testing. These include mtDNA deletion disorders (typically involving several thousand nucleotides) not present in blood that cause **chronic progressive external ophthalmoplegia** (CPEO) or **Kearns-Sayre syndrome** (KSS) spectrum disorder, as well as different tissue (muscle or liver)-specific mtDNA depletion disorders (e.g., reduced mtDNA tissue content) that confirm a mitochondrial pathophysiology in a given patient and highlight a likely underlying nuclear gene cause for their disease, because mtDNA maintenance requires a host of nuclear-encoded proteins. **Electron transport chain enzyme** activity analyses are the accepted gold standard to evaluate for mitochondrial dysfunction in a previously frozen tissue sample. Skin biopsies are useful to establish fibroblast cell lines in which these same studies of mitochondrial function can be clinically performed. If detected, abnormalities can be revealing of a specific type of mitochondrial disorder, although not all mitochondrial diseases may be expressed or detectable in skin analysis. Thus if fibroblast testing is unrevealing, more invasive tissue studies may subsequently need to be pursued. RNA sequencing may lead to identification of the genetic etiology in an additional 10% of individuals with mitochondrial disease in

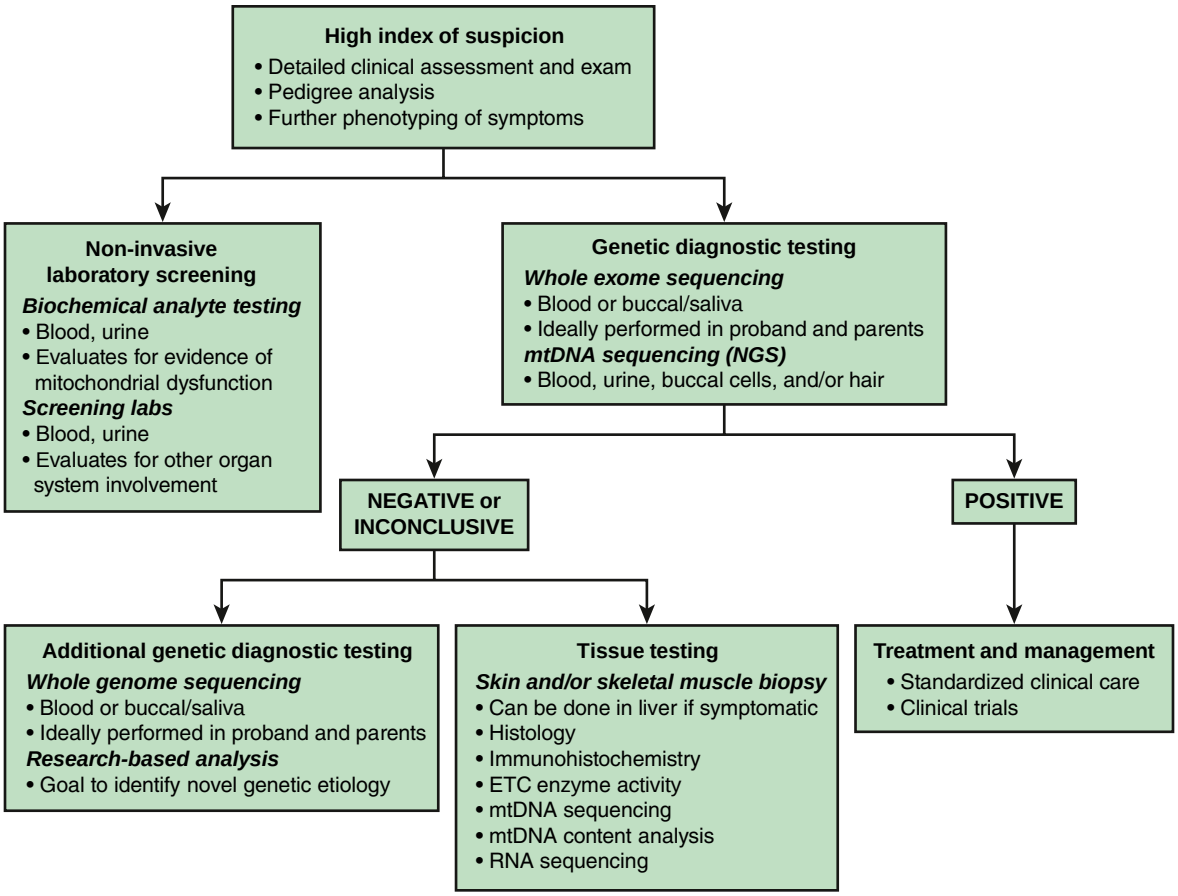

Fig. 108.3 Diagnostic algorithm for suspected mitochondrial disease. (*Modified from Murarescu CC, McCormick EM, Falk MJ. Mitochondrial disease: advances in clinical diagnosis, management, therapeutic development, and preventative strategies. Curr Genet Med Rep. 2018;6:62–72.*)

whom DNA-based sequencing did not identify the disease-causing variants. Only a small number of clinical laboratories offer this testing; this test can be performed in muscle, fibroblasts, or blood. Fibroblast cell lines, and occasionally blood-based lymphoblastoid cell lines, also provide a minimally invasive cell source to allow other clinical enzymatic analyses to be performed, as well as novel disease gene validation and research-based therapeutic modeling.

TREATMENT PRINCIPLES FOR MITOCHONDRIAL DISEASE

Effective therapies for both primary and secondary mitochondrial diseases are lacking. Clinical complexity and imprecisely defined or understood biochemical phenotypes of different mitochondrial disease subtypes have made it difficult for clinicians to effectively apply or monitor targeted therapies for RC disease. *Mitochondrial cocktails* consisting of combinatorial regimens of vitamins and supplements variably include vitamins (B_1, B_2, C), antioxidants (CoQ_{10}, lipoic acid, vitamin E, *N*-acetylcysteine), and metabolic modifiers (creatine, L-carnitine, L-arginine, folinic acid, taurine). Although the efficacy, toxicity, and optimal dose of these drugs are not known and have not been objectively assessed via clinical trials in human RC disease patients, they continue to be empirically prescribed in hopes of enhancing residual RC enzymatic function or quenching toxic metabolites theorized to accumulate in RC dysfunction and because of patient-based reports of improved well-being. However, provision of these therapies has often adopted a one-size-fits-all approach, ignoring the inherent variation in primary mitochondrial disease subtypes, the tissue-specific manifestations, and the major pathogenic factors, such as the predominant downstream metabolic and signaling alterations that occur in different disease subclasses (Fig. 108.4).

Although few mitochondrial diseases have efficacious therapies that have gained regulatory approval, improved molecular delineation has enabled selected therapies to advance from the theoretical, empirical, and largely ineffective stage to a promising horizon of rational, personalized, and effective interventions. An increasing number of mitochondrial disease diagnoses have interventions involving the initiation or *avoidance* of specific medications (corticosteroids, valproic acid, phenytoin, barbiturates, propofol for prolonged duration beyond 30-60 minutes, certain anesthetics, statins, β-blocking agents, amiodarone, nucleoside reverse transcriptase inhibitors), provision of cofactors or diets, and screening regimens for progressive clinical involvement of modifiable manifestations. General therapies for **Leigh syndrome** such as L-arginine and citrulline may prevent or reverse neurodevelopmental sequelae from a metabolic stroke. Nutritional therapies in these disorders are tailored to specific disease genes, such as thiamine and biotin for *SLC19A3* disease, ubiquinol for *PDSS2* (CoQ_{10} deficiency) disease, and thiamine and the ketogenic diet for *PDHA1* (pyruvate dehydrogenase) deficiency. Establishing the precise molecular diagnosis can further be lifesaving by avoiding fasting and mitochondrial-toxic medicines or general anesthetics in specific mitochondrial disease subsets, improving recurrence counseling for risk reduction of manifesting mitochondrial disease, enabling targeted screening for reported medical complications, and in some cases providing necessary cofactors or vitamins that may not otherwise have been considered. In addition, reproductive methodologies emerging in some countries for mitochondrial disease prevention, such as PGD and mitochondrial replacement technologies (MRTs), are only appropriate to consider in the setting of known pathogenic, inherited mtDNA variants.

Chapter 109

Mucopolysaccharidoses

Christina Lampe

Mucopolysaccharidoses are hereditary progressive diseases caused by pathogenic variants of genes coding for the lysosomal enzymes needed to degrade glycosaminoglycans (acid mucopolysaccharides). *Glycosaminoglycans* (GAGs) are long-chain complex carbohydrates composed of uronic acids, amino sugars, and neutral sugars. The major GAGs are chondroitin-4-sulfate, chondroitin-6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronan. These substances are synthesized and, with the exception of hyaluronan, linked to proteins to form *proteoglycans,* major constituents of the ground substance of connective tissue and of nuclear and cell membranes. Degradation of proteoglycans starts with the proteolytic removal of the protein core, followed by the stepwise degradation of the GAG moiety. Failure of this degradation because of absent or grossly reduced activity of mutated lysosomal enzymes results in the intralysosomal accumulation of GAG fragments (Fig. 109.1). Distended lysosomes accumulate in the cell, interfere with cell function, and lead to characteristic patterns of clinical, radiologic, and biochemical abnormalities (Table 109.1 and Fig. 109.2). Within these patterns, specific diseases can be recognized that evolve from the intracellular accumulation of different degradation products (Table 109.2). As a general rule, the impaired degradation of heparan sulfate is more closely associated with **intellectual disability** and that of dermatan, chondroitin, and keratan sulfate with **mesenchymal abnormalities**. Variable expression within a given entity results from allelic pathogenic variants and varying residual activity of mutated enzymes. For instance, different allelic variants of the gene encoding L-iduronidase may result in severe **Hurler disease** (Hurler syndrome) with early death or in mild **Scheie disease** (Scheie syndrome) manifesting only with limited joint mobility, mild skeletal abnormalities, and corneal opacities. In addition, the features of an individual patient will be modified by secondary effects of lysosomal dysfunction and environmental factors.

Mucopolysaccharidoses are autosomal recessive disorders, with the exception of **Hunter disease** (Hunter syndrome), which is X-linked recessive. Their birth prevalence varies between 1.2 per 100,000 births (United States) and 16.9 per 100,000 births (Saudi Arabia). In the United States the most common subtype is MPS-III, followed by MPS-I and MPS-II.

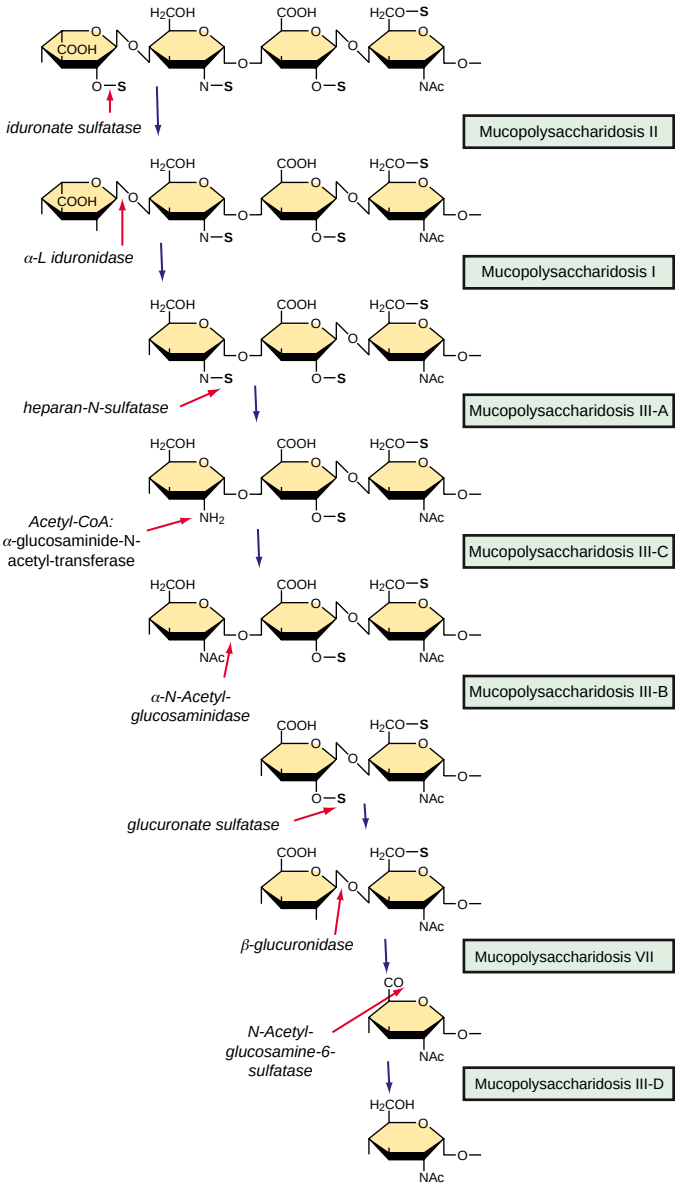

Fig. 109.1 Degradation of heparan sulfate and mucopolysaccharidoses resulting from the deficiency of individual enzymes. Some of the enzymes are also involved in the degradation of other glycosaminoglycans (not shown).

CLINICAL ENTITIES

Mucopolysaccharidosis I

Mucopolysaccharidosis I (MPS-I) is caused by pathogenic variants of the *IUA* gene on chromosome 4p16.3 encoding α-L-iduronidase. Two major alleles, W402X and Q70X, account for more than half of the MPS-I alleles in the White population. Other pathogenic variants typically occur in only one or a few individuals.

Deficiency of α-L-iduronidase results in a wide range of clinical involvement. Homozygous nonsense pathogenic variants result in the absence of enzyme and severe forms of MPS-I (Hurler syndrome). In contrast, missense pathogenic variants are more likely to preserve some residual enzyme activity and be associated with a milder form of the disease, including the milder Scheie syndrome.

Hurler Disease

The Hurler form of MPS-I **(MPS I-H)** is a severe, progressive disorder with involvement of multiple organ and tissue involvement that results in premature death, usually by 10 years of age. An infant with Hurler syndrome appears normal at birth, but inguinal hernias may be present. Diagnosis is usually made at 6-24 months, with evidence of hepatosplenomegaly, coarse facial features, corneal clouding, large tongue, enlarged head circumference, joint stiffness, short stature, and skeletal dysplasia. Acute cardiomyopathy has been found in some infants <1 year. Most patients have recurrent upper respiratory tract and ear infections, noisy breathing, and persistent copious nasal discharge. Valvular heart disease, notably with incompetence of the mitral and aortic valves, regularly develops, and narrowing of the coronary arteries occurs. Obstructive airway disease, especially during sleep, may necessitate tracheotomy. Obstructive airway disease, respiratory infection, and cardiac complications are the common causes of death.

Most children with Hurler syndrome acquire only limited language skills because of developmental delay, combined conductive and neurosensory hearing loss, and an enlarged tongue. Progressive ventricular enlargement with increased intracranial pressure caused by communicating hydrocephalus also occurs. Corneal clouding, glaucoma, and retinal degeneration are common. Radiographs show a characteristic skeletal dysplasia known as *dysostosis multiplex* (Figs. 109.3 and 109.4). The earliest radiographic signs are thick ribs and ovoid vertebral bodies. Skeletal abnormalities (in addition to those shown in the figures) include enlarged, coarsely trabeculated diaphyses of the long bones with irregular metaphyses and epiphyses. With progression of disease, macrocephaly develops with thickened calvarium, premature closure

of lambdoid and sagittal sutures, shallow orbits, enlarged J-shaped sella, and abnormal spacing of teeth with dentigerous cysts.

Hurler-Scheie Disease

The clinical phenotype of the Hurler-Scheie form of MPS-I **(MPS I-H/S)** is intermediate between Hurler and Scheie diseases and is characterized by progressive somatic involvement, including dysostosis multiplex with little or no intellectual dysfunction. The onset of symptoms is usually observed between 3 and 8 years of age, and survival to adulthood is common. Cardiac involvement and upper airway obstruction contribute to clinical morbidity. Some patients have spondylolisthesis, which may cause cord compression.

Scheie Syndrome

MPS I-S is a comparatively mild disorder characterized by joint stiffness, aortic valve disease, corneal clouding, and mild dysostosis multiplex. Onset of significant symptoms is usually after age 5 years, with diagnosis made between 10 and 20 years. Patients with Scheie syndrome have normal intelligence and stature but have significant joint and ocular involvement. A carpal tunnel syndrome often develops. Ophthalmic features include corneal clouding, glaucoma, and retinal degeneration. Obstructive airway disease, causing sleep apnea, develops in some patients, necessitating tracheotomy. Aortic valve disease is common and has required valve replacement in some patients.

Table 109.1 Recognition Pattern of Mucopolysaccharidoses

	MUCOPOLYSACCHARIDOSIS (MPS) TYPE

Mucopolysaccharidosis II

Hunter disease (MPS-II) is an X-linked disorder caused by the deficiency of iduronate 2-sulfatase (IDS). The gene encoding IDS is located on Xq28. Single-nucleotide variants or small deletions of *IDS* have been detected in approximately 50% of patients with MPS-II. Major deletions or rearrangements of *IDS* have been found in the rest, usually associated with a more severe and complex clinical phenotype. As an X-linked recessive disorder, Hunter syndrome manifests almost exclusively in males. However, it has been observed in females because of unfavorable skewing of inactivation of the normal X chromosome carrying the normal gene.

Marked molecular heterogeneity explains the wide clinical spectrum of Hunter disease. Patients with severe MPS-II have features similar to those of Hurler disease, except for the lack of corneal clouding and the somewhat slower progression of somatic and central nervous system (CNS) deterioration. Coarse facial features, short stature, dysostosis multiplex, joint stiffness, and intellectual disability manifest between 2 and 4 years of age. Grouped skin papules are present in some patients. Extensive congenital dermal melanocytosis (Mongolian spots) present at birth have been observed in African and Asian patients and may be an early marker of the disease. Gastrointestinal (GI) storage may produce chronic diarrhea. Communicating hydrocephalus and spastic paraplegia may develop due to thickened meninges. In severely affected patients, extensive, slowly progressive neurologic involvement precedes death, which usually occurs at age 10-15 years.

Patients with the mild form have a near-normal or normal life span, minimal CNS involvement, and slow progression of somatic deterioration with preservation of cognitive function in adult life. Survival to ages 65 and 87 years has been reported, and some patients have had children. Somatic features are Hurler-like but milder with a greatly

Fig. 109.2 Patients with various types of mucopolysaccharidoses. MPS-I: Hurler syndrome, age 3 years; MPS-II: Hunter syndrome, 12 years; MPS-III: Sanfilippo syndrome, 4 years; MPS-IV: Morquio syndrome, 10 years; MPS-VI: Maroteaux-Lamy syndrome, 15 years.

Table 109.2 Mucopolysaccharidoses: Clinical, Molecular, and Biochemical Aspects

MPS TYPE	EPONYM	INHERITANCE	GENE/ CHROMOSOME	MAIN CLINICAL FEATURES	DEFECTIVE ENZYME	ASSAY	MIM NUMBER
I-H	(Pfaundler-) Hurler	AR	*IDUA* 4p16.3	Severe Hurler phenotype, mental deficiency, corneal clouding, death usually before age 14 yr	α-L-iduronidase	L, F, Ac, Cv	252800 607014
I-S	Scheie	AR	*IDUA* 4p16.4	Stiff joints, corneal clouding, aortic valve disease, normal intelligence, survive to adulthood	α-L-iduronidase	L, F, Ac, Cv	607016
I-HS	Hurler-Scheie	AR	*IDUA* 4p16.4	Phenotype intermediate between I-H and I-S	α-L-iduronidase	L, F, Ac, Cv	607015
II	Hunter	XLR	*IDS* Xq27.3-28	Severe course: similar to I-H but clear corneas Mild course: less pronounced features, later manifestation, survival to adulthood with mild mental deficiency or without mental deficiency	Iduronate sulfate sulfatase	S, F, Af, Ac, Cv	309900
IIIA	Sanfilippo A	AR	*SGSH* 17q25.3	Behavioral problems, sleeping disorder, aggression, progressive dementia, mild dysmorphism, coarse hair, clear corneas Survival to adulthood possible	Heparan-S-sulfamidase	L, F, Ac, Cv	252900 605270
IIIB	Sanfilippo B	AR	*NAGLU* 17q21		*N*-Acetyl-D-glycosaminidase	S, F, Ac, Cv	252920
IIIC	Sanfilippo C	AR	*HGSNAT* 8p11.21		Acetyl-CoA-glucosaminide *N*-acetyltransferase	F, Ac	252930

IVA	Morquio A	AR	*GALNS* 16q24.3	Short-trunk dwarfism, fine corneal opacities, characteristic bone dysplasia; final height <125 cm	*N*-Acetylgalactosamine-6-sulfate sulfatase	L, F, Ac	253000
IVB	Morquio B	AR	*GLB1* 3p21.33	Same as IVA, but milder; adult height >120 cm	β-Galactosidase	L, F, Ac, Cv	253010 230500
VI	Maroteaux-Lamy	AR	*ARSB* 5q11-q13	Hurler phenotype with marked corneal clouding but normal intelligence; mild, moderate, and severe expression in different families	*N*-Acetylgalactosamine-α-4-sulfate sulfatase (arylsulfatase B)	L, F, Ac	253200
VII	Sly	AR	*GUSB* 7q21.11	Varying from fetal hydrops to mild dysmorphism; dense inclusions in granulocytes	β-Glucuronidase	S, F, Ac, Cv	253220
IX	Hyaluronidase deficiency	AR	*HYAL1* 3p21.3	Periarticular masses, no Hurler phenotype	Hyaluronidase 1	S	601492
MPSPS	MPS plus syndrome	AR	*VPS33A*	Mild Hurler phenotype, cognitive deficiency, organomegaly, skeletal dysplasia, pancytopenia, renal insufficiency, optic atrophy, early death	No lysosomal enzyme deficiency	L, F	617303

AR, Autosomal recessive; XLR, X-linked recessive; L, Leukocytes; S, serum; F, cultured fibroblasts; Ac, cultured amniotic cells; Af, amniotic fluid; Cv, chorionic villus sampling; MIM, Mendelian Inheritance in Man Catalogue.

reduced rate of progression. Adult height may exceed 150 cm. Airway involvement, valvular cardiac disease, hearing impairment, carpal tunnel syndrome, and joint stiffness are common and can result in significant loss of function in both the mild and severe forms.

Mucopolysaccharidosis III

Sanfilippo disease makes up a genetically heterogeneous but clinically similar group of four recognized types. Each type is caused by a different enzyme deficiency involved in the degradation of heparan sulfate (see Fig. 109.1). Pathogenic variants have been found in all the MPS-III disorders for which genes have been isolated.

Phenotypic variation exists in MPS-III patients, but to a lesser degree than in other MPS disorders. Patients with Sanfilippo disease are characterized by slowly progressive, severe CNS involvement with mild somatic disease. Such disproportionate involvement of the CNS versus the connective tissue system is unique to MPS-III. Onset of clinical features usually occurs at age 2-6 years in a child who previously appeared normal. Presenting features include delayed development,

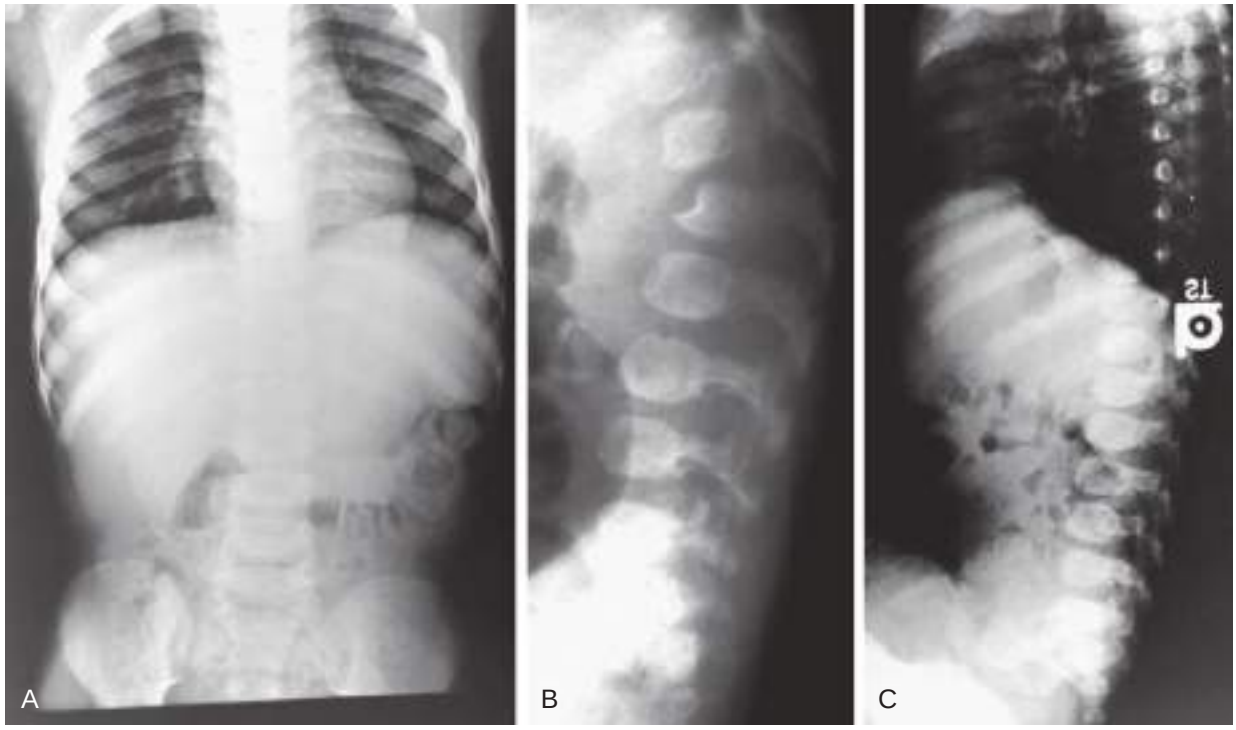

Fig. 109.3 Dysostosis multiplex. **A,** Sanfilippo syndrome, patient age 4 years; the ribs are wide. **B,** Sanfilippo syndrome, age 4 years; immature, ovoid configuration of the vertebral bodies. **C,** Hurler syndrome, age 18 months; anterosuperior hypoplasia of first lumbar vertebra (L1) resulting in hook-shaped appearance.

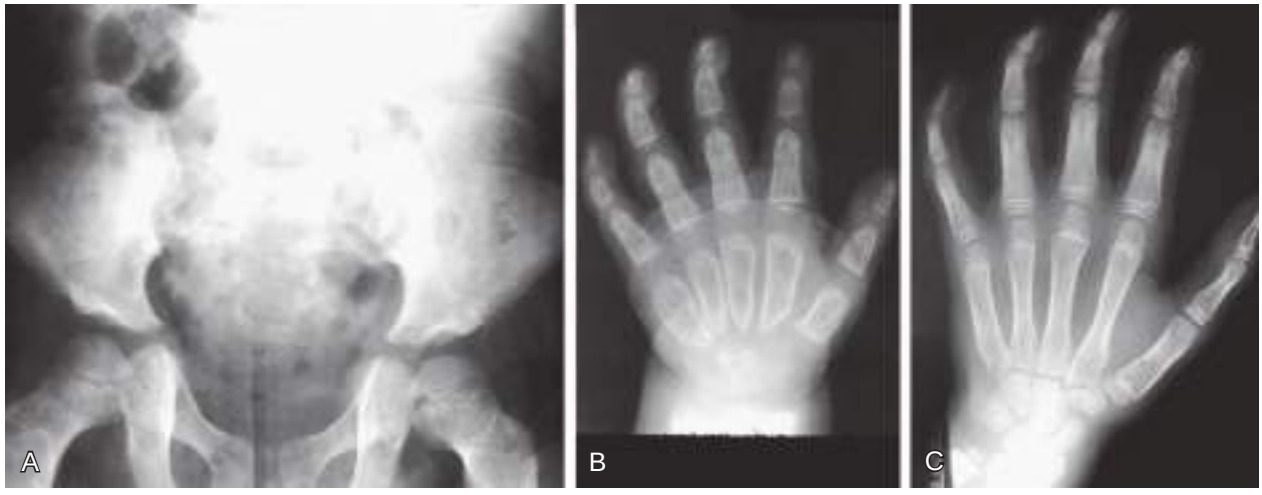

Fig. 109.4 Dysostosis multiplex. **A,** Mucopolysaccharidosis I-H, patient age 10 years. The inferior portions of the ilia are hypoplastic, with resulting iliac flare and shallow acetabular fossae. The femoral necks are in the valgus position. **B,** MPS I-H, age 4 years. Metacarpals and phalanges are abnormally short, wide, and deformed with proximal pointing of the metacarpals and bullet-shaped phalanges. Bone trabeculation is coarse, and the cortices are thin. **C,** MPS I-S, age 13 years. The carpal bones are small, leading to a V-shaped configuration of the digits. The short, tubular bones are well modeled. Flexion of the middle and distal phalanges II-V is caused by joint contractures.

hyperactivity with aggressive behavior, coarse hair, hirsutism, sleep disorders, and mild hepatosplenomegaly. Subclinical cardiac defects are common. Delays in the diagnosis of MPS-III are common because of mild physical features, hyperactivity, and slowly progressive neurologic disease. Severe neurologic deterioration occurs in most patients by age 6-10 years, accompanied by rapid deterioration of social and adaptive skills. Severe behavior problems, such as sleep disturbance, uncontrolled hyperactivity, temper tantrums, destructive behavior, and physical aggression, are common. Profound developmental regression and behavior problems often occur in patients with normal physical strength, making management particularly difficult.

Mucopolysaccharidosis IV

Morquio disease (MPS-IV) is caused by a deficiency of *N*-acetylgalactosamine-6-sulfatase (MPS-IVA) or of β-galactosidase (MPS-IVB). Both result in the defective degradation of keratan sulfate. The gene encoding *N*-acetylgalactosamine-6-sulfatase is *GALNS* on chromosome 16q24.3, and the gene encoding β-galactosidase is *GLB1* on chromosome 3p21.33. β-Galactosidase catalyzes GM_1 ganglioside in addition to endohydrolysis of keratan sulfate, and most pathogenic variants of *GLB1* result in generalized **gangliosidosis**, a spectrum of neurodegenerative disorders associated with dysostosis multiplex. A W273L pathogenic variant of the *GLB1* gene, either in the homozygous

state or as part of compound heterozygosity, commonly results in Morquio B disease.

Both types of Morquio syndrome are characterized by short-trunk dwarfism, fine corneal deposits, a skeletal dysplasia that is distinct from other mucopolysaccharidoses, and preservation of intelligence. MPS-IVA is usually more severe than MPS-IVB, with an adult height of <125 cm in the former and more than 150 cm in the latter. However, there is considerable variability of expression in both subtypes. The appearance of genu valgum, kyphosis, growth retardation with short trunk and neck, and waddling gait with a tendency to fall are early symptoms of MPS-IV. Extraskeletal manifestations include mild corneal clouding, small teeth with abnormally thin enamel, frequent caries formation, and occasionally hepatomegaly and cardiac valvular lesions. Instability of the odontoid process and ligamentous laxity is regularly present and can result in atlantoaxial instability and life-threatening dislocation. Surgery to stabilize the upper cervical spine, usually by posterior spinal fusion, before the development of cervical myelopathy, can be lifesaving.

Mucopolysaccharidosis VI

Maroteaux-Lamy disease (MPS-VI) is caused by pathogenic variants of the *ARSB* gene on chromosome 5q11-13 encoding *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B). It is characterized by severe to mild somatic involvement, as seen in MPS-I, but with preservation of intelligence. The somatic involvement of the severe form of MPS VI is characterized by corneal clouding, coarse facial features, joint stiffness, valvular heart disease, communicating hydrocephalus, and dysostosis multiplex. In the severe form, growth can be normal for the first few years of life but seems to virtually stop after age 6-8 years. The mild to intermediate forms of Maroteaux-Lamy syndrome can be easily confused with Scheie syndrome. Spinal cord compression from thickening of the dura in the upper cervical canal with resultant myelopathy is common in patients with MPS-VI.

Mucopolysaccharidosis VII

Sly disease (MPS-VII) is caused by pathogenic variants of the *GUSB* gene. Pathogenic variants result in a deficiency of β-glucuronidase, intracellular storage of glycosaminoglycan fragments, and a very wide range of clinical involvement. The most severe form presents as lethal nonimmune fetal hydrops and may be detected in utero by ultrasound. Some severely affected newborns survive for months and have, or develop, signs of lysosomal storage, including thick skin, visceromegaly, and dysostosis multiplex. Less severe forms of MPS-VII present during the first years of life with features of MPS-I but slower progression. Corneal clouding varies. Patients with manifestation after 4 years of life have coarse facial features with depressed nasal roots, malpositioned teeth with malformed roots, and skeletal abnormalities of dysostosis multiplex. Intelligence is normal, and corneae are usually clear. Patients may be found incidentally based on a blood smear that shows coarse granulocytic inclusions.

Mucopolysaccharidosis IX

MPS-IX disease is caused by pathogenic variants in *HYAL1* encoding one of three hyaluronidases. Clinical findings in the first patient, a 14-year-old girl, were bilateral nodular soft tissue periarticular masses, lysosomal storage of histiocytes, mildly dysmorphic craniofacial features, short stature, normal joint movement, and normal intelligence. Clinical findings in the only three additional patients known today were indistinguishable from those in rheumatoid arthritis.

Mucopolysaccharidosis Plus Syndrome

Coarse facial features, organomegaly, joint contractures, dysostosis multiplex, cognitive deficiency, increased mucopolysacchariduria, and massive intracellular accumulation of heparan sulfate have been found in 13 children in northeastern Siberia and two Turkish children. Additional findings include optic atrophy, intracerebral calcifications, pancytopenia, and renal insufficiency. Most patients died within the first 2 years of life from cardiorespiratory failure. Lysosomal enzyme activities were normal in children with MPS plus syndrome. This autosomal recessive multisystem disorder is caused by biallelic pathogenic variants of *VPS33A* encoding a protein involved in lysosomal fusion processes.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinical suspicion of an MPS justifies a skeletal survey. Radiographs of the chest, spine, pelvis, and hands may show early signs of dysostosis multiplex. The next diagnostic step is to assay the urinary excretion of GAGs. Semiquantitative spot tests for increased urinary GAG excretion are quick, inexpensive, and useful for initial evaluation but are subject to both false-positive and false-negative results. Quantitative analysis of a single GAG in material derived from dried blood spots is preferable with few false-negative results. Using tandem mass spectrometry, type-specific profiles can be obtained. Morquio disease is often missed in urinary assays but can be reliably diagnosed in serum using monoclonal antibodies to keratan sulfate.

Newborn screening for MPS (type I, II, VI) is essential for the early detection of subclinical cases and their therapy. It is available from dried blood spots using tandem mass spectrometry of glycosaminoglycans or fluorescence-based enzyme function assays. Any individual with a suspected MPS disorder based on screening tests, clinical features, and radiographic results should have a definitive diagnosis established by enzyme assay. Serum, leukocytes, or cultured fibroblasts are used as the tissue source for measuring lysosomal enzymes (see Table 109.2).

Prenatal diagnosis is available for all MPSs and is carried out on cultured cells from amniotic fluid or chorionic villus biopsy. Molecular analysis is typically performed using appropriate gene panels. In many cases the type and location of the pathogenic variant are related to the future course of the disease and thus have a prognostic value. Carrier testing in Hunter syndrome, an X-linked disorder, requires analysis of *IDS* once the specific pathogenic variant or chromosome arrangement in the family is known. Prenatal molecular analysis should be offered in a male fetus of a proven female carrier of the *IDS* gene. His risk to be affected is 50%. In a female fetus, the risk is small, but not zero, as a result of skewed maternal X chromosome inactivation.

Mucolipidoses and oligosaccharidoses manifest with the same clinical and radiographic features as MPS. In these conditions the urinary excretion of GAGs is not elevated. Hurler-like facial features, joint contractures, dysostosis multiplex, and elevated urinary GAG excretion differentiate the MPSs from congenital disorders of glycosylation and other neurodegenerative and dwarfing conditions.

TREATMENT

Hematopoietic stem cell transplantation and enzyme replacement therapy are performed in specialized institutions.

Bone marrow transplantation from related or unrelated donors and cord blood transplantation have resulted in significant clinical improvement of somatic disease in MPSs I, II, III, and VII. Clinical effects include increased life expectancy with resolution or improvement of growth, hepatosplenomegaly, joint stiffness, facial appearance, skin changes, obstructive sleep apnea, heart disease, communicating hydrocephalus, and hearing loss. Enzyme activity in serum and urinary GAG excretion normalize. This is true for MPS I-H, II, and III. Some patients with MPS-I who have undergone transplantation before 9 months of age have been reported with normal cognitive development. Transplantation before 24 months and with a baseline mental development index >70 have improved long-term outcomes. Transplantation does not significantly improve the neuropsychologic outcome of MPS patients with impaired cognition at transplantation. Early transplantation in the MPS-II patient may have the same effect. Transplantation in the MPS-VI patient stabilizes or improves cardiac manifestations, posture, and joint mobility. Stem cell transplantation does not correct skeletal or ocular anomalies, and they should be treated with appropriate orthopedic and ophthalmologic procedures. Cord blood transplantation is the therapy of choice in children with MPS-IH, and possibly MPS-II, before the age of 2 years, but transplantation-related death or primary graft failure, which occurs in approximately one third of the patients, must be weighed against other therapeutic options.

Enzyme replacement therapy (ERT) using recombinant α-L-iduronidase has been approved for patients with MPS-I (Table 109.3). It reduces organomegaly and airway infections, improves rate of growth, improves joint mobility, pulmonary function, and endurance, and reduces the number of episodes of sleep apnea and urinary GAG excretion. The enzyme does not cross the blood-brain barrier and does not prevent deterioration of cognition and other neurologic functions. Consequently, ERT is reserved for patients with mild CNS involvement. To stabilize extraneural manifestations it is also recommended in young patients before stem cell transplantation. ERT also ameliorates somatic complications in patients with more severe CNS involvement. Recombinant iduronate-2-sulfatase ameliorates the nonneural manifestations of Hunter disease, such as respiratory dysfunction, reduced physical endurance, and daily activity. ERT with recombinant human *GALNS* improves physical endurance, respiratory function, and daily living activity of patients with MPS-IV. Similar effects produce recombinant *N*-acetylgalactosamine-4-sulfatase in patients with MPS-VI and recombinant β-glucuronidase in MPS VII.

Advanced therapies include enzyme replacement mediated via insulin receptors in MPS I and II or transferrin receptors in MPS II to assist in crossing the blood-brain barrier. A phase I/II and a phase III study using the transferrin receptor have started for MPS II. In MPS IIIA, an intravenous ERT phase 1/2 study with a chemically modified variant of recombinant human sulfamidase and a recombinant human alpha-*N*-acetylglucosaminidase for MPS IIIB were recently completed. However, the study results were not convincing. A phase I/II study for MPS III using the transferrin receptor is in planning. Gene therapies for MPS I, II, and III are under investigation. Autologous hematopoietic stem/progenitor cells transduced ex vivo with an α-L-iduronidase–encoded lentiviral vector has resulted in beneficial metabolic correction in peripheral and central nervous system tissues. A clinical trial to ameliorate the intracellular inflammation and, consequently, the CNS involvement in MPS III with anakinra (Kineret) was completed with results pending.

Symptomatic therapy focuses on respiratory and cardiovascular complications, hearing loss, carpal tunnel syndrome, spinal cord compression, hydrocephalus, and other problems (Table 109.4). The

Table 109.3 Therapies For Mucopolysaccharidoses

MPS TYPE	HEMATOPOIETIC STEM CELL TRANSPLANTATION	ENZYME REPLACEMENT THERAPY	REMARKS
I	Yes	Laronidase (Aldurazyme)	Developmental trajectory dependent on time of transplantation. Little effect on connective tissue manifestations. Enzyme replacement immediately after diagnosis. Autologous hematopoietic stem/progenitor cells transduced ex vivo with gene encoding lentiviral vector.
II	Yes	Idursulfase (Elaprase)	
III	No	No	Experimental intraventricular chimeric fusion of recombinant human N-acetyl-D-glucosaminidase and truncated insulin-like growth factor 2 in MPS IIIB
IV	Yes	Elosulfase (Vimizim)	Improved daily activities. No effect on growth or skeletal dysplasia.
VI	Yes	Galsulfase (Naglazyme)	Improved daily activities. Improved growth. No effect on skeletal dysplasia.
VII	Yes	Vestronidase alfa (MEPSEVII)	Improved daily activity. No effect on skeletal dysplasia.

Table 109.4 Symptomatic Management of Mucopolysaccharidoses

PROBLEM	PREDOMINANTLY IN	MANAGEMENT
NEUROLOGIC		
Hydrocephalus	MPS I, II, VI, VII	Fundoscopy, CT scan
Chronic headaches	All	Ventriculoperitoneal shunting
Behavioral disturbance	MPS-III	Behavioral medication, sometimes CT scan, ventriculoperitoneal shunting
Disturbed sleep–wake cycle	MPS-III	Melatonin
Seizures	MPS I, II, III	EEG, anticonvulsants
Atlantoaxial instability	MPS IV	Cervical MRI, upper cervical fusion
Spinal cord compression	All	Laminectomy, dural excision
OPHTHALMOLOGIC		
Corneal opacity	MPS I, VI, VII	Corneal transplant
Glaucoma	MPS I, VI, VII	Medication, surgery
Retinal degeneration	MPS I, II	Nightlight
EARS, AIRWAYS		
Recurrent otitis media	MPS I, II, VI, VII	Ventilating tubes
Impaired hearing	All except MPS-IV	Audiometry, hearing aids
Obstruction	All except MPS-III	Adenectomy, tonsillectomy, bronchodilator therapy, CPAP at night, laser excision of tracheal lesions, tracheotomy
CARDIAC		
Cardiac valve disease	MPS I, II, VI, VII	Endocarditis prevention, valve replacement
Coronary insufficiency	MPS I, II, VI, VII	Medical therapy
Arrhythmias	MPS I, II, VI, VII	Antiarrhythmic medication, pacemaker

Table 109.4 Symptomatic Management of Mucopolysaccharidoses—cont'd

PROBLEM	PREDOMINANTLY IN	MANAGEMENT
ORAL, GASTROINTESTINAL		
Hypertrophic gums, poor teeth	MPS I, II, VI, VII	Dental care
Chronic diarrhea	MPS-II	Diet modification, loperamide
MUSCULOSKELETAL		
Joint stiffness	All except MPS IV	Physical therapy
Scoliosis	All	Bracing, surgery
Weakness	All	Physical therapy, wheelchair
Gross long-bone malalignment	All	Corrective osteotomies
Carpal tunnel syndrome	MPS I, II, VI, VII	Electromyography, surgical decompression
ANESTHESIA	All except MPS III	Avoid atlantoaxial dislocation; use angulated video intubation laryngoscope and small endotracheal tubes

CT, Computed tomography; CPAP, continuous positive airway pressure; EEG, electroencephalogram; MRI, magnetic resonance imaging.

multisystem involvement and progressive nature of MPS syndromes usually require the standardized and complex care provided by medical centers.

Chapter 110

Disorders of Purine and Pyrimidine Metabolism

H. A. Jinnah

The purines and pyrimidines consist of a family of small organic molecules that are found in all cells. They are often considered together because they provide the fundamental building blocks for nucleic acids, which include DNA and RNA. The purines and pyrimidines are also involved in numerous other cellular processes. Although they share certain biochemical characteristics, the associated clinical disorders are quite varied. Historically, most were identified by characteristic abnormalities found with metabolic tests. Currently, they are increasingly being identified after discovery of a pathogenic variant in a relevant gene in tests that involve broad gene panels or exome sequencing. Most of these disorders are genetic, and most are rare. *However, they are important to recognize because specific treatments are available for some of them* (Table 110.1).

PURINES

The purines are divided into two groups. The first group involves the base adenine, its corresponding nucleoside (adenosine), and nucleotide (AMP, ADP, ATP) derivatives (Fig. 110.1). ATP serves as one of four building blocks for RNA, and its deoxy derivative (dATP) serves as one of four building blocks for DNA. ATP also provides the energy source for the majority of energy-requiring activities. ATP derivatives act as signaling factors as "second messengers" (cAMP) or cofactors (FAD, NAD, NADP) for a large number of cellular processes. Some purines such as adenosine and the adenine nucleotides serve as extracellular signaling molecules, including acting as neurotransmitters in the nervous system.

The second group of purines involves the base guanine, its corresponding nucleoside (guanosine), and nucleotide (GMP, GDP, GTP) derivatives (see Fig. 110.1). Like the adenine nucleotides, guanine nucleotide derivatives also serve as building blocks for nucleic acids (DNA and RNA). GTP also provides an energy source for some energy-requiring activities. Guanine nucleotides also play a critical role in intercellular signaling (cGMP) via membrane-bound receptors that require GTP during signal transduction (G-proteins). They also play a role in intracellular signaling via a large family of cytosolic GTPases and guanine nucleotide exchange factors.

Because purines play a critical role for so many fundamental cellular processes, their amounts are tightly regulated. The amounts of purines reflect a balance between synthesis, catabolism, and recycling (Fig. 110.2). Purines are synthesized by the de novo purine synthesis pathway. This pathway has six enzymes that carry out 10 reactions. When there is a demand for more purines, these six enzymes aggregate dynamically into giant macromolecular complexes known as *purinosomes* to accelerate synthesis. After the demand is met, these aggregates disperse and synthesis abates. In humans, purines are catabolized via several routes. The major end product of purine catabolism is uric acid, produced by the enzyme encoded by the *XDH* gene. The enzyme is known as *xanthine oxidase, xanthine reductase,* or *xanthine oxidoreductase.* Most of this uric acid is eliminated from the body in the urine, although some is also eliminated by secretion into the gastrointestinal tract. Because the synthesis of purines is energetically costly, purines are actively recycled (see Fig. 110.2). The key enzymes of purine salvage include hypoxanthine-guanine phosphoribosyl transferase (encoded by *HPRT1*) and adenine phosphoribosyl transferase (encoded by *APRT*).

The metabolism of purines differs considerably across different cells and tissues. For example, the synthetic pathway is absent in erythrocytes, because these postmitotic cells do not require large quantities of new purines to make nucleic acids for cell division. Erythrocytes rely instead predominantly on purine salvage to maintain purine levels. A similar situation is thought to occur for postmitotic neurons of the nervous system. Another example of tissue-specific differences in purine metabolism involves uric acid. The vast majority of uric acid in the human body is produced by the liver, because hepatocytes express high levels of *XDH,* whereas many other cells and tissues express little or none. In addition to tissue differences, several enzymes of purine metabolism have multiple isoforms with different tissue distributions, leading to tissue-specific consequences in disorders where one isoform is affected.

PYRIMIDINES

The pyrimidines are divided into three groups delineated by the bases cytosine, thymine, and uracil (see Fig. 110.1). Each has a corresponding nucleoside derivative (cytidine, thymidine, uridine) and nucleotide

Table 110.1 Disorders of Purines and Pyrimidines with Specific Treatments

DISORDER	GENE SYMBOL	TREATMENT	OUTCOME
APRT deficiency	*APRT*	XOR inhibitor	Prevents renal stones and renal failure
Uridine-responsive epileptic encephalopathy	*CAD*	Uridine	Suppresses seizures, reverses neurobehavioral and hematologic abnormalities
Familial juvenile hyperuricemic nephropathy	*UMOD, REN, MUC,* or *HNF-1b*	XOR inhibitor	Prevents renal stones, renal failure, and gout
Renal hypouricemia	*SLC2A9* or *SLC22A12*	XOR inhibitor	Prevents renal stones and renal failure
Hereditary orotic aciduria	*UMPS*	Uridine	Reverses neurobehavioral and hematologic deficits
Hereditary xanthinurias			
Type 1	*XOR*	XOR inhibitor	Prevents renal stones and renal failure
Type 2	*MOCOS*	XOR inhibitor	Prevents renal stones and renal failure
Molybdenum cofactor deficiencies	*MOCS1-3, GPHN*	XOR inhibitor	Prevents renal stones and renal failure
MOCS1 deficiency	*MOCS1*	cPMP	Reverses neurobehavioral deficits
HPRT1-associated disorders	*HPRT1*	XOR inhibitor	Prevents renal stones, renal failure, and gout
PRPP synthetase hyperactivity	*PRPS1*	XOR inhibitor	Prevents renal stones, renal failure, and gout
Nucleotidase-associated pervasive developmental delay	Unknown	Uridine	Reverses neurobehavioral deficits

The most common XOR inhibitors include allopurinol, febuxostat, and topiroxostat.
cPMP, Cyclic pyranopterin monophosphate; XOR, xanthine oxidoreductase.

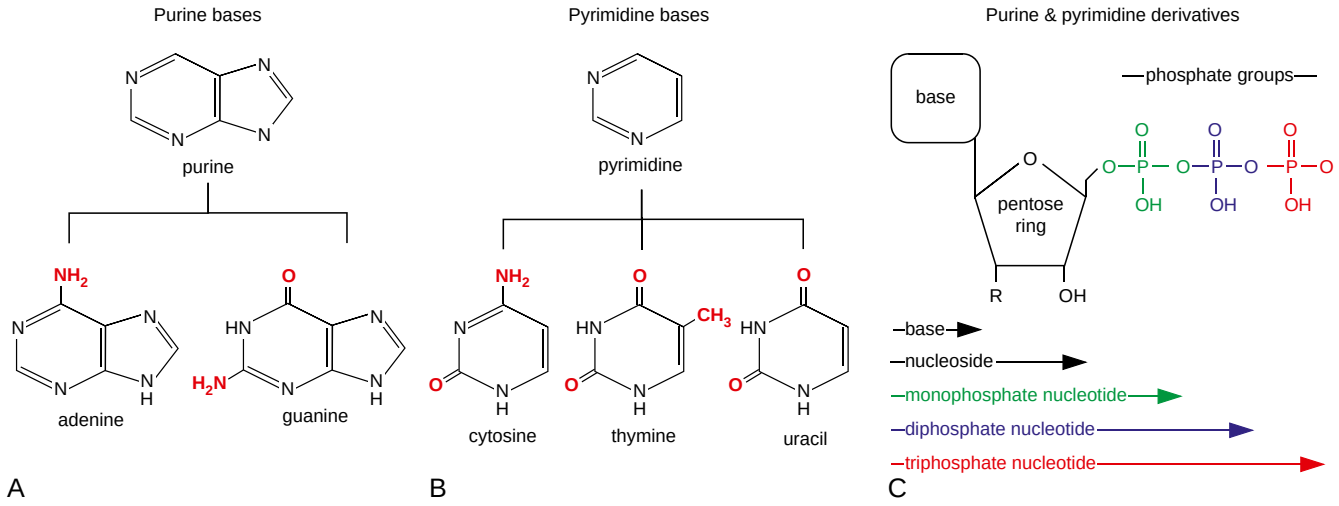

Fig. 110.1 The structure of purines and pyrimidines. A, The fundamental purine base and its variants adenine and guanine. B, The fundamental pyrimidine base and its variants cytosine, thymine, and uracil. C, The major purine and pyrimidine derivatives. Nucleosides are composed of a purine or pyrimidine base attached to a pentose ring. The R moiety in the pentose ring can be either an OH group (ribose for RNA) or a hydrogen (deoxyribose for DNA). Nucleotides are composed of a nucleoside attached to phosphate groups. (*Copyright H.A. Jinnah.*)

derivatives (see Fig. 110.1). Like the purines, the pyrimidines are key ingredients for nucleic acids. Nucleotide derivatives of cytidine are used to make DNA and RNA. Nucleotide derivatives of thymidine are used in DNA, but nucleotide derivatives of uridine replace thymidine in RNA.

The pyrimidines also have additional functions; CTP is used to make CDP-choline, an important intermediate in the production of membrane phospholipids such as phosphatidylcholine. UTP is used to make UDP-glucose, an intermediate used in the synthesis of glycogen, as well as other glycosylation reactions, to make glycolipids or glycoproteins. UTP is also used to make UDP-glucuronic acid, an intermediate used in the generation of glucuronide conjugates. Glucuronide conjugates of certain drugs and drug metabolites are excreted in the bile, and glucuronide conjugates of other endogenous biomolecules such as steroid hormones facilitate transport between tissues in the body.

The body's pyrimidine levels reflect a balance between synthesis, catabolism, and recycling. Pyrimidines are synthesized in a pathway that involves three enzymes which carry out six steps leading to the central metabolite UMP (Fig. 110.3). UMP can then be directed toward the synthesis of other pyrimidines. Pyrimidines are catabolized via several routes. Cytidine and uridine derivatives are both converted to uracil, and ultimately to β-alanine. Thymidine is converted to β-aminoisobutyrate. Both β-alanine and β-aminoisobutyrate serve as intermediates in the citric acid cycle. Free pyrimidines are also recycled at several steps by kinases that convert nucleosides to their corresponding nucleotides (see Fig. 110.3). Pyrimidine disorders are rare and clinically heterogeneous. The heterogeneity likely reflects the different functions of pyrimidines in different tissues combined with differences in the

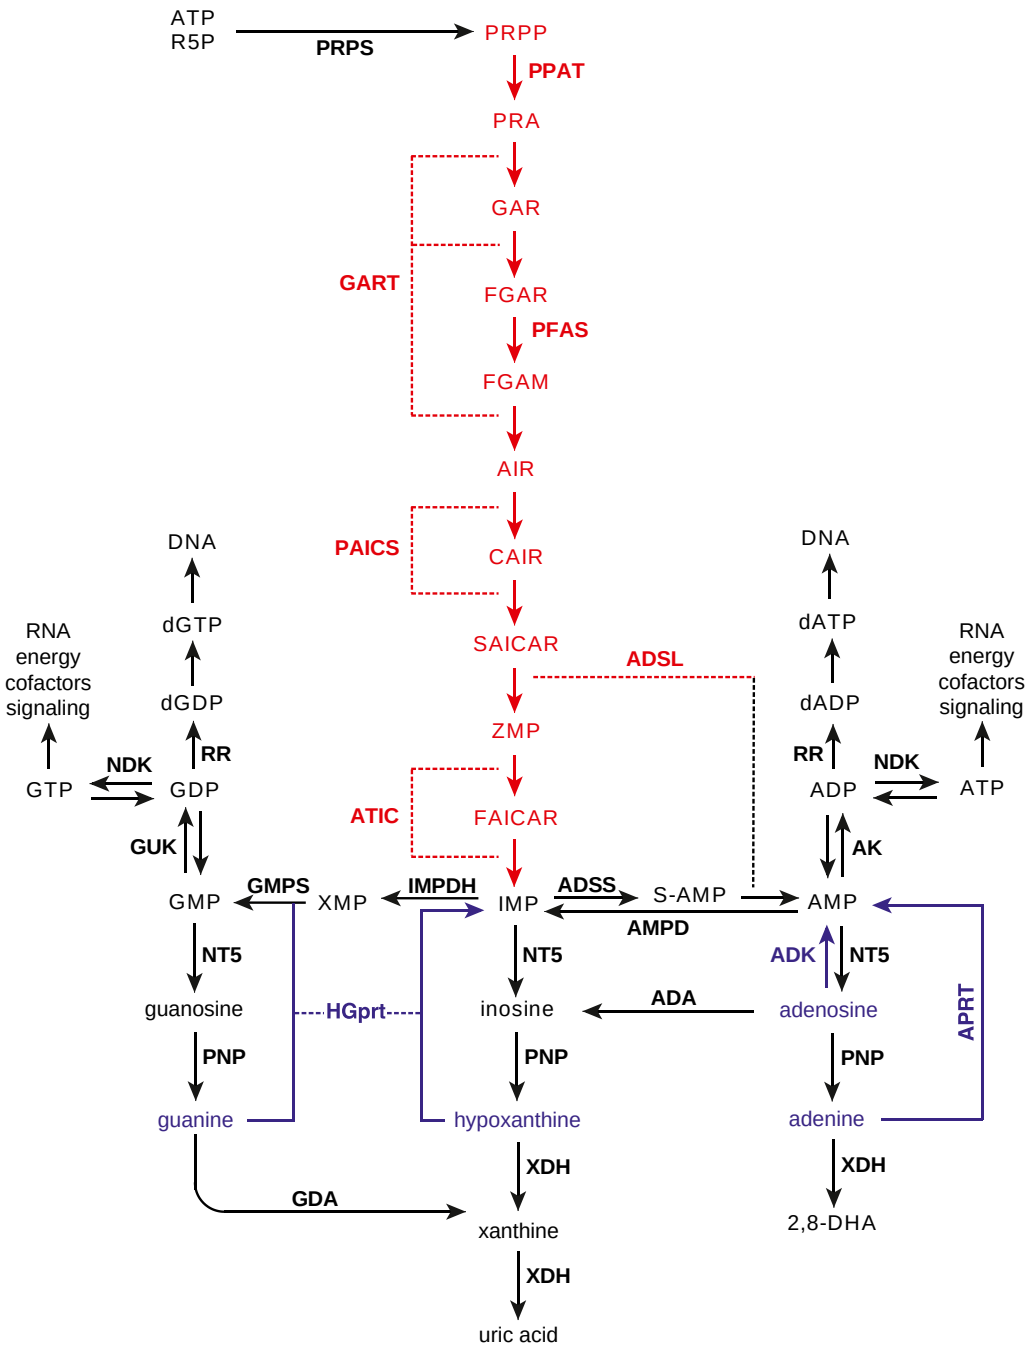

Fig. 110.2 Purine metabolism. The six enzymes and 10 reactions of de novo purine synthesis are shown in *red*. The two enzymes and three reactions of the salvage pathways are shown in *purple*. Enzyme gene names are shown in **bold font**, and metabolites are shown in regular font. For enzymes with multiple isoforms, only the core gene name is shown, without isoform numbers or letters. *Dashed lines* show enzymes with multiple functions. 2,8-DHA, Dihydroxyadenine; ADA, adenosine deaminase; ADP, adenosine diphosphate; ADK, adenosine kinase; ADSL, bifunctional adenylosuccinate lyase; ADSS, adenylosuccinate synthase; AICAR, aminoimidazole carboxamide ribotide; AMPD, adenylate deaminase; AMP, adenosine monophosphate or adenylate; APRT, adenine phosphoribosyltransferase; ATIC, bifunctional AICAR transformylase/IMP cyclohydrolase; AK, adenylate kinase; ATP adenosine triphosphate; CAIR, 5′-Phosphoribosyl-4-carboxy-5-aminoimidazole; dADP, deoxy adenosine diphosphate; dGDP, deoxy guanosine diphosphate; FAICAR, formylaminoimidazole carboxamide ribotide; GART, trifunctional phosphoribosylglycinamide formyltransferase/phosphoribosylglycinamide synthetase/phosphoribosylaminoimidazole synthetase; GDA, guanine deaminase (aka guanase or cypin); GDP, guanosine diphosphate; GMP, guanosine monophosphate or guanylate; GMPS, GMP-synthase; GTP, guanosine triphosphate; GUK, guanylate kinase; HGprt, hypoxanthine-guanine phosphoribosyltransferase; IMP, inosine monophosphate or inosinate; IMPDH, IMP-dehydrogenase; NDK, nucleoside diphosphate kinase; NT5, 5′-nucleotidase; PNP, purine nucleoside phosphorylase; PAICS, bifunctional phosphoribosylaminoimidazole carboxylase; PFAS, phosphoribosyl formylglycinamide synthase; PPAT, bifunctional phosphoribosylaminoimidazole carboxylase; PRA, 5-phosphoribosylamine; PRPP, phosphoribosylpyrophosphate; PRPS, PRPP-synthase; RR, ribonucleotide reductase; S-AMP, adenylosuccinate; SAICAR, succinylaminoimidazole carboxamide ribotide; XDH, xanthine dehydrogenase, xanthine oxidase, or xanthine oxidoreductase; XMP, xanthine monophosphate or xanthylate; ZMP, 5-aminoimidazole-4-carboxamide ribonucleotide or Z-nucleotide monophosphate. (*Copyright H.A. Jinnah.*)

expression levels of different enzymes in different tissues and sometimes tissue-specific isoforms of the same enzyme.

DISORDERS OF PURINE METABOLISM

Uric Acid

Serum uric acid levels reflect a balance among production, absorption, and excretion. Most uric acid is produced in the body as a by-product of purine metabolism (see Fig. 110.2). Some also comes from the diet, when DNA and RNA of foods are metabolized by the gut and liver. About two thirds of the body's uric acid is eliminated by the kidneys, with the remainder eliminated by the gut. Normal serum uric acid levels are age dependent. Relatively low levels in young children reach adult values by puberty. After puberty, serum uric acid is lower in females than in males.

In adults, numerous epidemiologic studies have linked abnormal serum uric acid levels with a large number of disorders. High levels of uric acid have been linked with gout, kidney disease, tophi, hypertension, diabetes mellitus, obesity, metabolic syndrome, heart disease, stroke, hemolytic anemia, Down syndrome, asthma, and others. Causal links between uric acid and disease with well-defined biologic mechanisms are well established for gout, kidney disease, and tophi. Low levels of uric acid have been linked with Parkinson disease, Alzheimer disease, multiple sclerosis, and other autoimmune disorders. For these disorders, uric acid has been proposed to have antioxidant properties, so chronically low levels may contribute to cell injury during aging.

In children, low (or even absent) levels of serum uric acid do not appear to have any detrimental clinical effects, but high levels cause problems. Uric acid is normally near its limits of solubility in the body, so even small increases risk precipitation in vulnerable regions. The joints are one of these vulnerable regions, because of the low pH of synovial fluid. Such precipitates can cause an inflammatory arthritis known as **gout**. These precipitates tend to occur in cool regions of the body, such as distal joints of the toes. The typical presentation of gout is acute inflammation of one joint, often the metatarsophalangeal joint of the large toe, although any joint can be involved. Uric acid crystals also precipitate in cool regions of the skin, forming tophi at tendon insertion points over joints or the pinna of the ear. These tophi appear as visible and palpable subcutaneous masses. Excess uric acid is concentrated by the kidneys in the renal collecting system, where high levels precipitate in two different ways. Microscopic crystals may produce an inflammatory nephropathy with painless chronic renal failure. Larger stones may cause urinary obstruction with acute renal colic, dysuria, hematuria, and recurrent urinary infections. These pathologies may also overlap in some cases.

Hyperuricemia and its pathologic consequences are common in adults, especially males. These problems often reflect an inherited predisposition for high uric acid together with lifestyle related to diet and exercise. Hyperuricemia and its consequences are very uncommon in children. Their occurrence in children often signifies an underlying disorder of purine metabolism. Uric acid is a component of many routine clinical chemistry screening panels. As a result, abnormal levels of uric acid often provide an early clue to one of these disorders (Table 110.2). Kidney stones are common in adults, but they are very uncommon in children. Nephrolithiasis and renal failure also provide an important clue to disorders of uric acid and some other disorders of purine and pyrimidine metabolism (Table 110.3). Some are rare inherited disorders affecting specific biochemical pathways; others are acquired or iatrogenic.

Individual Disorders

Individuals with **renal hypouricemia** have marked reductions in serum uric acid (<2 μg/dL or <120 μM) from birth. The disorder is autosomal recessive and caused by pathogenic variants in the *SLC22A12* or *SLC2A9* genes, which code for transporters important for renal retention of uric acid. Many affected individuals remain asymptomatic for life. Some experience renal impairments after strenuous exercise because physical activity is associated with increased purine turnover and transient elevations of serum uric acid. When a sudden bolus of uric acid after exercise is concentrated quickly in the renal collecting system, there is a transient risk for stones or "sludge" with nephropathy. This sludge reflects a somewhat viscous mixture of tiny stones and partly solubilized uric acid. Gout is uncommon in renal hypouricemia.

Familial juvenile hyperuricemic nephropathy is an autosomal dominant disorder that has been linked to pathogenic variants in *UMOD* (uromodulin), *REN* (renin), *MUC* (mucin), or *HNF*-1b (hepatocyte nuclear factor 1b). All of these genes encode proteins involved in renal handling of uric acid. Affected individuals present in childhood or adolescence with hyperuricemia, renal failure, and/or gout. Individuals with pathogenic variants in the *ABCG2* gene have reduced intestinal secretion of uric acid, along with chronic hyperuricemia and gout.

Overproduction of uric acid may also occur in inherited **disorders of carbohydrate metabolism**. They include disorders associated with pathogenic variants in *ALDOB* (aldolase B deficiency, hereditary fructose intolerance, fructosemia), *SLC37A4* (glucose-6-phosphatase deficiency, glycogen storage disease type I, or von Gierke disease), *AGL* (glycogen debranching enzyme deficiency, glycogen storage disease type III, or Cori disease), *PYGM* (muscle glycogen phosphorylase deficiency, glycogen storage disease type V, or McArdle disease), and *PFKM* (muscle phosphofructokinase deficiency, or glycogen storage disease type VII, or Tarui disease). These disorders may be associated with chronic or episodic hyperuricemia, sometimes with gout or renal impairments. Hyperuricemia is often triggered by exercise because the metabolic defect impairs energy metabolism during muscle activity and leads to catabolism of adenosine triphosphate (ATP).

Some disorders of uric acid are *acquired* rather than inherited. Because uric acid is eliminated largely by the kidneys, acute or chronic renal insufficiency may lead to hyperuricemia, which may be severe. A transient but marked elevation of serum uric acid may also occur in **tumor lysis syndrome**, where the treatment of hematologic malignancies is associated with sudden death of many cells in a short period, leading to generation of large amounts of DNA and RNA that are degraded into uric acid. The sudden bolus of uric acid is rapidly concentrated by the kidneys, leading to a risk for kidney stones, sludge, and renal failure. Relatively more modest increases in serum uric acid have been associated with other childhood disorders, including obesity, metabolic syndrome, Down syndrome, asthma, cyanotic congenital heart disease, chronic hemolytic anemia, and certain medications. Medications causing hyperuricemia include thiazide diuretics, cyclosporine, and some anticonvulsants (valproate and phenobarbital).

Treatment and Prognosis

All renal purine stones, including those made of uric acid, are radiolucent. Unless they calcify, they cannot be detected with plain films or CT, so diagnosis may require ultrasound. Stones passed in the urine may be collected and chemically analyzed. Treatment of small kidney stones may require analgesics for renal colic and/or antibiotics for associated urinary tract infection until the stones are eliminated in the urine. Larger kidney stones may obstruct the urinary collecting system and may require lithotripsy or surgical removal. Because uric acid is more soluble in an alkaline environment, alkalinization of the urine with potassium-sodium citrate or sodium bicarbonate may be useful for individuals at risk for recurrent stones.

The diagnosis of gout can be made finding typical birefringent crystals in an aspirate of joint fluid. Because purine stones are radiolucent, chronic tophaceous gout may have a punched-out appearance on plain films of the joints, where the uric acid crystals have eroded normal bone. The treatment of acute painful gout usually involves nonsteroidal antiinflammatory drugs. However, for both gout and renal stones, treatments directed at uric acid levels are essential to prevent recurrences that may lead to permanent joint damage or chronic renal insufficiency. Chronic hyperuricemia can be treated with three different strategies. One strategy is to increase renal excretion of uric acid with drugs such as probenecid, sulfinpyrazone, benzbromarone, or lesinurad. Another strategy is to use drugs that inhibit uric acid production by xanthine oxidoreductase (XOR) such as allopurinol, febuxostat, and topiroxostat. The third involves administration of recombinant uricase
