Temper tantrums are common during early childhood. They are typically developmentally normative expressions of children's frustration with their own limitations or anger about not being able to get their way. It is important for parents to recognize the different triggers for tantrums to determine the best course of action to prevent or manage this behavior as it arises. Dealing with tantrum behavior can become very frustrating for parents and these feelings should be validated, while also helping make sure parents are aware that many tantrums can be averted by awareness or attunement to certain cues given by their child. In particular, parents should be aware that when a child is tired, hungry, or has to make a transition, it can be expected that the child will be more likely to have a tantrum because limit setting or unmet expectations may feel particularly overwhelming in these circumstances. In this case, it is advised that parents plan ahead and take a preventive stance by being aware of triggers and minimizing the potential for a tantrum. Parents should not make a tired or hungry child accompany them on an extended outing unless absolutely necessary. Additionally, depending on the child's developmental level, it is helpful to have a clear discussion ahead of time about the expectations in certain scenarios. An example of setting expectations to help prevent a tantrum is: "When we go into the store I need you to (1) stay with me, (2) keep your hands to yourself, and (3) not whine for treats. If you can do these three things, we can pick one treat to bring home." When children are able to demonstrate good control, their behavior should be acknowledged, praised, and rewarded when appropriate. This will increase the likelihood that they will engage in the desired response more often, even in situations they find frustrating.

When children tantrum as an expression of anger or sadness in not getting their way, parents may feel inclined to give in or respond to the negative behavior with yelling or threats. Unfortunately, these responses can reinforce and even escalate the oppositional behavior. Parents should attempt to avert defiance by giving the child choices (e.g., you can walk to the car on your own two feet or I can carry you). Active ignoring can be used for mild tantrum behaviors because paying attention, even negative attention, can be reinforcing. If a child is tantruming in a way that is unsafe, they can be removed from the unsafe situation and given a consequence by being placed in time-out. If the tantrum was to avoid a task, the child should be required to complete the task once time-out is over.

Breath-holding spells occasionally occur during a tantrum and can be frightening to parents. These are reflexive events in which the crying child becomes apneic, pale, or cyanotic, may lose consciousness, and occasionally will have a brief seizure. Parents are best advised to ignore breath holding during a tantrum once it has started. Without reinforcement, breath-holding generally disappears.

Subtypes of breath-holding spells include cyanotic, pallid, or mixed episodes. Cyanotic spells are the dominant type. Pallid spells may be similar to vasovagal-related syncopal events in older children and may be initiated by similar stimuli. Iron deficiency with or without anemia may be present, and some children with breath-holding spells respond to iron therapy. There is no increased risk of seizure disorders in children who have had a short seizure during a breath-holding spell. Medical conditions to rule-out in breath-holding spells (usually pallid) include seizures, Chiari crisis, familial dysautonomia, cardiac arrhythmias, cataplexy, hereditary hyperekplexia, and other central nervous system lesions.

The first key to the management of temper tantrums and breath-holding spells is to help parents intervene before the child is highly distressed. The parent can be instructed to calmly remind the child of the expected behavior and the potential consequence if the expected behavior does not occur. In addition, distraction to another activity or conversation may help. If the child does not comply, he or she should be placed in time-out for a period approximating 1 min for each year of age. Parents should state the reason the child is being placed in time-out beforehand in a calm and neutral tone, but they should not discuss the reasons during time-out. Once the time-out is over and the child is calm, it may be helpful for parents to discuss with the child the reasons for the child's frustration and their expectations for how the child will respond in the future.

Time-out can be effectively used in children up to approximately 10 years of age. Parents should also be advised to be mindful of their own reactions to their child's tantrum behavior to avoid an escalation of the child's behavior caused by an angry parental response.

If behavioral measures such as time-out fail, pediatricians must assess other aspects of parent–child interactions, such as the frequency of positive interactions, the consistency of parental responses to child behavior, and the ways that parents handle anger, before making further recommendations. In the absence of frequent positive parent–child interactions, time-out may not be effective, and inconsistent responding to problem behavior increases the likelihood of the negative behavior continuing. Children can be frightened by the intensity of their own angry feelings and by angry feelings they arouse in their parents. Parents should model the anger control that they want their children to exhibit. Some parents are unable to see that if they lose control themselves, their own angry behavior does not help their children to behave differently. Advising parents to calmly provide simple choices will help the child to feel more in control and to develop a sense of autonomy. Providing the child with options also typically helps reduce the child's feelings of anger and shame, which can later have adverse effects on social and emotional development. Providing choice also reduces power struggles between the parent and child and can aid in enhancing the parent–child relationship and building problem-solving skills.

When tantrum behavior, including breath holding, does not respond to parent coaching or is accompanied by head banging or high levels of aggression, referral for a mental health evaluation is indicated. Further evaluation is also recommended if tantrum behavior persists into the latency period and preteen years.

Chapter 44

Lying, Stealing, and Truancy

Keneisha R. Sinclair-McBride, Erica H. Lee, David R. DeMaso, and Heather J. Walter

Young children lie for a multitude of reasons. Lies for this age group can be considered developmentally normative attempts at understanding language, communication, rules, and expectations. In early childhood, lying often occurs as a child experiments with language. By observing the reactions of parents, preschoolers learn about expectations for honesty in communication. Lying can also be a form of fantasy for children, who often describe things as they wish them to be rather than as they are. To avoid an unpleasant confrontation, a child who has not followed a rule or met an expectation may lie. At this stage, children often do not understand that lying only postpones a confrontation. Parents should keep in mind that lying behavior in this age group is rarely malicious or premeditated.

In *older children*, lying is generally an effort to cover up actions that do not fit into the child's conceptualization of themselves. Children in this age group may lie as an attempt to maintain self-esteem. Of course, lying is also often used to avoid a negative consequence for misbehavior. Older children are also more likely to intentionally leave out critical parts of a story in an attempt to deceive or avoid a negative consequence. Lying can also be promoted by poor adult modeling. Many children and adolescents lie to avoid adults' disapproval. If children and teens are responded to in harsh and punitive ways, they may lie to avoid this. Alternatively, lying may be used as a method of rebellion, especially in adolescence. Lying about forbidden activities, social media use, or other behaviors may be an attempt to continue to break the rules without detection. Chronic lying can occur in combination with several other antisocial behaviors and is a sign of underlying psychopathology or family dysfunction.

Parents should address lying by giving the child a clear message of what is acceptable. Sensitivity and support combined with limit setting are necessary for a successful intervention. Although habitual lying can become frustrating for parents, they should be discouraged from making accusations or focusing on catching their child in a lie and instead should work toward creating an atmosphere that makes it easier for their child to tell the truth. Parents should let the child know that telling the truth about a difficult situation will allow the parents to help them better problem-solve the issue at hand. Should a situation arise where a child has lied and the parents are aware of the true details, the lie should be confronted while providing the facts of what is known and also stating the desired or expected behavior. This should be done in a calm, neutral manner. For example, if a parent is aware that a child played video games instead of doing homework and the child denies it, the parent can state, "I notice that your homework is incomplete and that you are playing without permission. Our rule is that you complete homework first. There will be no more video games for the rest of the week." This response reminds the child how he can meet his goals in an acceptable way and an appropriate consequence can then be given. Parents should be encouraged to address the expectations for their home and children in a family meeting or in regular discussions with their child outside the context of the child's lying.

Regardless of age or developmental level, when lying becomes a common way of managing conflict, intervention is warranted. If this behavior cannot be resolved through the parents' understanding of the situation and the child's understanding that lying is not a reasonable alternative, a mental health evaluation is indicated.

STEALING

Many children steal something at some point in their lives. Often, when very *young children* steal, the behavior is an impulsive action to acquire something they want. A common example is the child who takes candy or a toy from the store shelf. If a parent notices this behavior, they can use the situation as a teaching opportunity to explain that community and family expectations are that we have to pay for things at the store and not take them without permission. It should not be expected that a very young child will be aware of all the rules around shopping or stealing. It may also be difficult for a child who has been used to being able to freely take whatever she wants to be aware of all the expected behaviors across different settings. When preschoolers and school-age children begin to steal frequently even after they have been told not to, the behavior may be a response to stressful environmental circumstances and requires further exploration and evaluation.

For some *older children*, stealing can be an expression of anger or revenge for perceived frustrations with parents or other authority figures. In such instances, stealing becomes one way the child and adolescent can manipulate and attempt to control their world. Stealing can also be learned from adults. Some children will report that the behavior is "exciting" for them, and they may also engage in the behavior for peer approval. In some cases, youth living in poverty may engage in the behavior as a survival mechanism.

Kleptomania, an impulse-control disorder, may begin in adolescence and is characterized by an intense impulse to steal objects that may not be rationally needed by the patient. There are often comorbid disorders such as anxiety, eating disorders, substance misuse, and depression. Treatment includes cognitive-behavioral therapy (CBT) in addition to various drugs such as lithium, naltrexone, and selective serotonin reuptake inhibitors (SSRIs).

Parents should work with their children to rectify stealing through restitution. Parents should require that their child return stolen items or pay for them with their own money (i.e., allowance or gift money). When this is not possible, another reasonable consequence should be given, such as losing a privilege or completing additional chores. When stealing is part of a pattern of broader conduct problems, referral for a mental health evaluation is warranted.

TRUANCY

Truancy and running away are never developmentally appropriate. Truancy may represent an unsafe environment of disorganization within the home including lack of appropriate supervision or older children being required to caretake for younger siblings. Truancy can also be a sign of developing conduct problems or behavioral health problems including depression or anxiety. When truancy occurs in younger children, there are usually psychosocial concerns with the parents or adult caretakers in the home that prevent them from following through with the required demands of getting their children to school each day. Families struggling with housing and food insecurity may have difficulties having their children attend school regularly. Parents with intellectual disability or their own mental health or substance abuse problems may become overwhelmed with managing the home and caring for their children; thus they might not consistently ensure their child gets to school. In addition, children might decide to remain at home to take care of parents who are impaired.

Truancy is more common in *preteens and adolescents* and can be a function of multiple factors, including but not limited to learning difficulties, social anxiety, depression, traumatic exposure, bullying, peer pressure, and substance use. In any of these cases, the child should be referred for further evaluation to assess the barriers to returning to school. Best practices for dealing with truancy resulting from school avoidance and anxiety include addressing the underlying psychologic symptoms causing the school avoidance and empowering parents, children, and school staff to work on a consistent plan for a return to school.

Younger children may threaten running away out of frustration or a desire to "get back at" parents. Older children who run away are almost always expressing a serious underlying problem within themselves or their family, including violence, abuse, and neglect. Adolescent runaways are at high risk for substance abuse and other risk-taking behaviors as well as at risk for being victims of abuse (e.g., sexual exploitation).

Youth exhibiting truancy or running away should be referred for a mental health evaluation.

Chapter 45

Aggression

Keneisha R. Sinclair-McBride, Erica H. Lee, David R. DeMaso, and Heather J. Walter

Aggressive behavior is a serious symptom associated with significant morbidity and mortality. Early intervention is indicated for persistent aggressive behavior given that children may not simply "grow out of" this pattern of behavior. Aggressive tendencies are heritable, although environmental factors can promote aggression in susceptible children. Both enduring and temporary stressors affecting a family can increase aggressive behavior in children. Aggression in childhood is correlated with both poverty and chaotic family situations, including chronic unemployment, family discord, and exposure to community and domestic violence, criminality, and psychiatric disorders. Children born to teenage mothers and parents with limited resources and support are also at risk. Males are reported to be more aggressive than females. A difficult temperament and later aggressiveness are related. When children with temperament difficulties are responded to with punitive discipline strategies within the family environment, it can set up a cycle of increasing aggression. Aggressive children often misinterpret social cues in such a way that they perceive hostile intent in ambiguous or benign interactions, and then may react with verbal or physical aggression toward peers and parents.

It is important to differentiate the causes and motives for childhood aggression. Intentional aggression may be primarily instrumental (i.e., to achieve an end), primarily hostile (i.e., to inflict physical or psychologic pain), or primarily impulsive. Impulsive aggression can often be effectively managed with simple behavioral interventions at home. Children who are callous, not empathetic, and more consistently aggressive require intervention in the specialty mental health setting (see Chapter 42). These children are at high risk for suspension from school and eventual school failure. Because learning disorders are common in this population, aggressive children should be referred for screening. Aggressive behavior is often present in a variety of other psychologic conditions, including attention-deficit/hyperactivity and oppositional defiant, intermittent explosive, conduct, and disruptive mood dysregulation disorders (see Chapters 39 and 42).

Aggressive behavior in males is relatively consistent from the preschool period through adolescence. Without effective intervention, a male with a high level of aggressive behavior between 3 and 6 years of age has a high probability of carrying this behavior into adolescence. The developmental progression of aggression among females is less well studied. Fewer females show physically aggressive behavior in early childhood. However, interpersonal coercive behavior, especially in peer relationships, is seen in females. This behavior may be related to the development of physical aggression for females in adolescence (e.g., fighting) or other conduct problems (e.g., stealing).

Children exposed to aggressive models on television, in video games, or in play have more aggressive behavior compared with children not exposed to these models. Parents' anger and aggressive or harsh punishment can model behavior that children may imitate when they are physically or psychologically hurt. Parents' abuse may be transmitted to the next generation by several modes: children imitate aggression that they have witnessed; abuse can cause neurologic damage, which itself predisposes the child to violence; and internalized rage often results from abuse.

Aggressive behavior in youth is often oriented toward peers through bullying (see Chapter 15.1). Although it is developmentally normative for children to engage in some teasing behavior, bullying has a more serious tone. Bullying is defined as unwanted aggressive behavior in which there is a real or perceived imbalance of power or strength between the bully and the victim. Typically, it involves a pattern of behavior repeated over time. Although most often perceived as physical aggression, bullying can take on a variety of forms, including relational bullying, the most common form engaged in by females. Cyberbullying is a particular risk during the middle and high school years because of increased exposure and access to multiple social media platforms at this developmental stage. Parents should be advised to closely monitor their child's social media and maintain open communication with their children. Children may bully others because of impulse-control and social skills deficits, strong need for power and negative dominance, satisfaction in causing harm to others, or psychologic or material rewards. Children who bully are at risk for a variety of negative school and psychologic outcomes.

Victims of bullying are particularly at risk for negative outcomes, especially if the behavior is not addressed by adults. Victimization experiences are associated with school avoidance and school dropout, social isolation, somatic symptoms, and increased psychologic problems such as depression and anxiety. There have been numerous cases of suicide in children who reported a prior history of being bullied. Should a concern arise around bullying in the school setting, parents should be advised to reach out to their child's teacher, school counselor, and school administrative staff to have the bullying behavior addressed. Many schools also have a bullying intervention protocol that can be implemented, and state departments of education have antibullying policies with formal protocols to address concerns. Given the significant psychologic risks for both victims and perpetrators of bullying, it is essential that all children who are persistently involved in these incidents be referred for mental health evaluation.

Chapter 46

Self-Injurious Behavior

Kiera M. James and Molly C. Adrian

Self-injurious behaviors, or deliberate engagement in self-inflicted harm, comprise both **suicidal behaviors** and **nonsuicidal self-injury (NSSI)** (see Chapter 40). NSSI, specifically, involves intentional self-inflicted damage to bodily tissue without the intent to die, though it can unintentionally result in significant harm or even death.

Suicidal behaviors and NSSI are both transdiagnostic behaviors occurring in the context of numerous psychiatry disorders as well as in the absence of any diagnosis at all. Nonetheless, the vast majority of youth who engage in NSSI meet diagnostic criteria for a psychiatry disorder. Self-injurious behavior may also be associated with developmental disabilities often as a manifestation of stereotypic movement disorder (Chapter 37.2).

Chapter 45

Aggression

Keneisha R. Sinclair-McBride, Erica H. Lee, David R. DeMaso, and Heather J. Walter

Aggressive behavior is a serious symptom associated with significant morbidity and mortality. Early intervention is indicated for persistent aggressive behavior given that children may not simply "grow out of" this pattern of behavior. Chapter 46

Self-Injurious Behavior

Kiera M. James and Molly C. Adrian

Self-injurious behaviors, or deliberate engagement in self-inflicted harm, comprise both **suicidal behaviors** and **nonsuicidal self-injury (NSSI)** (see Chapter 40). NSSI, specifically, involves intentional self-inflicted damage to bodily tissue without the intent to die, though it can unintentionally result in significant harm or even death.

Suicidal behaviors and NSSI are both transdiagnostic behaviors occurring in the context of numerous psychiatry disorders as well as in the absence of any diagnosis at all. Nonetheless, the vast majority of youth who engage in NSSI meet diagnostic criteria for a psychiatry disorder. Self-injurious behavior may also be associated with developmental disabilities often as a manifestation of stereotypic movement disorder (Chapter 37.2).

Although NSSI and suicidal behavior are distinct constructs based on the *intent* of the behavior, they are also highly comorbid. Research exploring the attitudes of youth who have engaged in NSSI indicates that there is a strong identification with suicide and death for this population, which makes NSSI a significant clinical issue and risk factor that cannot be ignored or minimized. Although some youth engage in repeated NSSI without ever attempting suicide, studies suggest that 50–75% of adolescents who have a history of NSSI will make a suicide attempt at some point.

NSSI has been documented in children as young as 7 years of age, with rates increasing from childhood (~8%) to adolescents (~18%), and decreasing during adulthood (~5.5%). Although traditionally thought to be more prevalent in females than males, NSSI occurs in both sexes. Emerging research suggests that, if present at all, gender differences in rates of NSSI are more likely in clinical than community populations. Notably, however, rates of NSSI are particularly high among transgender and gender nonconforming teens with up to 55% reporting past-year engagement in NSSI. There are no significant ethnicity or class differences among youth who engage in NSSI. Youth identified as those with the highest risk include females ages 15-19 and males 20-24.

Cutting is the most commonly reported form of NSSI. For those youth who engage in NSSI for the first time, approximately 20% will repeat the behavior within the same year; cutting is the most commonly repeated method of NSSI. Other methods of NSSI include scratching, burning, carving, piercing, hitting or punching, biting, picking at wounds, and digging nails into the skin. The most common areas of injury are the arms, legs, and torso, though NSSI may also occur on other parts of the body (e.g., breasts, genitals, groin, neck). Objects used in cutting include razors, scissors, broken glass, hard plastic, knives, staples, paper clips, or any other objects sharp enough to cause injury. Importantly, there are gender differences in methods such that females are more likely to engage in cutting, scratching, biting, hair pulling, and wound picking whereas males are more likely to engage in burning and self-battery, including hitting and head banging.

Youth often report exposure to NSSI before engaging in the behavior. Some youth report that they have friends who self-injure (e.g., cut) to attempt to alleviate negative emotions. Others may view stories of their peers' engagement in NSSI on websites and social media. Impressionable youth have also reported learning about NSSI for the first time from celebrities who have engaged in the behavior.

NSSI is associated with depression, anxiety, peer (bullying) victimization, social isolation, low self-esteem, substance abuse, eating disorders, impulsivity, poor school performance, delinquency, and neglectful or highly punitive parenting practices, as well as trauma, including a history of physical or sexual abuse. The behavior may begin as an impulsive response to internal distress for younger children, but for those who are older, the behavior can take on a self-reinforcing function. Youth may feel a sense of *relief* or *mastery* over negative emotions once the behavior has been completed. Some youth report that they engage in NSSI when feeling intense negative emotions, overwhelmed, or panicked to regulate their emotions. Others engage in the behavior when they are feeling numb, to "feel something" again. NSSI may also serve as a *distraction* from emotional pain, provide a sense of *control* over the body, or be used as a form of *self-punishment* for a perceived wrongdoing. NSSI may also function to *communicate* distress or strength or provide peer group *affiliation*. Youth often report that they are unable to resist the urge to engage in the behavior and will continue to feel increasing levels of distress until they engage in NSSI. Others plan or schedule the behavior, building it into their routine. Youth who view NSSI as an effective, private, and necessary coping strategy tend to have more dependence on the behavior and more resistance to stopping it.

Some adolescents and young adults engage in repeated NSSI for years without disclosing the behavior. Due to the shame associated with this stigmatized behavior, youth will often go to great lengths to keep it a secret. Some wear bracelets to cover scars on their arms or wear long sleeves in summer to hide the scarring. They report feeling ashamed of the behavior and fear rejection or disappointment from family and friends should they find out. At times, fear of being rejected or a disappointment to others can increase feelings of depression and anxiety and can serve to perpetuate the behavior. In contrast, others are more open about showing their scars and sharing their behavior with others. In either case, the behavior is a way to communicate or manage some level of *distress*. Many youth who engage in NSSI may never be seen in a hospital emergency department or by a mental health professional. Factors that protect against engagement in NSSI include a lack of awareness of, or exposure to, NSSI; an aversion to physical pain; an aversion to NSSI-related stimuli (e.g., blood); a positive view of the self; the use of other more adaptive emotion regulation strategies; and social norms. *Youth with repetitive NSSI should be referred to behavioral health services.* Effective treatment strategies include conducting a functional analysis around NSSI behavior, identifying and teaching alternative emotion regulation strategies, and reducing access to means to harm oneself. Reduction of NSSI has been observed with dialectical behavior therapy for adolescents, cognitive-behavioral therapy, cognitive analytic therapy, and mentalization-based therapy for adolescents. There are no psychopharmacologic treatments that have demonstrated efficacy; thus behavioral approaches should be prioritized.

Parents should be advised to monitor youth social media access and be aware of their peer group. Maintaining open communication can assist parents in recognizing an increase in concerning behaviors or patterns of behaviors. Parents should talk with their child about strategies for managing strong emotions and provide emotion coaching to support their child through experiences of distress. They should also be encouraged to talk with their child about their use of and exposure to drugs and alcohol as substance use can be associated with NSSI. Learning that their child has been engaging in self-injury can be frightening for parents because they are unsure of what to do or why their child is engaging in this behavior. It is important that parents receive psychoeducation about NSSI to reduce common misconceptions that make it difficult to understand their child's engagement in NSSI and respond effectively. Such information should be digestible and accurate, including written suggestions and examples. Parents should also seek mental health services for their child. *It is recommended that the child receive a full assessment for risk of suicide when NSSI is a concern.*

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) has classified NSSI as a condition requiring further study before consideration for possible placement in forthcoming editions of DSM. Proposed diagnostic criteria include self-inflicted injury without suicidal intent occurring on 5 or more days in the past year, with lack of suicidal intent either stated by the individual or inferred by the individual's repeated engagement in a behavior not likely to result in death. The individual expects that the self-injurious behavior will relieve a negative feeling or thought, resolve an interpersonal difficulty, or induce a positive feeling state. The self-injurious behavior is associated with interpersonal difficulties or negative feelings or thoughts, preoccupation with the intended behavior that is difficult to control, or frequent thoughts about the intended behavior. The proposed criteria also specify that the behavior is not socially sanctioned (e.g., body piercing, tattooing) and is not restricted to skin picking or nail biting. The behavior must be associated with significant *distress* or functional impairment.

Chapter 47

Childhood Psychoses

Jennifer A. Zaspel and Rosa K. Kim

Psychosis is a severe disruption of thought, perception, and behavior resulting in *loss of reality testing*. Psychosis can occur as part of a mood disorder, such as major depressive disorder or bipolar I disorder; between mood disorder episodes, as in schizoaffective disorder; or without mood disorder episodes, as in schizophrenia. Transient psychotic episodes can arise during times of psychologic or physiologic stress in patients who are vulnerable because of personality, developmental, or genetic disorders. **Positive symptoms**, including delusions, hallucinations, disorganized thinking, and grossly disorganized behavior, are key features that define psychoses across disorders, likely because of shared pathophysiologic mechanisms. **Negative symptoms**, on the other hand, are most typical of schizophrenia.

Delusions are fixed, unchangeable, false beliefs held despite conflicting evidence. They may include a variety of themes, including persecutory, referential (the belief that irrelevant events or details in the world are related directly to oneself), somatic, religious, and grandiose. Delusions are considered bizarre if they are clearly implausible. **Hallucinations** are vivid, clear, perceptual disturbances that occur without external stimulus and have the full force and impact of normal perceptions. They may occur in any sensory modality; auditory hallucinations are the most common associated with psychosis. **Disorganized thinking** is inferred from an individual's speech by examining their thought process and thought content and is typically severe enough to impair one's ability to communicate. **Grossly disorganized behavior** may range from childlike silliness to unpredictable agitation to catatonic behavior. **Negative symptoms** include diminished emotional expression, avolition (decreased drive to perform purposeful tasks), alogia (lack of speech), anhedonia, and social withdrawal. Negative symptoms account for a substantial portion of the long-term morbidity associated with schizophrenia.

Given the centrality of hallucinations and delusions in making a diagnosis of a psychotic illness, their differentiation from developmentally normal fantasy is essential. When children are imagining, they control the fantasy and do not have the perceptual experience of seeing and hearing. When children are hallucinating, they do not control the hallucination. Almost two thirds of children will endorse at least one psychotic-like experience, most often a hallucination. When not persistent or accompanied by distress, these experiences are not usually a cause for concern. The largest population-based study to date evaluating psychotic symptoms and neurocognition in youth 11-21 years old found that those who endorsed more psychotic-like experiences than is typical for their age had reduced accuracy across neurocognitive domains, reduced global functioning, and increased risk of depression, anxiety, behavioral disorders, substance use, and suicidal ideation. Thus psychotic-like symptoms that are frequent, distressing, and cause impairment signal a need for further evaluation and monitoring; however, only a small minority of these children will develop persisting psychotic illnesses.

47.1 Schizophrenia Spectrum Disorders

Jennifer A. Zaspel and Rosa K. Kim

Schizophrenia spectrum and other psychotic disorders as described in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) include brief psychotic disorder, schizophreniform disorder, schizophrenia, schizoaffective disorder, substance/medication-induced psychotic disorder, psychotic disorder caused by another medical condition, catatonia associated with another mental disorder, catatonic disorder due to another medical condition, unspecified catatonia, delusional disorder, schizotypal personality disorder, and other specified/unspecified schizophrenia spectrum and other psychotic disorders.

DESCRIPTION

The **schizophrenia spectrum** and other psychotic disorders are primarily characterized by the presence of symptoms of psychosis, specifically delusions, hallucinations, disorganized speech, or grossly disorganized or catatonic behavior, and negative symptoms. **Brief psychotic disorder** is characterized by the duration of one or more of these symptoms for at least 1 day but less than 1 month followed by complete resolution. Emergence of symptoms may or may not be preceded by an identifiable stressor (Table 47.1). Although brief, the level of impairment in this disorder may be severe enough that supervision is required to ensure that basic needs are met and that the individual is protected from the consequences of poor judgment and cognitive impairment.

If two or more psychotic symptoms persist for between 1 and 6 months, the condition is called **schizophreniform disorder** (Table 47.2). To meet DSM-5 criteria for **schizophrenia**, two or more psychotic symptoms must have been present for a significant portion of time for at least 1 month (unless suppressed by treatment), and the level of psychosocial functioning must either be markedly below the level achieved before the onset or there is failure to achieve the expected level of functioning. In addition, there must be continuous signs of the disturbance for at least 6 months (Table 47.3).

Individuals with schizophrenia can display inappropriate affect, dysphoric mood, disturbed sleep patterns, and lack of interest in eating, or food refusal. Depersonalization, derealization, somatic concerns, and anxiety and phobias are common. Cognitive deficits are observed, including decrements in declarative memory, working memory, language function, and other executive functions, as well as slower processing speed. These individuals may have no

Table 47.1 DSM-5 Diagnostic Criteria for Brief Psychotic Disorder

A. Presence of one (or more) of the following symptoms. At least one of these must be (1), (2), or (3):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (e.g., frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior

Note: Do not include a symptom if it is a culturally sanctioned response.

B. Duration of an episode of the disturbance is at least 1 day but less than 1 mo, with eventual full return to premorbid level of functioning.

C. The disturbance is not better explained by major depressive or bipolar disorder with psychotic features or another psychotic disorder such as schizophrenia or catatonia, and is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

With marked stressor(s) (brief reactive psychosis): If symptoms occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

Without marked stressor(s): If the symptoms do not occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

With postpartum onset: If onset is during pregnancy or within 4 wk postpartum.

Table 47.2 DSM-5 Diagnostic Criteria for Schizophreniform Disorder

A. Two (or more) of the following, each present for a significant portion of time during a 1 mo period (or less if successfully treated). At least one of these must be (1), (2), or (3):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (e.g., frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (i.e., diminished emotional expression or avolition)

B. An episode of the disorder lasts at least 1 mo but less than 6 mo. When the diagnosis must be made without waiting for recovery, it should qualified as "provisional."

C. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

D. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

With good prognostic features: This specifier requires the presence of at least two of the following features: onset of prominent psychotic symptoms within 4 wk of the first noticeable change in usual behavior or functioning; confusion or perplexity; good premorbid social and occupational functioning; and absence of blunted or flat affect.

Without good prognostic features: This specifier is applied if two or more of the previous features have not been present.

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. pp 96–97. Copyright 2013. American Psychiatric Association.

Table 47.3 DSM-5 Diagnostic Criteria for Schizophrenia

A. Two (or more) of the following, each present for a significant portion of time during a 1 mo period (or less if successfully treated). At least one of these must be (1), (2), or (3):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (e.g., frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (i.e., diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 mo. This 6 mo period must include at least 1 mo of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

F. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least a month (or less if successfully treated).

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. pp 99–100. Copyright 2013. American Psychiatric Association.

insight or awareness of their disorder, which is a predictor of nonadherence to treatment, higher relapse rates, and poorer prognosis. Hostility and aggression can be associated with schizophrenia, although spontaneous or random assault is uncommon. Aggression is more frequent for younger males and for individuals with a history of violence, nonadherence with treatment, substance abuse, and impulsivity.

The essential features of schizophrenia are the same in childhood as in adulthood, but it is more difficult to make the diagnosis. In children, delusions and hallucinations may be less elaborate, visual hallucinations may be more common, and disorganized speech may be better attributed to an autism spectrum or communication disorder. In youth with schizophrenia, the most frequent psychotic symptoms are auditory hallucinations (82%), delusions (78%), thought disorder (66%), disorganized or bizarre behavior (53%), and negative symptoms (50%). Childhood-onset schizophrenia tends to represent a more severe form of the disorder spectrum, with more genetic risk factors, more brain abnormalities, and more prominent prepsychotic developmental disorders.

EPIDEMIOLOGY

Brief psychotic disorder is reported to account for 9% of first-onset psychosis in the United States and is more common in females than males. The incidence of schizophreniform disorders in the United States appears as much as fivefold less than that of schizophrenia. The lifetime prevalence of schizophrenia is approximately 0.3–0.7%, although variations are reported by race/ethnicity, across countries, and by geographic origin for immigrants. The male-to-female ratio is approximately 1.4:1. Males generally have poorer premorbid adjustment, lower educational achievement, more prominent negative symptoms, and more cognitive impairment than females. Childhood (preadolescent)-onset is exceedingly rare, with an incidence of less than 0.04%, and 2:1 ratio in males versus females.

CLINICAL COURSE

Brief psychotic disorder most often appears in adolescence or early adulthood, with the average age of onset in the mid-30s but can occur throughout the life span. A diagnosis of brief psychotic disorder requires *full remission* within 1 month of onset and gradual return to premorbid level of function. The age of onset of schizophreniform disorder is similar to that of schizophrenia. Recovery from an episode of the disorder is within 6 months; however, about 65% of patients relapse and eventually receive a diagnosis of schizophrenia or schizoaffective disorder. Abrupt onset, confusion, absence of blunted affect, and good premorbid functioning predict a better outcome in schizophreniform disorder.

Schizophrenia typically develops between the late teens and the mid-30s; onset before adolescence is rare. The peak age at onset for the first psychotic episode is in the early to mid-20s for males and in the late 20s for females. The onset may be abrupt or insidious, but most individuals manifest a slow and gradual development of symptoms, with about 50% of individuals complaining of depressive symptoms. The predictors of course and outcome are largely unexplained. The course is favorable in approximately 20% of cases; a small number of individuals are reported to recover completely. However, many remain chronically ill, with exacerbations and remissions of active symptoms, whereas others experience

progressive deterioration. Most individuals diagnosed with schizophrenia require some form of daily living support. Positive symptoms tend to diminish over time, and negative symptoms are the most persistent, along with cognitive deficits.

It is important to recognize hallmark phases in the assessment and management of schizophrenia. In the **prodrome phase**, most patients experience functional deterioration over the course of months (e.g., social withdrawal, idiosyncratic preoccupations, unusual behaviors, academic failure, deteriorating self-care skills, and/or dysphoria) before the onset of overt psychotic symptoms. The **acute phase** is characterized by prominent positive symptoms and deterioration in functioning and is the phase in which most patients present for care. During the **recovery phase**, negative symptoms and disorganization may persist as active psychosis remits. The **residual phase** has minimal to no positive symptoms, although negative symptoms may cause continued impairment. Some patients will experience **chronic impairment** despite adequate treatment.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for the psychotic disorders is broad and includes reactions to substances/medications (dextromethorphan, LSD, hallucinogenic mushrooms, psilocybin, peyote, cannabis, stimulants, inhalants, corticosteroids, anesthetics, anticholinergics, antihistamines, amphetamines); medical conditions causing psychotic-like symptoms (Table 47.4; see Table 32.4); and other psychiatric disorders (depressive, bipolar, obsessive-compulsive, factitious, body dysmorphic, posttraumatic stress, autism spectrum, communication, personality). The differential diagnosis can be difficult because many conditions that can be mistaken for psychosis also increase the risk for it.

There are many indications that suggest psychotic symptoms may be related to a physical illness rather than a primarily psychiatric illness (Table 47.5). When psychotic symptoms are caused by identifiable medical conditions, there are often impairments in attention, orientation, recent memory, and intellectual function. Hallucinations associated with medical illness are more often tactile or visual, whereas auditory hallucinations are more common in primary psychotic disorders. Patients whose hallucinations are caused by medical illness are more likely to recognize that they do represent reality. A positive family or prior personal history of psychosis or other serious psychiatric illnesses is less likely to be present.

Autoimmune encephalitis caused by anti–*N*-methyl-D-aspartate (NMDA) receptor or other autoantibodies may manifest with psychosis, anxiety, depression, agitation, aggression, delusions, catatonia, visual or auditory hallucinations, disorientation, and paranoia in combination with sleep disturbances, autonomic dysfunction, dyskinesias, movement disorders, seizures, memory loss, and a depressed level of consciousness (Fig. 47.1; see Table 32.5). The cerebrospinal fluid (CSF) and MRI are usually, but not always, abnormal. The constellation of a relatively rapid onset psychosis and encephalitic features should suggest the diagnosis, although at presentation, behavioral problems may be the dominant feature (see Chapter 638.4; Table 47.6). A small number of patients present with purely psychiatric symptoms without other neurologic findings.

Determining when identifiable medical conditions are causing delirium with prominent psychotic symptoms may be difficult

Table 47.4 Possible Causes of Secondary Psychosis

	EXAMPLES	INVESTIGATIONS
Trauma	Traumatic head injury	CT, MRI
Autoimmune disorders	Systemic lupus erythematosus, NMDA receptor encephalitis and others	Autoantibody titers
Cytogenetic/congenital disorders	Velocardiofacial syndrome, agenesis of corpus callosum	Karyotyping, MRI
Toxic/substance-induced disorders	PCP, MDMA, LSD, cannabis, alcohol, cocaine, synthetic cannabinoids (bath salts) Lead, mercury or arsenic poisoning, ginseng, St. John's Wort, ma huang	Careful medication history; urine screen for drugs, heavy metal screen; trial off the offending agent
Iatrogenic disorders	Antimalarials, steroids, isoniazid	Careful medication history; trial off the offending agent
Cerebrovascular disorders	Stroke, subdural hematomas	CT, MRI
Space-occupying disorders	Cerebral tumors	CT, MRI
Metabolic disorders	Pheochromocytoma, metachromatic leukodystrophy, Wilson disease, adult Tay-Sachs disease, acute intermittent porphyria	Urinary catecholamines; arylsulfatase-A levels, copper and ceruloplasmin levels
Dietary disorders	Pellagra, B_{12} deficiency; thiamine deficiency	B_{12}, folate, thiamine levels
Sepsis/infectious disorders	Neurosyphilis, toxoplasmosis, HIV disease, encephalitis	RPR to rule out syphilis; HIV antibody titers; glucose, protein in CSF
Unknown cause/degenerative/demyelinating disorders	Lewy body dementia, Parkinson disease, Huntington disease, multiple sclerosis, Friedreich ataxia	MRI, CT, EEG, evoked potentials
Seizure disorders	Partial complex seizures, temporal lobe epilepsy	EEG, including sleep deprivation; telemetric EEG as indicated
Endocrine disorders	Hyperthyroidism, hypothyroidism, hyperparathyroidism	Serum calcium, thyroid/parathyroid hormone levels

CSF, Cerebrospinal fluid; EEG, electroencephalography; LSD, lysergic acid diethylamide; MDMA, 3,4-methylenedioxy-*N*-methylamphetamine; NMDA, *N*-methyl-D-aspartate; PCP, phencyclidine; RPR, rapid plasma reagin.

Modified from Keshavan MS, Kaneko Y. Secondary psychoses: An update. *World Psychiatry*. 2013;12(1):4–15:Table 1, p 5.

Table 47.5 Red Flags and Features Suggesting Secondary Etiologies of Psychosis

ATYPICAL FEATURES
- Normal before event
- Very early (≤13 yr) age of onset
- Acute or subacute onset (days, ≤1 mo)
- Catatonia
- Dyskinesias
- Isolated misidentification delusion (Capgras syndrome)
- Depressed level of consciousness; disorientation; somnolence
- Cognitive and recent memory decline
- Poor orientation
- Intractability despite adequate therapy
- Rapidly progressive and/or fluctuating (polymorphic) symptoms
- Multimodal hallucinations: visual, auditory, olfactory, gustatory
- Poor response to antipsychotics

HISTORY
- Infectious prodrome (fever)
- New or worsening headache; change in headache pattern
- Paresthesias
- Past, current substance misuse
- Recent onset incontinence
- Anorexia/weight loss
- Risk factors for cerebrovascular disease or central nervous system infections
- Malignancy
- Immunocompromised status
- Head trauma
- Seizures
- Hepatobiliary disorders
- Systemic lupus erythematosus/other autoimmune diseases
- Biologic relatives with similar medical complaints
- Aphasia, mutism, dysarthria

PHYSICAL EXAMINATION
- Autonomic hyperactivity: tachycardia, hypertension, mydriasis, sleep disturbance
- Incoordination, or gait difficulty; nystagmus
- Toxidrome
- Abnormal neurologic exam: upper and lower motor neuron focal findings
- Movement disorder
- Neuroendocrine changes

DIAGNOSTIC ABNORMALITIES
- Abnormal electroencephalogram (extreme delta brush, diffuse slowing)
- Abnormal cerebrospinal fluid (pleocytosis: greater than 5 lymphocytes)
- Positive urine toxicology
- Screening laboratory tests including *N*-methyl-D-aspartate receptor and other antibodies
- Abnormal neuroimaging studies (unilateral or bilateral hippocampal/medial temporal lobe hyperdensities: limbic encephalitis)
- Hyponatremia

Modified from Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis*. 2nd ed. Elsevier, 2023: Table 31.9, p 526

and is more fully explored in Chapter 48. In general, **delirium** is hallmarked by fluctuating levels of consciousness and is often associated with abnormalities in the neurologic exam and vital signs. Psychosis may be present in patients with delirium, but it will be accompanied by clear signs and symptoms of physical illness.

The diagnosis of a psychotic disorder should be made only after other explanations for the observed symptoms have been thoroughly considered. Mistakenly diagnosing psychosis when it is not present can lead to inappropriate use of antipsychotics with their attendant risks. The persistence, frequency, and form of possible psychotic symptoms, as well as the degree of accompanying distress and functional regression, need to be considered in determining the likelihood of an underlying psychotic pathophysiology.

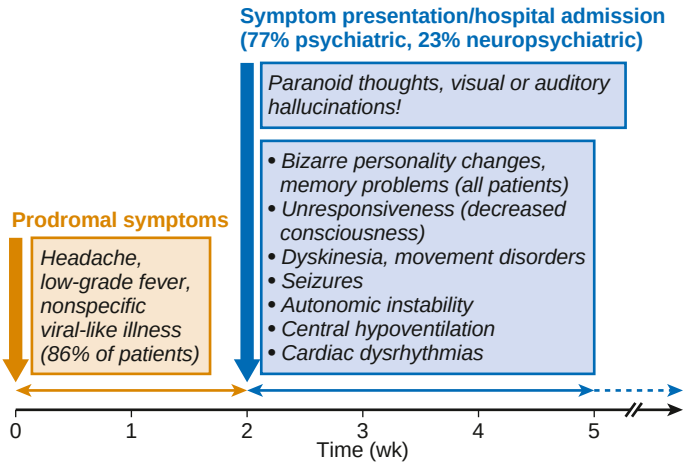

Fig. 47.1 Clinical characteristics of patients with anti–NMDA-receptor encephalitis. (*Modified from Wandinger KP, Saschenbrecker S, Stoecker W, Dalmau J. Anti-NMDA-receptor encephalitis: A severe, multistage, treatable disorder presenting with psychosis. J Neuroimmunol. 2011;231:86–91. Fig 2.*)

Table 47.6 Proposed Diagnostic Criteria for Autoimmune Psychosis

For a diagnosis of possible autoimmune psychosis:

The patient must have current psychotic symptoms of abrupt onset (rapid progression of <3 months) with at least one of the following:
- Currently or recently diagnosed with a tumor
- Movement disorder (catatonia or dyskinesia)
- Adverse response to antipsychotics, raising suspicion of neuroleptic malignant syndrome (rigidity, hyperthermia, or raised creatine kinase)
- Severe or disproportionate cognitive dysfunction
- A decreased level of consciousness
- The occurrence of seizures that are not explained by a previously known seizure disorder
- A clinically significant autonomic dysfunction (abnormal or unexpectedly fluctuant blood pressure, temperature, or heart rate)

If a patient has possible autoimmune psychosis, they should be investigated as per section 5 ("Consensus multimodal approach to the systematic investigation of patients with suspected autoimmune psychosis"), including electroencephalography, MRI, serum autoantibodies, and CSF analysis (including CSF autoantibodies). The results should lead to a diagnosis of non-autoimmune psychosis or probable/definite autoimmune psychosis.

For a diagnosis of probable autoimmune psychosis:

The patient must have current psychotic symptoms of abrupt onset (rapid progression of <3 mo) with at least one of the seven clinical criteria listed previously for possible autoimmune psychosis and at least one of the following:
- CSF pleocytosis of >5 white blood cells/μL
- Bilateral brain abnormalities on T2 weighted fluid-attenuated inversion recovery MRI highly restricted to the medial temporal lobes

Or two of the following:
- Electroencephalogram encephalopathic changes (i.e., spikes, spike-wave activity, or rhythmic slowing [intermittent rhythmic delta or theta activity] focal changes, or extreme delta brush
- CSF oligoclonal bands or increased IgG index
- The presence of a serum antineuronal antibody detected by cell-based assay

After exclusion of alternative diagnoses.

For a diagnosis of definite autoimmune psychosis:

The patient must meet the criteria for probable autoimmune psychosis with IgG class antineuronal antibodies in CSF.

Note that these criteria do not exclude a diagnosis being made in a patient with an acute onset (<3 mo) of psychosis, even if that patient has had a previous psychotic, other psychiatric, or encephalopathic episode that resolved.

From Pollak TA, Lennox BR, Müller S, et al. Autoimmune psychosis: an international consensus on an approach to the diagnosis and management of psychosis of suspected autoimmune origin [published correction appears in *Lancet Psychiatry*. 2019 Dec;6(12):e31]. *Lancet Psychiatry*. 2020;7(1):93–108: Panel 1, p 100.

COMORBIDITY

Among youth with schizophrenia, rates of comorbidity are approximately 34% for posttraumatic stress disorder, 34% for attention-deficit/hyperactivity and/or disruptive behavior disorders, and 32% for substance abuse/dependence. At least 10–20% of children diagnosed with schizophrenia have intellectual delays; it is unclear if this is related to the impact of the illness on cognitive testing. Children with schizophrenia also demonstrate impairments in language, communication, and information processing. Co-occurring *rates* of schizophrenia and autism spectrum disorder (ASD) are higher than would be expected in general populations; childhood-onset schizophrenia has been linked to ASD, with an estimated 30–50% of cases preceded by a diagnosis of an ASD.

SEQUELAE

Follow-up studies of early-onset schizophrenia suggest moderate to severe impairment across the life span. Poor outcome is predicted by low premorbid functioning, insidious onset, higher rates of negative symptoms, childhood onset, and low intellectual functioning. When followed into adulthood, youth with schizophrenia demonstrated greater social deficits, lower levels of employment, and lower likelihood of independent living, relative to those with other childhood psychotic disorders.

Approximately 5–10% of individuals with schizophrenia die by suicide or accidental death directly related to behaviors caused by psychotic thinking, approximately 20% attempt suicide on one or more occasions, and many more have suicidal ideation. Life expectancy is reduced in individuals with schizophrenia because of associated medical conditions; a shared vulnerability for psychosis and medical disorders may explain some of the medical comorbidity of schizophrenia.

ETIOLOGY AND RISK FACTORS

Etiologic evidence for schizophrenia supports a neurodevelopmental and neurodegenerative model, with multiple genetic and environmental risks having important roles. It has been hypothesized that although psychotic disorders have their origins in early development, it is not until youth are in their mid-teens that the underlying neural structures manifest the disabling functional deficits and resultant psychotic symptoms.

Genetic Factors

The lifetime risk of developing schizophrenia is 5-20 times higher in first-degree relatives of affected probands than the general population. Concordance rates of 40–60% and 5–15% have been reported in monozygotic and dizygotic twins, respectively. Genome-wide association studies have implicated variants in >100 different genes that are statistically significant but individually only demonstrate small increases in the risk for schizophrenia. The risk for schizophrenia increases with increasing burden of these risk alleles; approximately 30% of the risk is attributable to common genetic variants. Rare variants of larger effect have also been implicated as increasing risk. Some rare copy number variants, where segments of the genome encompassing many genes are either duplicated or deleted, increase the risk of schizophrenia more markedly, with odds ratios of 2-25. Although these copy number variants may be responsible for 0.5–1.0% of typical adolescent/adult-onset schizophrenia, data indicate that they are responsible for about 12% of schizophrenia cases with onset before age 13 years.

Environmental Factors

In utero exposure to maternal famine, advanced paternal age, prenatal infections, obstetric complications, marijuana use, and immigration have been hypothesized to contribute to the development of schizophrenia. Cannabis use in teens is associated with a higher risk of eventually developing psychosis, but it is difficult to determine whether this is related to drug effects or an unmasking of underlying disease potential. Environmental exposures may mediate disease risk through direct neurologic damage, gene-environment interactions, epigenetic effects, or de novo mutations. There is no evidence that psychologic or social factors alone cause schizophrenia. Rather, environmental factors potentially interact with biologic risk factors to mediate the timing of onset, course, and severity of an acute episode. Expressed emotion within the family setting can influence the onset and exacerbation of acute episodes and relapse rates.

NEUROANATOMIC ABNORMALITIES

Increased lateral ventricle volumes, along with reductions in hippocampus, thalamus, and frontal lobe volumes, have been reported in schizophrenia. Youth with schizophrenia have reductions in gray matter volumes and reduced cortical folding. Neurotransmitter systems, particularly central nervous system dopamine circuits, are hypothesized to have a key role in the pathophysiology of schizophrenia. The dopamine hypothesis is derived in part from the identification of D_2 receptor blockade as the mechanism for the action of antipsychotic medications. On neurologic exam, those with schizophrenia are often found to have deficits in smooth-pursuit eye movements and autonomic responsivity.

PREVENTION

There has been significant interest in prospectively identifying youth at risk for schizophrenia spectrum and other psychotic disorders to provide early intervention before the development of a chronic psychotic disorder. Those considered to be at clinically high risk may express a variety of unusual or odd beliefs. They may have unusual perceptual experiences, including frank hallucinations, but retain insight into their unreality. Their speech and behavior may be unusual, but not overtly disorganized. Individuals who had been socially active may become withdrawn. The symptoms are described as present at least once per week for the past month and have begun or worsened over the past year. Although the symptoms are less severe and more transient than in a psychotic disorder, 20–40% of patients with these attenuated symptoms appear to go on to a psychotic disorder within several years of symptom presentation. There is evidence that premorbid lower cognitive and social skills as well as a history of substance abuse contribute to the risk of developing a schizophrenia spectrum disorder.

Some evidence indicates that antipsychotic medication may delay conversion to a psychotic disorder and ameliorate attenuated symptoms in active treatment, yet there appear to be no lasting effects after the medication is withdrawn. Additionally, the known adverse effects of antipsychotics argue against their being used broadly to prevent psychosis in these patients, given that about 65% do not go on to develop a psychotic disorder.

Antidepressants have been associated with symptomatic improvement in adolescents who are at risk of developing a schizophrenia spectrum disorder. Psychologic interventions, including social skills, cognitive, and interaction training programs, as well as educational family interventions and cognitive-behavioral therapy (CBT), are reported to improve symptoms and psychosocial functioning in youth with early symptoms and decrease the rate of conversion to psychosis.

Despite improvements in diagnostic predictive validity, significant concern remains regarding a high false-positive rate that may cause individuals to be stigmatized or exposed to unnecessary treatment. In this context, youth with early symptoms suggestive of psychosis should be referred to a child and adolescent psychiatrist or other qualified mental health specialist.

SCREENING

There are no validated tools for screening for schizophrenia spectrum disorders in children or adolescents. A widely accepted premorbid phenotype for childhood-onset schizophrenia has yet to be established.

Of children with childhood-onset schizophrenia, 67% show disturbances in social, motor, and language functioning, as well as learning disabilities. Many meet criteria for comorbid ASDs, mood disorders, and anxiety disorders.

Pediatric practitioners can make general inquiries of youth and their parents regarding problems with thinking or perceptions, including hallucinations and delusions. For younger children, the clinician must ensure that the child understands the questions. True psychotic symptoms are generally confusing to the individual. Highly descriptive, detailed, organized, and situation-specific reports are less likely to represent true psychosis. Overt evidence of psychosis is not always present on mental status examination, but in the absence of this, the validity of symptom reports should be scrutinized. Given the strong genetic component of schizophrenia spectrum disorders, a thorough family history is key in supporting the workup of psychosis in children. Youth presenting with possible psychosis warrant assessment and treatment by a child and adolescent psychiatrist or other qualified mental health specialist.

ASSESSMENT

The diagnostic assessment of schizophrenia in youth is uniquely complicated; misdiagnosis is common. Most children who report hallucinations do not meet criteria for schizophrenia, and many do not have a psychotic illness. The persistence, frequency, and form of possible psychotic symptoms; the presence of distress; functional impairment; and insight need to be considered in arriving at a diagnosis. Expertise in childhood psychopathology and experience in assessing reports of psychotic symptoms in youth are important prerequisite skills for clinicians evaluating youth for psychosis. Comprehensive diagnostic assessments, which reconcile mental status findings with the rigorous application of diagnostic criteria, help improve accuracy.

All children who present with psychotic symptoms should receive a thorough pediatric and neurologic evaluation to focus on ruling out nonpsychiatric causes of psychosis (see Tables 47.4 and 32.4). There is no neuroimaging or laboratory test that establishes a diagnosis of schizophrenia spectrum disorders; these diagnostic tests are instead used to further assist with the medical evaluation while also establishing baseline laboratory parameters for monitoring medication therapy. Routine laboratory testing typically includes blood counts; basic metabolic panel; and assessment of liver, renal, and thyroid function. More extensive evaluation is indicated for atypical presentations, such as a gross deterioration in cognitive and motor abilities, focal neurologic symptoms, or delirium (see Table 47.5). Neuroimaging may be indicated when neurologic deficits are present, or EEG may be indicated for a clinical history suggestive of seizures or encephalopathy. Toxicology screens are indicated for acute onset or exacerbations of psychosis when exposure to drugs of abuse cannot be ruled out. Genetic testing is indicated if there are associated dysmorphic or syndromic features. Tests to rule out specific syndromes or diseases are indicated for clinical presentations suggestive of a specific syndrome (e.g., amino acid screens for inborn errors of metabolism, ceruloplasmin for Wilson disease, porphobilinogen for acute intermittent porphyria, neuronal antibodies for autoimmune encephalitis). Neuropsychologic testing cannot establish the diagnosis but may be important for documenting cognitive deficits for academic planning.

TREATMENT

Treatment goals include decreasing psychotic symptomatology, directing the child toward a developmentally typical trajectory, and reintegrating the child into the home and community. Children and families facing schizophrenia spectrum disorders require an array of mental health services to address their psychologic, social, educational, and cultural needs. Given the insidious onset and chronic course of these disorders, the patient must be followed longitudinally, with periodic reassessment to hone diagnostic accuracy and tailor services to meet the patient's and family's needs. Integrated psychopharmacologic, psychotherapeutic, psychoeducational, and case management services are often necessary.

Psychoeducation about the illness with an assessment of the potential role of stigma in treatment participation is critical for improving adherence with treatment recommendations. Assessing a child's strengths and vulnerabilities as well as available environmental resources is critical in devising an effective treatment plan. School and community liaison work to develop and maintain a day-to-day schedule for the patient is important. Specialized educational programs should be considered within the school system. Cognitive remediation has led to some promising gains in planning ability and cognitive flexibility. Effective and collaborative communication among the family, the pediatrician, a child and adolescent psychiatrist, and other mental health providers increases the potential for the patient's optimal functioning.

Pharmacotherapy

First-generation (typical) and second-generation (atypical) antipsychotic medications are effective in reducing psychotic symptoms. Antipsychotics appear to outperform placebo and to have approximately equal effectiveness, except for ziprasidone and clozapine, which may be less and more effective than the others, respectively. Risperidone, aripiprazole, quetiapine, olanzapine, and lurasidone are FDA-approved second-generation antipsychotics for treating schizophrenia in patients 13 years and older, and paliperidone for those 12 years and older. Several first-generation antipsychotics are also FDA-approved for children and adolescents. The choice of which agent to use first is typically based on FDA approval status, side effect profile, patient and family preference, clinician familiarity, and cost. Although clozapine is effective in treating both positive and negative symptoms, it has a risk for agranulocytosis and seizures, which limits its use to those patients with *treatment-resistant* disorders. Ziprasidone and paliperidone are associated with QT prolongation; this finding along with the inferior effectiveness of ziprasidone limits its use with children and adolescents. All antipsychotics carry some degree of risk of sedation, weight gain, and extrapyramidal symptoms (see Chapter 33).

Most patients require long-term treatment and are at significant risk of relapse if their medication is discontinued. However, more than 75% of youth with schizophrenia discontinue their medication within 6 months. Common reasons for discontinuation include lack of efficacy, intolerable side effects, and general lack of adherence with treatment plan. Many patients will continue to experience some degree of positive or negative symptoms, requiring ongoing treatment. Patients should maintain regular physician contact to monitor symptom course, side effects, and adherence. Depot or long-acting injectable antipsychotics have not been studied well in pediatric age groups and have inherent risks with long-term exposure to adverse side effects. They are typically only considered when there is a well-documented history of psychotic symptoms as well as poor medication adherence.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) may be used with severely impaired adolescents if medications are either not helpful or cannot be tolerated. It has not been systematically studied in children, but its use is supported in adults with schizophrenia, typically in combination with antipsychotic therapy.

47.2 Non-Schizophrenia Spectrum Psychotic Disorders

Jennifer A. Zaspel and Rosa K. Kim

Beyond the schizophrenia spectrum of psychotic disorders, substance/medication-induced psychotic disorder (Table 47.7) and psychotic disorder due to another medical condition (Table 47.8) can be seen in pediatric populations.

The hallmark features of **substance/medication-induced psychosis** are delusions and hallucinations that develop within the context of substance exposure: typically a drug of abuse, a medication, or a toxin exposure (see Tables 47.4 and 32.4 for a brief list). Synthetic cannabinoids (bath salts) are a common drug producing psychotic effects. A substance-induced psychosis is distinguished from a primary psychotic disorder by examining the onset and course of symptoms; the onset of a primary psychosis may precede substance exposure and may occur during periods of sustained abstinence. Once they arise, psychotic symptoms may be present as long as substance exposure is continued. Although the prevalence of substance/medication-induced psychotic disorder in the general population is unknown, it is estimated that 7–25% of individuals presenting with a first episode of psychosis meet criteria for this diagnosis. Symptoms can be managed with antipsychotics until they remit, which often happens shortly after the offending substance is removed. Patients can develop a schizophrenia spectrum disorder following substance exposure, but this tends to occur in individuals who are at high risk for developing a primary psychotic disorder regardless of substance exposure.

Psychosis due to **another medical condition** (see Table 47.8) is also characterized by prominent hallucinations or delusions, but history, physical exam, and laboratory findings support a direct pathophysiologic connection between these symptoms and another medical condition (see Tables 32.4, 47.4, 47.5, and 47.8). Any sensory modality can be affected by hallucinations. The hallucinations vary in complexity depending on their etiology, and their description may be highly suggestive of a particular diagnosis, like olfactory hallucinations in temporal lobe epilepsy. Associations between delusions and medical conditions tend to be less specific. The list of medical conditions that can cause psychosis is long, and includes epilepsy, strokes, neoplasms, endocrine disorders, genetic syndromes like velocardiofacial syndrome, autoimmune disorders, and the permanent sequelae of toxic exposures (see Tables 32.4 and 47.4). Notably, delirium is excluded from psychosis due to another medical condition. When narrowing the differential between schizophrenia spectrum disorders, psychosis due to another medical condition, and any other etiology, it is important to consider the timeline of symptoms, the presence of features that are atypical for a primary psychosis, and the possibility of substance or medication exposure. Treatment of the underlying medical condition may or may not require adjunctive antipsychotic treatment for management of psychosis, and the course and prognosis of the psychosis will likely depend on the etiology.

A notable example of psychosis due to another medical condition is **psychosis associated with epilepsy.** The disorder manifests with delusions or hallucinations associated with poor insight, and can be further differentiated into ictal, interictal, and postictal psychosis. Ictal-induced psychosis is a form of **nonconvulsive status epilepticus**, usually a complex partial status that can last for hours to days and is associated with periods of impaired consciousness. Brief interictal psychosis can last days to weeks and is associated with paranoia, delusions, and auditory hallucinations. Chronic interictal psychosis resembles schizophrenia and manifests with paranoia, visual hallucinations, and catatonia. Postictal psychosis is the most common type (observed in 2–7% of patients with epilepsy) and lasts up to 1 week and then spontaneously remits. The diagnosis requires a strong index of suspicion and EEG monitoring. Treatment requires appropriate anticonvulsant drugs and, if the psychosis persists, initiating low-dose antipsychotic medication.

Table 47.7 DSM-5 Diagnostic Criteria for Substance/Medication Induced Psychotic Disorder

A. Presence of one or both of the following symptoms:
   1. Delusions
   2. Hallucinations
B. There is evidence from the history, physical examination, or laboratory findings of both (1) and (2):
   1. The symptoms of Criterion A developed during or soon after substance intoxication or withdrawal or after exposure to a medication.
   2. The involved substance/medication is capable of producing the symptoms in Criterion A.
C. The disturbance is not better explained by a psychotic disorder that is not substance/medication induced.
D. The disturbance does not occur exclusively during the course of a delirium.
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

With onset during intoxication: If the criteria are met for intoxication with the substance and the symptoms develop during intoxication.

With onset during withdrawal: If the criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, withdrawal.

From the *Diagnostic and Statistical Manual of Mental Disorders,* 5th ed. pp 110–115. Copyright 2013. American Psychiatric Association. .

Table 47.8 DSM-5 Diagnostic Criteria for Psychotic Disorder Due to Another Medical Condition

A. Prominent hallucinations or delusions.
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct pathophysiologic consequence of another medical condition.
C. The disturbance is not better explained by another mental disorder.
D. The disturbance does not occur exclusively during the course of a delirium.
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify whether:

With delusions: If delusions are the predominant symptom.

With hallucinations: If hallucinations are the predominant symptom.

47.3 Catatonia in Children and Adolescents

Jennifer A. Zaspel and Rosa K. Kim

Catatonia is a constellation or syndrome of psychomotor features, the most notable of which are decreased purposeful motor activity, decreased engagement in interviews and physical exams, or excessive and peculiar motor activity. The most characteristic symptoms are waxy flexibility and bizarre poses, but these may or may not be present (Table 47.9). Diagnosis can be challenging, as psychomotor disturbances can range from unresponsiveness to agitation. Catatonia has been associated with a broad array of conditions affecting children, adolescents, and adults, including psychotic, affective, drug-related, autoimmune, encephalitic, and neurodevelopmental conditions (Table 47.10). Autoimmune encephalitis may be the most common etiology in childhood. In addition, catatonia *(autism shut down syndrome)* may complicate ASD (Chapter 58).

Table 47.9 Catatonia

Excitement: Extreme hyperactivity; constant motor unrest, which is apparently nonpurposeful
Immobility/stupor: Extreme hypoactivity, immobility; minimally responsive to stimuli
Mutism: Verbally unresponsive or minimally responsive
Staring: Fixed gaze, little or no visual scanning of environment, decreased blinking
Posturing/catalepsy: Maintains posture(s), including mundane (e.g., sitting or standing for hours without reacting)
Grimacing: Maintenance of odd facial expressions
Echopraxia/echolalia: Mimics of examiner's movements/speech
Stereotypy: Repetitive, non–goal-directed motor activity (e.g., finger play; repeatedly touching, patting, or rubbing self)
Mannerisms: Odd, purposeful movements (hopping or walking tiptoe, saluting passersby, exaggerated caricatures of mundane movements)
Verbigeration: Repetition of phrases or sentences
Rigidity: Maintenance of a rigid posture despite efforts to be moved
Negativism: Apparently motiveless resistance to instructions or to attempts to move/examine the patient; contrary behavior does the opposite of the instruction
Waxy flexibility: During reposturing of the patient, offers initial resistance before allowing themselves to be repositioned (similar to that of bending a warm candle)
Withdrawal: Refusal to eat, drink, or make eye contact
Impulsivity: Suddenly engaging in inappropriate behavior (e.g., runs down the hallway, starts screaming, or takes off clothes) without provocation; afterward, cannot explain
Automatic obedience: Exaggerated cooperation with examiner's request, or repeated movements that are requested once
Passive obedience *(mitgehen)*: Raising arm in response to light pressure of finger, despite instructions to the contrary
Negativism *(gegenhalten)*: Resistance to passive movement that is proportional to strength of the stimulus; response seems automatic rather than willful
Ambitendency: Appears stuck in indecisive, hesitant motor movements
Grasp reflex: Striking the patient's open palm with two extended fingers of the examiner's hand results in automatic closure of the patient's hand
Perseveration: Repeatedly returns to the same topic or persists with the same movements
Combativeness: Belligerence or aggression, usually in an undirected manner, without explanation
Autonomic abnormality: Abnormality of body temperature (fever), blood pressure, pulse rate, respiratory rate, inappropriate sweating

From Dhossche DM, Wachtel LE. Catatonia is hidden in plain sight among different pediatric disorders: A review article. *Pediatr Neurol*. 2010;43:307–315.

Table 47.10 Conditions Associated with Catatonia

Psychotic Disorders
- Paranoid schizophrenia, catatonic schizophrenia, psychosis, autism, Prader-Willi syndrome, intellectual impairment

Mood Disorders
- Bipolar disorder: manic or mixed episodes

Major Depressive Disorder

Medical Conditions
- Hyper-hypothyroidism, euthyroid autoimmune thyroiditis, Addison disease, infections, electrolyte imbalances, pathogenic variants in *SCN2A* gene, systemic lupus erythematosus

Neurologic Conditions
- Epilepsy, strokes, traumatic brain injury, multiple sclerosis, infectious and autoimmune encephalitis, acute disseminated encephalomyelitis, neuromyelitis optica spectrum

Drugs
- Withdrawal: benzodiazepines, L-dopa, gabapentin
- Overdose: LSD, PCP, cocaine, MDMA (Ecstasy), disulfiram, levetiracetam

LSD, Lysergic acid; MDMA, 3,4-methylenedioxy-*N*-methylamphetamine; PCP, phencyclidine. Adapted from Weder ND, Muralee S, Penland H, Tampi RR. Catatonia: A review. *Ann Clin Psychiatry*. 2008;20(2):97–107:Table 2.

Table 47.11 DSM-5 Criteria for Catatonia Due to Another Medical Condition

A. The clinical picture is dominated by three (or more) of the following symptoms:
   1. Stupor (i.e., no psychomotor activity; not actively relating to environment).
   2. Catalepsy (i.e., passive induction of a posture held against gravity).
   3. Waxy flexibility (i.e., slight, even resistance to positioning by examiner).
   4. Mutism (i.e., no, or very little, verbal response [*Note:* not applicable if there is an established aphasia]).
   5. Negativism (i.e., opposing or not responding to instructions or external stimuli).
   6. Posturing (i.e., spontaneous and active maintenance of a posture against gravity).
   7. Mannerism (i.e., odd, circumstantial caricature of normal actions).
   8. Stereotypy (i.e., repetitive, abnormally frequent, non–goal-directed movements).
   9. Agitation, not influenced by external stimuli.
   10. Grimacing.
   11. Echolalia (i.e., mimicking another's speech).
   12. Echopraxia (i.e., mimicking another's movements).

B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct pathophysiologic consequence of another medical condition.
C. The disturbance is not better explained by another mental disorder (e.g., a manic episode).
D. The disturbance does not occur exclusively during the course of a delirium.
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other areas of functioning.

Coding note: Include the name of the medical condition in the name of the mental disorder (e.g., F06.1 catatonic disorder due to hepatic encephalopathy). The other medical condition should be coded and listed separately immediately before the catatonic disorder due to the medical condition (e.g., K71.90 hepatic encephalopathy; F06.1 catatonic disorder due to hepatic encephalopathy)

Adapted from Weder ND, Muralee S, Penland H, Tampi RR. Catatonia: A review. *Ann Clin Psychiatry*. 2008;20(2):97–107:Table 2.

The exact pathophysiology of catatonia is unknown, but neuroanatomic, neuroendocrine, immunologic, and neurotransmitter-based theories have all been proposed based on the various underlying etiologies of catatonia. Morbidity and mortality are high in adults who have experienced catatonia and are presumed to be high in pediatric populations based on limited data primarily because of the severity of an underlying illness that could cause catatonia. Patients with schizophrenia spectrum disorders and catatonia tend to be more impaired than those who do not experience catatonia, and suicide rates are estimated to be 500-fold higher than in the general population.

Catatonia is defined as 3 or more of the 12 symptoms listed in Table 47.11 and can be described by both etiology and presentation. The DSM-5 broadly splits etiology into presentations related to mental disorders and presentations related to another medical condition, the diagnosis of which must be supported by the patient's history, physical exam, and any accompanying laboratory findings. Pediatric prevalence rates range from 0.6–17% in child psychiatric inpatients and up to 17% in medically hospitalized children, but rates are difficult to determine due to underdiagnosis of the condition. Catatonia can be further subdivided into three presentation categories: stuporous, excited, and malignant. **Stuporous** presentations are characterized by immobility, mutism, staring, and rigidity, whereas **excited** presentations include prolonged periods of psychomotor agitation. **Malignant catatonia** is an emergent condition, presenting with hyperthermia, hypertension, rhabdomyolysis, and psychomotor agitation in addition to the psychiatric and motor

Table 47.12 Standard Examination of Catatonia

The method described here is used to complete the 23-item Bush-Francis Catatonia Rating Scale (BFCRS) and the 14-item Bush-Francis Catatonia Screening Instrument (BFCSI). Item definitions on the two scales are the same. The BFCSI measures only the presence or absence of the first 14 signs.

Ratings are based solely on observed behaviors during the examination, with the exception of completing the items for "withdrawal" and "autonomic abnormality," which may be based on directly observed behavior or chart documentation.

As a general rule, only items that are clearly present should be rated. If the examiner is uncertain as to the presence of an item, rate the item as "0."

PROCEDURE

1. Observe the patient while trying to engage in a conversation.
2. The examiner should scratch his or her head in an exaggerated manner.
3. The arm should be examined for cogwheeling. Attempt to reposture and instruct the patient to "keep your arm loose." Move the arm with alternating lighter and heavier force.
4. Ask the patient to extend his or her arm. Place one finger beneath his or her hand and try to raise it slowly after stating, "Do not let me raise your arm."
5. Extend the hand stating, "Do not shake my hand."
6. Reach into your pocket and state, "Stick out your tongue. I want to stick a pin in it."
7. Check for grasp reflex.
8. Check the chart for reports from the previous 24-hour period. Check for oral intake, vital signs, and any incidents.
9. Observe the patient indirectly, at least for a brief period each day, regarding the following:
   - Activity level
   - Abnormal movements
   - Abnormal speech
   - Echopraxia
   - Rigidity
   - Negativism
   - Waxy flexibility
   - Gegenhalten
   - Mitgehen
   - Ambitendency
   - Automatic obedience
   - Grasp reflex

Gegenhalten, Resistance to movements that is equal and opposite to the pressure exerted by examiner; *mitgehen*, extreme mitmachen where even slightest pressure moves limb; mitmachen, passive movement of extremity despite instruction not to move.

From Bush G, Fink M, Petrides G, Dowling F, Francis A. Catatonia. I. Rating scale and standardized examination. *Acta Psychiatr Scand.* 1996;93(2):129–136.

symptoms seen in catatonia. The differential diagnosis for this type includes neuroleptic malignant syndrome or serotonin syndrome (see Chapter 33). Most children will present with a stuporous clinical picture, whereas the remaining cases present as excited or malignant, 19% and 5%, respectively. The severity of symptoms can be measured and tracked using the Bush-Francis Catatonia Rating Scale, a validated tool that accompanies a standardized physical examination and observation of patient behavior (Table 47.12). The diagnostic approach is driven by the search for the underlying cause for catatonia and the monitoring of its potentially dangerous effects on the body.

Beyond supportive care and discontinuation of any precipitating agents, treatment of catatonia should be expeditious to reduce the medical sequelae of prolonged symptoms. Benzodiazepines, in particular lorazepam, are typically first-line pharmacologic treatment for catatonia. Low-dose lorazepam is often trialed as a confirmatory "challenge" for patients with suspected catatonia, where a positive result is improvement or even resolution of symptoms within hours of administration of the medication. If the initial challenge test does reverse symptoms, increasing doses of lorazepam are indicated, with careful monitoring to avoid side effects (Fig. 47.2). Rapid withdrawal of benzodiazepines can, in turn, precipitate catatonia in those who are susceptible. The use of antipsychotics in catatonia is controversial, as they have been associated with an increased incidence of malignant catatonia or neuroleptic malignant syndrome. ECT has also been used in both adults and children, though it is underutilized due to caretaker and ethical concerns. Its use is typically recommended when other viable treatment options have either not been successful or cannot be safely administered. It has been successful in treating refractory catatonia in children with autism.

47.4 Hallucinations of Childhood

Jennifer A. Zaspel and Rosa K. Kim

Hallucinations are perceptions that occur in the absence of identifiable external stimuli. Nondiagnostic hallucinations are those that fall within the realm of normal human experience, such as hearing footsteps, knocking, or one's name being called. **Hypnogogic** and **hypnopompic** hallucinations are experienced as one transitions into and out of sleep, respectively, and on their own carry no psychopathologic implications. In younger children, reported hallucinations can reflect a developmentally appropriate blurring between fantasy and reality, especially regarding dreams and imaginary friends. Children are also more susceptible to perceptual distortions or **illusions** (misinterpretations of external stimuli) but may communicate these phenomena to adults in a way that most would interpret as hallucinations. The first clinical task in evaluating youth who report hallucinations is to sort out those associated with severe mental illness from those derived from other causes (Fig. 47.3).

Acute phobic hallucinations are benign, common, and typically occur in otherwise healthy preschool children. The hallucinations are often visual or tactile, last 10-60 minutes, and most often occur at night. The children are quite frightened and might complain that bugs or snakes are crawling over themselves and attempt to remove them. The child's fear is not alleviated by reassurance by the parents or physician, and the child is not amenable to reason. Findings on physical and mental status examinations are otherwise normal, and the cause is unknown. Symptoms can persist for 1-3 days, slowly abating over 1-2 weeks.

In children with nonpsychotic hallucinations, all other symptoms of psychosis are absent. Nonpsychotic hallucinations typically occur in the context of severe traumatic stress, developmental difficulties, social and emotional deprivation, parents whose own psychopathology promotes a breakdown in the child's sense of reality, cultural beliefs in mysticism, and unresolved mourning. Auditory hallucinations of voices telling the child to do "bad things" may be associated with disruptive behavior disorders in an unconscious attempt to distance oneself from undesirable behaviors. Hearing a voice invoking suicide is often associated with depression. Trauma-related hallucinations are commonly associated with posttraumatic stress disorder and are likely a representation of flashbacks. Auditory and visual hallucinations may similarly be endorsed in complex bereavement. The content of the hallucinations is often relevant in understanding the underlying psychopathology and developmental issues.

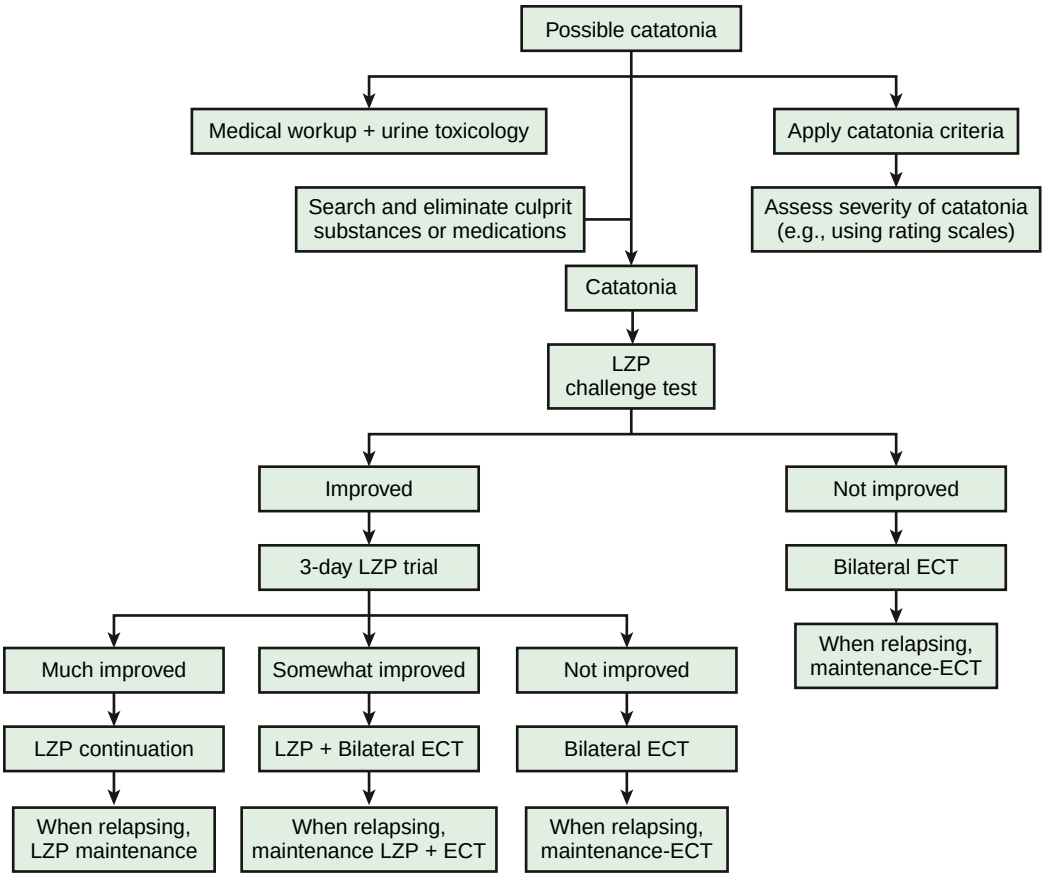

Fig. 47.2 Algorithm for the evaluation, diagnosis, and treatment of catatonia in children and adolescents. ECT, Electroconvulsive therapy; LZP, lorazepam. (*From Dhossche DM, Wilson C, Wachtel LE. Catatonia in childhood and adolescents: Implications for the DSM-5. Prim Psychiatry. 2010;17:23–26.*)

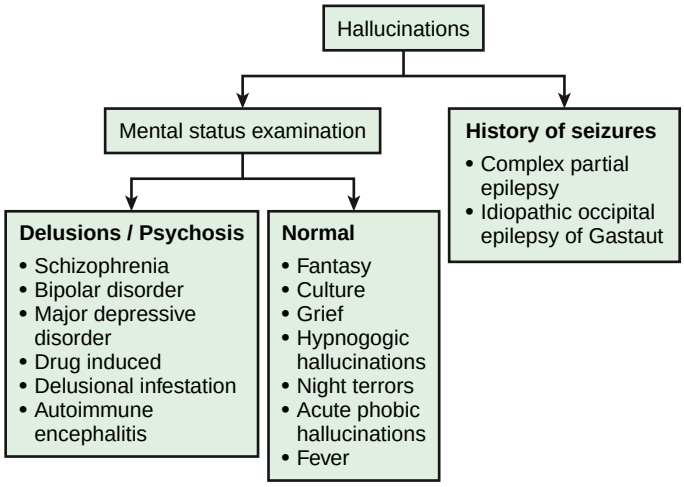

Fig. 47.3 Algorithm for the evaluation of hallucinations.

The evaluation of the underlying condition directs the type of treatment needed. Diagnostic nonpsychotic hallucinations suggest the need for disorder-specific psychotherapy and adjunctive medication, if indicated. CBT focused on helping the youth understand the origin of the hallucinations and on developing coping strategies for stressful situations may be helpful for older children and adolescents.

Chapter 48

Delirium

Colleen K. Manak and Rosa K. Kim

Delirium is defined as a disorder of **awareness** and **attention** and is characterized by its waxing and waning nature. It is not a primary psychiatric diagnosis and instead occurs secondary to an underlying medical condition, though at the time of initial presentation the underlying cause is often unknown. The symptoms of delirium are similar between adults and children. Delirium in children carries risks of adverse outcomes, including death, if it is not treated. Untreated delirium can serve to prolong the recovery course of comorbid and underlying conditions; the clinical features of delirium, including agitation, aggression, and confusion, can often interfere with necessary medical care. Delirium in children and adolescents is associated with a 12.5–29% mortality rate. Quick recognition, diagnosis, and treatment of delirium and its underlying cause is essential in ensuring the best outcome for patients.

DIAGNOSIS

Criteria for the diagnosis of delirium are included in the DSM-5 under Neurocognitive Disorders (Table 48.1). Delirium presents with an **acute onset**, developing quickly over the course of hours to days and symptoms tend to **wax and wane.** This fluctuation of symptoms can be dramatic over the course of a day, with a patient appearing

Table 48.1 DSM-5 Diagnostic Criteria for Delirium

A.	A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
B.	The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
C.	An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).
D.	The disturbances in Criteria A and C are not explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
E.	There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. p. 596. Copyright 2013. American Psychiatric Association.

Table 48.2 DSM-5 Delirium Subtypes

Hyperactive delirium	Increased psychomotor activity and mood lability • Confusion • Psychosis • Disorientation • Agitation • Hypervigilance • Hyper-alertness • Combativeness • Loud, pressured speech • Behavioral dysregulation • Pulling at lines/catheters
Hypoactive delirium	Decreased psychomotor activity • Sluggishness • Lethargy • Stupor • Confusion • Apathy
Mixed delirium	Normal level of psychomotor activity • Poor attention • Decreased awareness • Rapid fluctuation of activity level

Adapted from Meagher D, Moran M, Raju B, et al. A new data-based motor subtype schema for delirium. *J Neuropsychiatry Clin Neurosci.* 2008;20(2):185–193:Fig 1.

relatively well from a cognitive perspective during one assessment, and then seeming acutely altered at the next. At the core of delirium is an alteration in attention and awareness, and a disturbance in cognition. Patients with delirium will struggle to focus and sustain attention. They are often disoriented, showing confusion about where they are, poor orientation to time, and sometimes disorientation to self. In addition to these core features, delirium often presents with symptoms that have the potential to be mistaken for psychosis or mania. People with delirium may hallucinate, engage in bizarre or purposeless movements, and show alterations in their sleep–wake cycles.

Delirium can be further categorized into subtypes (Table 48.2). The **hyperactive** subtype is characterized by increased motor activity, loss of control of activity, restlessness, and wandering. The **hypoactive** subtype presents with reduction in activity, speed of actions, awareness of surroundings, quantity and speed of speech, and alertness. It is possible for patients to present with both hyperactive and hypoactive symptoms over the course of 24 hours, classified as having a **mixed motor subtype**. There has been emerging evidence of a fourth group, identified as the **no motor subtype**, in which they do not show characteristics of either hyper- or hypoactive subtypes.

Although these subtypes are often seen in both pediatric and adult delirium, diagnosing delirium in children can pose challenges not present in adult populations. Developmental differences, especially in young children, necessitate alternative approaches to assessing and diagnosing delirium. Bedside staff and caregivers can provide helpful insight into behaviors and cognitive changes, such as changes in attention, increased fussiness over baseline, and difficulty soothing, which might be missed by clinicians who are unable to evaluate symptoms of delirium using traditional methods (Fig. 48.1).

EPIDEMIOLOGY

The prevalence rate of pediatric delirium is an estimated to be 13–44% among *hospitalized* children, with higher rates seen in patients who are admitted to the intensive care unit (ICU) and/or those being mechanically ventilated. Increased risk for delirium may be associated with the underlying medical condition, prolonged hospitalization (especially ICU admission), young age, neurocognitive and developmental disorders, and a personal history of delirium. Potentially modifiable risk factors include polypharmacy, deep sedation, the use of benzodiazepines and anticholinergic medications, disrupted sleep, pain, sensory deprivation, and lack of familiar environment or caregivers. Delirium can occur at any age and has been observed in infants in the NICU.

ETIOLOGY

Although nearly any medical condition that requires hospitalization can lead to delirium, there are diagnoses that are more commonly associated with delirium (Table 48.3). Similarly, there are several drugs that are associated with the development of delirium in children including benzodiazepines, anticholinergic medications, sedatives, opiates, steroids, and some illicit substances (synthetic cathinone, synthetic cannabinoids).

ASSESSMENT

A thorough review of the medical record helps to identify predisposing and precipitating factors including exposures, changes in behavior, recent illness, and surgeries. If a reasonable cause is unable to be found on history, a further medical work-up is usually indicated.

It is possible for children with known psychiatric illnesses to develop delirium in response to medical stress. Having a comorbid psychiatric diagnosis should not delay the diagnosis of delirium. Psychiatric illnesses that can be confused with delirium include psychosis, mania, depression, and catatonia (Table 48.4). Key factors to look for in the history of patients with delirium are an acute onset without prodrome or other previous concern for worsening behavioral functioning, variable symptoms from moment to moment, and deficits in attention and orientation.

One of the factors that complicates assessment of delirium in children is the developmental level of the child. A young child will be unable to answer some of the standard assessment questions (e.g., questions about orientation), which means that a fair amount of the assessment will come from the bedside staff and the child's primary caregivers. More standard assessment strategies can be utilized in older children and adolescents.

In the patient interview, a good assessment will strive to evaluate affect, thought process, thought content, attention, and orientation to make the diagnosis of delirium. Because the nature of delirium is waxing and waning, it would not be atypical to have a seemingly normal exam in a patient one suspects to have delirium. Performing multiple assessments over the course of time is important to making an accurate diagnosis. In delirium, patients can have a disruption in their normal affect and may appear restricted or dysthymic.

Cornell Assessment of Pediatric Delirium (CAPD)

RASS score _____ (if –4 or –5 do not proceed)

Please answer the following questions based on your interactions with the patient over the course of your shift:

	Never 4	Rarely 3	Sometimes 2	Often 1	Always 0	Score
1. Does the child make eye contact with the caregiver?						
2. Are the child's actions purposeful?						
3. Is the child aware of his/her surroundings?						
4. Does the child communicate needs and wants?						
	Never 0	**Rarely 1**	**Sometimes 2**	**Often 3**	**Always 4**	
5. Is the child restless?						
6. Is the child inconsolable?						
7. Is the child underactive–very little movement while awake?						
8. Does it take the child a long time to respond to interactions?

Crit Care Med. 2014;42:656–663;* B *from Smith HA, Gangopadhyay M, Goben CM, et al. The Preschool Confusion Assessment Method for the ICU: Valid and Reliable Delirium Monitoring for Critically Ill Infants and Children. Crit Care Med. 2016;44:592–600:Fig. 2.*)

Table 48.3	Etiologies of Pediatric Delirium (CRITICAL CARE mnemonic)
Cardiovascular	Anemia, shock, vasculitis, hypertensive encephalopathy
Respiratory	Respiratory insufficiency, respiratory failure, pneumothorax
Infection	Sepsis, encephalitis, urinary tract infection, meningitis, fever, pneumonia, tracheitis, cellulitis, surgical site infection, COVID-19
Toxins	Polypharmacy, heavy metals, drug:drug interactions
Inflammatory process	Autoimmune and rheumatologic disease
CNS pathology	Stroke, seizure, head trauma, intracranial bleed, tumor, anoxic brain injury
Abuse, withdrawal, sedation	Alcohol, benzodiazepines, opioids, barbiturates, prolonged/excessive sedation
Liver	Liver insufficiency, hepatic failure, hyperammonemia
Catheters, central line infections	Invasive device or procedure complications
Alimentation	Electrolyte imbalance, nutritional deficiencies, dehydration
Renal	Renal insufficiency or failure
Endocrinopathies	Glycemic disturbance, thyroid disease, parathyroid disease, adrenal disease

Adapted from Malas N, Brahmbhatt K, McDermott C, Smith A, Ortiz-Aguayo R, Turkel S. Pediatric delirium: Evaluation, management, and special considerations. *Curr Psychiatry Rep*. 2017;19(9):65.

Thought processes are often disorganized, tangential, or circumstantial and may seem loosely associated with, or not at all related to, the reality of what is going on in the moment. Patient with delirium may also be perseverative in their thought content, with difficulty moving away from a subject or becoming highly fixated on, or preoccupied with, one thing. They may have altered thought content, with hallucinations. Visual hallucinations especially are one of the hallmark alterations of thought content associated with delirium. Attention is frequently impacted in delirium, with patients demonstrating decreased attention, with an impaired ability to attend to a conversation or a situation. Orientation in people with delirium is often altered, especially with regards to orientation to place and time. Although all of these changes are observed to wax and wane during the course of delirium, changes in orientation can be the most striking, with patients sometimes going from being fully oriented to quite confused in the span of hours.

RATING SCALES

There are multiple rating scales that have been created to help to screen for delirium, particularly in critical care or intensive care setting (see Fig. 48.1). The Cornell Assessment for Pediatric Delirium (CAPD), Pediatric Confusion Assessment Method for the Intensive Care Unit (pCAM-ICU), Preschool Confusion Assessment Method for the ICU (psCAM-ICU), and Richmond Agitation Sedation Scale (RASS) are all scales that are frequently used to help monitor for delirium. The CAPD, pCAM-ICU, and psCAM-ICU have all been validated for use in the pediatric population. Rating scales are not diagnostic on their own but can be useful for identifying patients at risk for delirium and for following response to treatment.

MEDICAL EVALUATION

Delirium is a clinical diagnosis and can be made with history and physical exam alone. There are no tests that are routinely recommended in

Table 48.4	Differential Diagnosis of Delirium			
CLINICAL FEATURE	**DELIRIUM**	**PSYCHOSIS**	**DEPRESSION**	**CATATONIA**
Course	Acute onset, hours, days or more	Insidious onset over many months, prodrome	Insidious onset, at least 2 wk, often over months	Onset variable
Attention	Markedly impaired attention and arousal	Normal to mild impairment	Mild impairment	Variable difficulty with attention and arousal
Fluctuation	Characterized by a waxing and waning course; disturbed day/night cycle	Absent	Absent	Less likely to fluctuate, motor signs may show more fluctuation
Perception	Misperceptions; hallucinations (visual, fleeting); paramnesia	Hallucinations, auditory with personal reference	May have mood-congruent hallucinations	May have hallucinations, especially if secondary to primary psychosis
Speech and language	Abnormal clarity, speed and coherence; disjointed and dysarthric; misnaming; characteristic dysgraphia	Disorganized with bizarre theme	Decreased amount of speech	Mutism; echolalia
Other cognition	Disorientation to time, place; recent memory and visuospatial abnormalities	Disorientation to person; concrete interpretations	Mental slowing; indecisiveness; memory retrieval difficulty	Global disorientation
Behavior	Lethargy; nonsystematized delusions; emotional lability	Systematized delusions; paranoia; bizarre behavior	Depressed mood; anhedonia; lack of energy; sleep and appetite disturbance	Stupor; catalepsy; negativism; posturing; stereotypy; agitation not influenced by external stimuli; grimacing; echopraxia
Electroencephalogram	Diffuse slowing; low voltage fast activity; specific patterns	Normal	Normal	Normal, focal abnormalities or generalized slowing

the evaluation for delirium, rather clinicians should be guided by the history and medical concerns. There are times when laboratory, imaging, and other testing modalities can be helpful particularly in patients with suspected delirium when the underlying medical etiology of delirium is unknown.

Central nervous system imaging may be recommended to help identify underlying processes that may be contributing to delirium; brain imaging on its own is not a tool that can diagnose delirium and is not recommended for the sole purpose of diagnosis.

Electroencephalogram (EEG) is one of the few tools that can be used to help confirm a delirium diagnosis if there is diagnostic ambiguity or uncertainty. Various studies have found 65–86% of children with delirium have *abnormal* EEGs. Findings associated with delirium typically include some degree of diffuse background slowing and disorganization. This EEG finding has been shown to effectively discriminate between children with delirium and healthy controls. However, these EEG findings are nonspecific and are not sufficient to diagnose delirium. Another caveat when utilizing EEG in the evaluation of delirium is the reality that several of the underlying causes of delirium, including metabolic derangement, seizures, infections, and intoxication, can also lead to EEG changes in the absence of delirium (see Table 48.3).

DIFFERENTIAL DIAGNOSIS

Both medical and psychiatric disorders may share or mimic some of the symptoms of delirium and can sometimes lead to complications when trying to make the diagnosis. **Catatonia**, **depression**, and **psychosis** are some of the more frequently occurring diagnoses that can be confused for delirium in children and especially adolescents (see Table 48.4; see Chapter 47). In particular, catatonia can be difficult to separate from delirium, especially because the two can co-occur. It is important to attempt to clarify the diagnosis because treatment of delirium and catatonia is different; the treatment for one can exacerbate the other. To help distinguish between the two, it is often helpful to assess for motor signs seen in catatonia that are not typically present in delirium (see Chapter 47.3). Additionally, catatonia is less likely to present with a waxing and waning course. The Bush-Francis Rating Scale can be used to help diagnose catatonia (see Table 47.12).

Delirium can also mimic psychosis, frequently presenting with hallucinations and sometimes delusions. One of the most profound differences between the two is the onset; delirium has an acute onset compared with the prodromal nature of a first episode of psychosis. It would be unusual for primary psychosis to develop over the course of days. However, this is characteristic of delirium. Hallucinations in delirium are often visual, whereas primary psychotic illnesses typically present with predominantly auditory hallucinations. Delusional thought content in delirium often lacks any internal structure or interconnectedness, while delusions in primary psychotic disorders are frequently structured around a common theme.

Patients with depression may have some characteristics of delirium. The course and onset can help to distinguish depression from delirium; with depression the timing of onset is often closer to that of delirium. Depression does not demonstrate a waxing and waning course, and while cognition can be affected, it is often slowed with some memory problems, whereas orientation remains intact.

TREATMENT

Nonpharmacologic Interventions

Nonpharmacologic interventions are a mainstay in both delirium treatment and prevention. The goal behind these interventions is to provide a supportive environment and to provide sensory and environmental modifications to help offset the challenges posed by the need for hospital-based care and treatment. Strategies such as frequent reorientation, adherence to normal routines, clustering care, and maintaining a normal sleep–wake cycle are all frequently implemented to prevent or manage delirium (Table 48.5)

Table 48.5 Nonpharmacologic Management of Delirium

Environmental modifications	• Maintain lighting consistent with the time of day • Minimize noise • Familiar objects • Visible clock, calendar
Sensory modifications	• Have appropriate sensory aides available (glasses, hearing aids) • Soft, calming music • Minimize lines, catheters, restraints • Maintain comfortable position and body alignment
Caregiver interventions	• Frequent reorientation • Fewer care team providers/different faces • Cluster cares to minimize interruptions • Promote normal sleep/wake schedule • Presence of familiar caregivers

Pharmacologic Treatment

Pharmacologic management of delirium focuses on both utilizing medications to help manage the symptoms of delirium while the underlying process is being treated and removing medications that may precipitate or worsen delirium.

Antipsychotics

Medications for the behavioral symptoms of delirium target disruptive behaviors that pose a danger to the patient and caregivers and interfere with necessary medical care. Although these medications do not treat the underlying cause of delirium, they can help to decrease distress and lead to a shorter overall course. Antipsychotic medications are the mainstay of treatment for the behavioral and psychiatric symptoms of delirium. Both first- and second-generation antipsychotics are effective, and the choice of medication is based on what other medical needs are co-occurring. It is recommended to "start low and go slow" to arrive at an effective dose. Although typically used only for a short course (days to weeks), it remains important to consider adverse effects of antipsychotic medications (see Chapter 33). All antipsychotics can cause QTc prolongation; thus it is recommended that electrocardiogram (ECG) monitoring be considered at the onset of and throughout the treatment. For a patient who is unable to take medications by mouth, intramuscular (IM) or intravenous (IV) haloperidol can be used. IV haloperidol is more potent than IM or oral haloperidol; switching between formulations and modes of administration must be done carefully. For patients who can take medications by mouth, second-generation antipsychotics are typically the preferred choice. Risperidone, quetiapine, and olanzapine have all been shown to be effective in treating children and adolescents with delirium. Risperidone and olanzapine are available in an oral disintegrating tablet, and quetiapine is available in a liquid solution, which makes them easy to administer for patients who are dependent on a nasogastric tube for nutrition. Choice of medication is often dependent on what is available in the treatment setting, and the preferred route of administration. In chronically ill medical patients, inquiring about a past history of delirium and treatment can be helpful in guiding medication choices.

Other Medications

Melatonin has some utility in the management of delirium as it can help to promote a normal circadian rhythm and the return to a healthy sleep–wake cycle. Trazodone has also been shown to have some benefit for patients who are struggling with nocturnal sleep maintenance.

Medications to Avoid

In addition to adding medications for the treatment of delirium, eliminating unnecessary or potentially deliriogenic medications is equally important. *Benzodiazepines worsen delirium and should be avoided as much as possible in patients at risk of developing delirium.* They should not be used to treat agitation in delirious patients. Anticholinergic medications are also known to potentiate delirium and should also be avoided. Minimizing polypharmacy to the extent possible can help to

eliminate potentially deliriogenic medications and aid in the *prevention of delirium*.

Pain Medications

Opiate pain medications can be associated with worsening delirium and should be used with care in patients at risk for delirium. Complicating this is the reality that untreated or undertreated pain can also be associated with the development and perpetuation of delirium, so ensuring adequate pain control will help to manage, and in some cases, prevent delirium.

Course and Sequelae

Course

The resolution of delirium can be variable. Some patients improve quickly once the underlying cause is identified and treated, while others may take weeks to months to show full resolution of symptoms. Patients who have delirium related to complex medical issues, such as autoimmune encephalitis, or prolonged hospital stays, may have longer lasting delirium. When symptoms improve, antipsychotic medications can be weaned; patients do not need to be on them long term.

Sequelae

Patients who have delirium are more likely to have subsequent episodes of delirium. There is evidence that patients with delirium go on to have impaired cognitive functioning compared to patients who have never had an episode of delirium.

Learning and Developmental Disorders

PART IV

Chapter 49

Neurodevelopmental and Executive Function and Dysfunction

Desmond P. Kelly and Darla H. McCain

TERMINOLOGY AND EPIDEMIOLOGY

A **neurodevelopmental function** is a basic brain process needed for learning and productivity and involves the following core neurodevelopmental domains: sensory, motor, language, visual-spatial/visual-perceptual, intellectual, memory, social cognition, and executive function. **Executive function (EF)** is a broad term used to describe specific neurocognitive processes involved in the regulating, guiding, organizing, and monitoring of thoughts and actions to achieve a specific goal. Processes considered to be "executive" in nature include inhibition/impulse control, cognitive/mental flexibility, emotional control, initiation skills, planning, organization, working memory, and self-monitoring.

Neurodevelopmental variation refers to differences in neurodevelopmental functioning. Wide variations in these functions exist within and between individuals. These differences can change over time and need not represent pathology or abnormality.

Neurodevelopmental and/or executive dysfunctions reflect any disruptions or weaknesses in these processes, which may result from neuroanatomic disturbance or neuropsychologic malfunctioning.

Neurodevelopmental and/or executive dysfunction places a child at risk for developmental, cognitive, emotional, behavioral, psychosocial, and adaptive challenges. Preschool-age children with neurodevelopmental or executive dysfunction may manifest delays in developmental domains such as language, motor, self-help, or social-emotional development and self-regulation. For the school-age child, an area of particular focus is academic skill development. It is at this age that disorders of learning are often diagnosed. The *Diagnostic and Statistical Manual of Mental Disorder, Fifth Edition* (DSM-5) classifies disorders of learning within the group of neurodevelopmental disorders as **specific learning disorder (SLD)**, with separate specifiers recognizing impairments in reading, written expression, and mathematics. In the *International Classification of Diseases, Tenth Edition* (ICD-10), neurodevelopmental disorders include **specific developmental disorders of scholastic skills** with specific reading disorder, mathematics disorder, and disorder of written expression. **Dyslexia** is a term used more frequently by neurologists and by some advocacy groups to describe reading disorders. **Disorders of EF** have traditionally been viewed as a component of **attention-deficit/hyperactivity disorder (ADHD)**, which is also classified in DSM-5 as a neurodevelopmental disorder. **Frontal lobe and executive function deficit** is a recognized diagnostic term used primarily by neuropsychologists.

There are no prevalence estimates specifically for neurodevelopmental dysfunction, but overall estimates for learning disorders range from 5% to 10% or more with a similar range reported for ADHD. These disorders frequently co-occur. The range in prevalence is related to differences in criteria used for classification and diagnosis, the overlap and interaction of neurodevelopmental variations, and differing methods of assessment.

ETIOLOGY AND PATHOGENESIS

Neurodevelopmental and executive dysfunction may result from a broad range of etiologic factors, including genetic, medical, psychologic, environmental, and sociocultural influences.

A high degree of **heritability** is reported in learning and attention disorders, with estimates ranging from 45% to 80%, but identification of specific gene associations is elusive. Neurodevelopmental dysfunctions generally fall along a continuum of traits with disorders becoming evident at extremes of dimensions or thresholds of dysfunction. The same genetic and early environmental risk factors that are associated with a disorder such as ADHD also predict trait levels in the general population. Specific genes have been identified as associated with reading disorders, including the *DYX2* locus on chromosome 6p22 and the *DYX3* locus on 2p12. Neuroimaging studies have confirmed links between gene variations and variations in cortical thickness in areas of the brain known to be associated with learning and academic performance, such as the temporal regions. Chromosomal abnormalities can lead to unique patterns of dysfunction, such as visual-spatial deficits in females diagnosed with Turner syndrome (see Chapter 99.4) or executive and language deficits in children with fragile X syndrome (see Chapter 99.6). Chromosome 22q11.2 deletion syndrome (see Chapter 99.3) has been associated with predictable patterns of neurodevelopmental and executive dysfunction that can be progressive, including a higher prevalence of intellectual disability and deficits in visual-spatial processing, attention, **working memory** (e.g., the ability to hold and manipulate information over short periods), verbal learning, arithmetic, and language.

Perinatal factors, including very low birthweight, severe intrauterine growth restriction, perinatal hypoxic-ischemic encephalopathy, and prenatal exposure to substances such as alcohol and drugs or infections, may independently disrupt neurodevelopment or exacerbate genetic vulnerabilities. Increased risk of neurodevelopmental and executive dysfunction has also been associated with environmental toxins, including lead (see Chapter 761); drugs such as cocaine; infections such as meningitis, HIV, and Zika; and brain injury associated with intraventricular hemorrhage, periventricular leukomalacia, or head trauma. The negative academic impact of concussion in children and adolescents, although usually temporary, has been well characterized, including impaired concentration and slowed processing speed. Repeated injuries have a much higher likelihood of long-term negative neurocognitive effects.

Early **psychologic trauma** may result in both structural and neurochemical changes in the developing brain, which may contribute to neurodevelopmental and executive dysfunction. Exposure to trauma, abuse, or other adverse experiences in early childhood in the absence of positive experiences—primarily safe, stable, and nurturing relationships—can lead to diminished regulatory influences mediated by key brain regions (hippocampus and prefrontal cortex) and may influence right hemisphere function with associated risk for problems with information processing, memory, focus, and self-regulation. Environmental and sociocultural deprivation can also lead to, or potentiate, neurodevelopmental and executive dysfunction, and numerous studies have indicated that parent/caregiver executive functioning affects the development of EFs in children.

Investigations of neuroanatomic substrates have yielded important information about the underlying **pathogenesis** in neurodevelopmental and executive dysfunction. Differences have been demonstrated in the left parietotemporal and left occipitotemporal brain regions of individuals with dyslexia compared to those without reading difficulties (see Chapter 51). Studies have also described the neural circuitry, primarily in the parietal cortex, underlying mathematical competencies such as the processing of numerical magnitude and mental arithmetic. The associations between executive dysfunction and the *prefrontal/frontal cortex* have been established, and injury to the frontal lobe regions often

result in dysfunction of executive abilities (e.g., poor inhibitory control). Although the prefrontal/frontal cortex may be the primary control region for EFs, there is considerable interconnectivity between the brain's frontal regions and other areas, such as *arousal* systems (reticular activating system), *motivational and emotional* systems (limbic system), *cortical association* systems (posterior/anterior; left/right hemispheres), and *input/output* systems (frontal motor/posterior sensory areas).

CORE NEURODEVELOPMENTAL FUNCTIONS

The neurodevelopmental processes that are critical to a child's successful functioning may best be understood as falling within **core neurodevelopmental domains** that are highly integrated.

Sensory and Motor Function

Sensory development begins well before birth in the primary visual, auditory, and somatosensory cortical regions along with the olfactory and gustatory cortices. This neurodevelopmental process is crucial in helping children experience, understand, and manipulate their environments. Sensory development progresses in association with environmental exposure and with the development of other cognitive processes, such as motor development. Through sensory experiences, children's brains mature as new neuronal pathways are created and existing pathways are strengthened.

There are three distinct, yet related, forms of **neuromotor** ability: fine motor, graphomotor, and gross motor coordination. **Fine motor function** reflects the ability to control the muscles that produce small, exact movements. Deficits in fine motor function can disrupt the ability to communicate in written form and to excel in artistic and crafts activities and can interfere with learning a musical instrument or mastering a computer keyboard.

Graphomotor function refers to the specific motor aspects of written output. Several subtypes of graphomotor dysfunction can significantly impede writing. Children who harbor weaknesses of visualization during writing have trouble picturing the configurations of letters and words as they write (orthographics), with poorly legible written output and inconsistent spacing between words. Others have weaknesses in orthographic memory and may labor over individual letters and prefer printing (manuscript) to cursive writing. Some exhibit signs of finger agnosia and have trouble localizing their fingers while they write, needing to keep their eyes very close to the page and applying excessive pressure to the pencil. Others struggle to produce the highly coordinated motor sequences needed for writing. It is important to emphasize that a child may show excellent fine motor dexterity (as revealed in mechanical or artistic domains) but very poor graphomotor fluency (with labored or poorly legible writing).

Gross motor function refers to control of large muscles. Children with gross motor incoordination often have problems in processing "outer spatial" information to guide gross motor actions. Affected children may be inept at catching or throwing a ball because they cannot form accurate judgments about trajectories in space. Others demonstrate diminished body position sense. They do not efficiently receive or interpret proprioceptive and kinesthetic feedback from peripheral joints and muscles. They are likely to evidence difficulties when activities demand balance and tracking of body position and movement. Others are unable to meet the motor planning demands of complex motor procedures such as those needed for dancing, gymnastics, or swimming.

The term **dyspraxia** relates to difficulty in developing an ideomotor plan and activating coordinated and integrated visual-motor actions to complete a task or solve a motor problem, such as assembling a model or learning a new movement.

Developmental coordination disorder is categorized in DSM-5 as a motor disorder where the learning and execution of coordinated motor skills is below age level given the child's opportunity for skill learning, and the motor difficulties significantly interfere with activities of daily living, academic productivity, and play.

Language

Language is one of the most critical and complex cognitive functions and can be broadly divided into **receptive** (auditory comprehension/understanding) and **expressive** (speech and language production and/or communication) functions (see Chapter 53). Children who primarily experience receptive language problems may have difficulty understanding verbal information, following instructions and explanations, and interpreting what they hear. Expressive language weaknesses can result from problems with speech production and/or problems with higher-level language development. **Speech production difficulties** include oromotor problems affecting articulation, verbal fluency, and naming. Some children have trouble with sound sequencing within words. Others find it difficult to regulate the rhythm or prosody of their verbal output. Their speech may be dysfluent, hesitant, and inappropriate in tone. Problems with **word retrieval** can result in difficulty finding exact words when needed (as in a class discussion) or substituting definitions for words (circumlocution).

The basic components of language include **phonology** (ability to process and integrate the individual sounds in words), **semantics** (understanding the meaning of words), **syntax** (mastery of word order and grammatical rules), **discourse** (processing and producing paragraphs and passages), **metalinguistics** (ability to think about and analyze how language works and draw inferences), and **pragmatics** (social understanding and application of language). Children who evidence higher-level expressive language impediments have trouble formulating sentences, using grammar appropriately, and organizing spoken (and possibly written) narratives.

To one degree or another, all academic skills are taught largely through language, and thus it is not surprising that children who experience language dysfunction often experience problems with academic performance. In fact, some studies suggest that up to 80% of children who present with a specific learning disorder also experience language-based weaknesses. Additionally, the role of language in executive functioning cannot be understated, because language serves to guide cognition and behavior.

Visual-Spatial/Visual-Perceptual Function

Important structures involved in the development and function of the visual system include the retina, the optic nerves, the brainstem (control of automatic responses, e.g., pupil dilation), the thalamus (e.g., lateral geniculate nucleus for form, motion, color), and the primary (visual space and orientation) and secondary (color perception) visual processing regions located in and around the occipital lobe. Other brain areas, although considered to be outside of the primary visual system, are also important to visual function, helping to process *what* is seen (temporal lobe) and *where* it is located in space (parietal lobe).

Critical aspects of visual processing development in the child include appreciation of **spatial** relations (ability to perceive objects accurately in space in relation to other objects), visual discrimination (ability to differentiate and identify objects based on their individual attributes, e.g., size, shape, color, form, position), and visual closure (ability to recognize or identify an object when the entire object cannot be seen). Visual-spatial processing dysfunctions are rarely the cause of reading disorders, but some investigations have established that deficits in orthographic coding (visual-spatial analysis of character-based systems) can contribute to reading disorders. Spelling and writing can emerge as a weakness because children with visual processing problems usually have trouble with the precise visual configurations of words. In mathematics, these children often have difficulty with visual-spatial orientation, with resultant difficulty aligning digits in columns when performing calculations and difficulty managing geometric material. In the social realm, intact visual processing allows a child to make use of visual or physical cues when communicating and interpreting the paralinguistic aspects of language. Secure visual functions are also necessary to process proprioceptive and kinesthetic feedback and to coordinate movements during physical activities.

Intellectual Function

A useful definition of **intellectual function** is the capacity to think in the abstract, reason, problem-solve, and comprehend. Intelligence is viewed as a global construct composed of more specific cognitive

functions (e.g., auditory and visual-perceptual processing, spatial abilities, processing speed, and working memory).

The expression of intellect is mediated by many factors, including language development, sensorimotor abilities, genetics, heredity, environment, and neurodevelopmental function. When an individual's measured intelligence is >2 standard deviations below the mean (a standard score of <70 on most IQ tests) and accompanied by significant weaknesses in adaptive skills, the diagnosis of **intellectual disability** may be warranted (see Chapter 56). Functionally, some common characteristics distinguish children with intellectual disability from those with average or above-average abilities. Typically, those at the lowest end of the spectrum (e.g., profound or severe intellectual disability) are incapable of independent function and require a highly structured environment with constant aid and supervision. At the other end of the spectrum are those with unusually well-developed intellect ("gifted"). Stronger intellect has been associated with better-developed concept formation, critical thinking, problem solving, understanding and formulation of rules, brainstorming and creativity, and *metacognition* (ability to "think about thinking"). Although high levels of intellectual functioning offer many opportunities, they can also be associated with functional challenges related to socialization, learning, and communication style.

Individuals whose intellect falls in the below-average range (sometimes referred to as the "borderline" or "slow learner" range) tend to experience greater difficulty processing and managing information that is abstract, making connections between concepts and ideas, and generalizing information (e.g., may be able to comprehend a concept in one setting but be unable to carry it over and apply it in different situations). In general, these individuals tend to do better when information is presented in more concrete and explicit terms (with repetition) and when working with rote information (e.g., memorizing specific material).

Memory

Memory is a term used to describe the complex, cognitive mechanism by which information is acquired, retained, and recalled. Major brain areas involved in memory processing include the hippocampus, fornix, temporal lobes, and cerebellum, with connections in and between most brain regions. Memory consists of multiple distinct and interconnected subsystems that are categorized based on the length of time information is stored (e.g., short-term memory, long-term memory), type of information stored (e.g., events, facts, procedures, emotional associations, conditioned reflexes), modality of the information (e.g., visual, auditory, olfactory), and whether memories are consciously recalled (**explicit memory**) or unconsciously recalled (**implicit memory**). Information processing models also include **working memory** as a distinct component.

Memory formation begins with sensory input (e.g., auditory, visual, tactile) that is identified, or **registered**, and subsequently **encoded**. Encoding is a mental process that transforms perceptual input into a representational code for the memory system. Information in **short-term memory** is transferred into **long-term memory** through the process of **consolidation** and **storage**. Information capacity in short-term memory is limited and brief, lasting for seconds to minutes, whereas information in long-term memory is potentially unlimited in terms of capacity and can be available for hours or as long as a life span.

Once information finds its way into long-term memory, it must be accessed. In general, information can be retrieved spontaneously (a process known as **free recall**) or with the aid of cues (**cued or recognition recall**). With deliberate, repeated practice, children can develop **automaticity**, the ability to instantaneously and effortlessly access information that has been learned in the past. Automaticity frees cognitive resources to process other information and promote learning. For example, automaticity in decoding words allows a child to focus on the meaning of the text.

Social Cognition

The development of effective social skills is heavily dependent on secure **social cognition**, which consists of mental processes that allow an individual to understand and interact with the social environment. Although some evidence shows that social cognition exists as a discrete area of neurodevelopmental function, multiple cognitive processes are involved with social cognition. These include the ability to recognize, interpret, and make sense of the thoughts, communications (verbal and nonverbal), and actions of others; the ability to understand that others' perceptions, perspectives, and intentions might differ from one's own (commonly referred to as "theory of mind"); the ability to use language to communicate with others socially (pragmatic language); and the ability to make inferences about others and the environment based on contextual information. It can also be argued that social cognition involves processes associated with memory and EFs, such as flexibility and shifting. Children with autism spectrum disorder harbor deficits in social cognition (see Chapter 58).

Executive Function

EF involves multiple skills (Table 49.1) that begin development early in life (early indications of inhibitory control and even working memory have been found in infancy), mature significantly during the preschool years, and continue to develop through adolescence and well into adulthood. Some studies suggest that secure EF may be more important than intellectual ability for academic success and have revealed that a child's ability to delay gratification early in life predicts competency, attention, self-regulation, frustration tolerance, aptitude, physical and mental health, and even risk for substance dependency in adolescence and adulthood. Conversely, deficits in other areas of neurodevelopment, such as language development, affect EF.

Attention is far from a unitary, independent, or specific brain function. This may be best illustrated through the phenotype associated with ADHD (see Chapter 50). Disordered attention can result from faulty mechanisms in and across subdomains of attention. These subdomains include *selective* attention (ability to focus attention on a particular stimulus and to discriminate relevant from irrelevant information), *divided* attention (ability to orient to more than one stimulus at a given time), *sustained* attention (ability to maintain one's focus), and *alternating* attention (capacity to shift focus between stimuli).

Attention problems in children can manifest at any point, from arousal through output. Children with diminished alertness and

Table 49.1 Symptom Expression of Executive Dysfunction

EXECUTIVE FUNCTION DEFICIT	SYMPTOM EXPRESSION
Inhibitory control	Impulsivity/poor behavioral regulation Interrupts "Blurts things out"
Shifting	Problems with transitioning from one task/activity to another Unable to adjust to unexpected change Repeats unsuccessful problem-solving approaches
Initiation	Difficulty independently beginning tasks/activities Lacks initiative Difficulty developing ideas or making decisions
Working memory	Challenges following multistep instruction (e.g., only completes one of three steps) Forgetfulness
Organization and planning	Fails to plan ahead Work is often disorganized Procrastinates and does not complete tasks "Messy" child
Self-monitoring	Fails to recognize errors and check work Does not appreciate impact of actions on others Poor self-awareness
Emotional control	Experiences behavioral and emotional outbursts (e.g., tantrums) Easily upset/frustrated Frequent mood changes

arousal can exhibit signs of mental fatigue in a classroom or when engaged in any activity requiring sustained focus. They are apt to have difficulty directing and sustaining their concentration, and their efforts may be erratic and unpredictable, with extreme performance inconsistency. Weaknesses in determining saliency often result in allocating cognitive resources to the wrong stimuli, at home, in school, and socially, and missing important information. **Distractibility** can take the form of listening to extraneous noises instead of a teacher, staring out the window, or constantly thinking about the future. Attention dysfunction can affect the output of work, behavior, and social activity. It is important to appreciate that most children with attentional dysfunction also have other forms of neurodevelopmental dysfunction that can be associated with academic disorders (with some estimates suggesting up to 60% comorbidity).

Inhibitory control (IC) can be described as one's ability to restrain, resist, and not act (cognitively or behaviorally/emotionally) on a thought. IC may also be seen as one's ability to stop thoughts or ongoing actions. Deficits in this behavioral/impulse regulation mechanism are a core feature of the **combined** or **hyperactive impulsive** presentation of ADHD and have a significant adverse impact on a child's overall functioning. In everyday settings, children with weak IC may exhibit difficulties with self-control and self-monitoring of their behavior and output (e.g., impulsivity), may not recognize their own errors or mistakes, and often act prematurely and without consideration of the potential consequences of their actions. In the social context, disinhibited children may interrupt others and demonstrate other impulsive behaviors that often interfere with interpersonal relationships. The indirect consequences of poor IC can include challenges with behavior, emotional regulation, and academic functioning and have adverse impacts on social interactions and safety.

Shifting is the ability to transition from one activity, topic, or aspect of a problem to another when needed. Effective shifting allows a child to flexibly move through their day, tolerating changes in schedule and routine. Additionally, shifting allows a child to change strategies when working a problem and adjust to changes in topics when conversing with others. Children with difficulties in shifting can become quickly upset in novel situations (e.g., when presented with a substitute teacher) and show marked resistance to change in routine. They can get stuck on one problem-solving strategy, which compromises their work efficiency. Socially, problems with shifting can result in one-sided conversations, negatively affecting a child's ability to build and maintain friendships.

Initiation refers to the ability to independently begin an activity, a task, or thought process (e.g., problem-solve). Children who present with initiation difficulties often have trouble "getting started." This can be exhibited behaviorally, such that the child struggles to start on physical activities like getting out of bed or beginning chores. Cognitively, weaknesses in initiation may manifest as difficulty coming up with ideas or generating plans. In school, children who have poor initiation abilities may be slow or unable to start homework assignments or tests. In social situations, initiation challenges may cause a child to have difficulty beginning conversations, calling on friends, or going out with friends.

Deficits in "primary" initiation are relatively rare and are often associated with significant neurologic conditions and treatments (e.g., traumatic brain injury, anoxia, effects of radiation treatment in childhood cancer). More often, initiation deficits are secondary to other executive problems (e.g., disorganization) or behavioral (e.g., oppositional/defiant behaviors), developmental (e.g., autism spectrum disorder), or emotional (e.g., depression, anxiety) disorders.

Working memory (WM) can be defined as the ability to hold, manipulate, and store information for short periods. In its simplest form, WM involves the interaction of short-term verbal and visual processes (e.g., memory, phonologic awareness, and spatial skills) with a centralized control mechanism that is responsible for coordinating all the cognitive processes involved (e.g., temporarily suspending information in memory while manipulating it). Ultimately, this function enables new information arriving in short-term memory to be linked to prior knowledge or procedures held in long-term memory. As such, working memory is critical to be able to complete multistep problems and more complex instructions and tasks. WM capacity can double or triple between the preschool years and adolescence. In the classroom, a child with a weakness in working memory might appear inattentive or careless when completing their work. When doing math, a child with WM dysfunction might have difficulty carrying a number and following the expected procedure. When reading a paragraph, a child might not recall key facts or be able to integrate information when reading, particularly long paragraphs. For writing tasks, a child might leave out ideas they intended to express while they are recalling grammar rules, such as placing a comma, and working on spelling a word correctly.

Planning refers to the ability to effectively generate, sequence, and put into motion the steps and procedures necessary to realize a specific goal. In real-world settings, children who struggle with planning are typically described by caregivers and teachers as being inept at independently gathering what is required to solve a problem or as unable to complete more weighty assignments. These children commonly exhibit poor time management skills.

Organization is an ability that represents a child's proficiency in arranging, ordering, classifying, and categorizing information. Planning and organizing depend on **discrimination** ability, which refers to the child's ability to determine what is and is not valuable when trying to problem-solve or organize. Common daily life challenges associated with organizational difficulties in childhood include problems with gathering and managing materials or items. When children struggle with organization, indirect consequences may include becoming overwhelmed with information and being unable to complete a task or activity. Effective organization is a vital component in learning (more specifically, in memory/retention); many studies, along with clinical experience, have shown that poor organization significantly affects how well a child recalls information.

Self-monitoring involves awareness and assessment of one's actions, whether it be a work product (e.g., writing an essay) or social interaction with another. This EF allows one to evaluate and make necessary corrections. Children with difficulty in self-monitoring fail to recognize errors in their work and struggle with editing. When interacting with others, they may not realize how their verbal and nonverbal behaviors are being perceived, ultimately missing opportunities to correct their behavior and resulting in poor social interactions.

Emotional control is the ability to regulate emotions in order to realize goals and direct one's behavior, thoughts, and actions. It has been well established that affective/emotional states have an impact on many aspects of functioning. Conversely, executive function or dysfunction often contributes to modulation of affect. Although emotional control is highly interrelated with different EFs (e.g., disinhibition, self-monitoring), separating it conceptually facilitates an appreciation for and recognition of the often-overlooked role that a child's emotional state plays in cognitive and behavioral functioning. Children with weak emotional control may exhibit explosive outbursts, poor temper/anger control, and oversensitivity. Understanding a child's emotional state is vital to understanding its impact not only on executive functioning but also on functioning as a whole (e.g., socially, mentally, behaviorally, academically).

Any discussion involving emotional control should also recognize **motivation**. *Motivation/effort* may be defined as the reason or reasons one acts or behaves in a certain way. Less motivated children are less likely to engage and utilize all their abilities. Such a disposition not only interferes with application of executive skills but also results in less-than-optimal performance and functioning. The less success a child feels, the less likely the child is to put forth effort and to persevere when things become more challenging. If a child's initial efforts are met with a negative reaction, the likelihood that the child will continue putting forth adequate effort diminishes. If left unchecked, a child's overall level of functioning will likely be compromised. More importantly, the child's sense of personal efficacy (e.g., self-esteem) and competence may suffer.

CLINICAL MANIFESTATIONS

The symptoms and clinical manifestations of neurodevelopmental and executive dysfunction differ with age. **Preschool-age children**

might present with delayed language development, including problems with articulation, vocabulary development, word finding, and rhyming. They often experience early challenges with learning colors, shapes, letters, numbers, the alphabet, and days of the week. Children with visual processing deficits may have difficulty learning to draw and write and have problems with art activities. These children might also have trouble discriminating between left and right. They might encounter problems recognizing letters and words. Difficulty following instructions, overactivity, and distractibility may be early symptoms of emerging executive dysfunction. Difficulties with fine motor development (e.g., grasping crayons/pencils, coloring, drawing) and social interaction may develop. These manifestations should be considered as potential "red flags" for future learning challenges (see "Assessment and Diagnosis").

School-age children with neurodevelopmental and executive dysfunctions can vary widely in clinical presentations. Their specific patterns of academic performance and behavior represent final common pathways of neurodevelopmental strengths and deficits interacting with environmental, social, or cultural factors; temperament; educational experience; and intrinsic resilience (Table 49.2). Children with language weaknesses might have problems integrating and associating letters and sounds, decoding words, deriving meaning, and being able to comprehend passages. Children with early signs of a mathematics weakness might have difficulty with concepts of quantity or with adding or subtracting without using concrete representation (e.g., their fingers when calculating). Difficulty learning time concepts and confusion with directions (right/left) might also be observed. Poor fine motor control and coordination and poor planning can lead to writing problems. Attention and behavioral regulation weaknesses observed earlier can continue, and together with other EF weaknesses (e.g., organization, initiation skills), further complicate the child's ability to acquire and generalize new knowledge. Children with weaknesses in WM may struggle to remember the steps necessary to complete an activity or problem-solve. In social settings, these children often have difficulty keeping up with more complex conversations.

Table 49.2 Neurodevelopmental Dysfunction Underlying Academic Disorders*

ACADEMIC DISORDER	POTENTIAL UNDERLYING NEURODEVELOPMENTAL DYSFUNCTION
Reading	Language • Phonologic processing • Verbal fluency • Syntactic and semantic skills Memory • Working memory Sequencing Visual-spatial Attention
Written expression, spelling	Language • Phonologic processing • Syntactic and semantic skills Graphomotor Visual-spatial Memory • Working memory Sequencing Attention
Mathematics	Visual-spatial Memory • Working memory Language Sequencing Graphomotor Attention

*Isolated neurodevelopmental dysfunction can lead to a specific academic disorder, but more often there is a combination of factors underlying weak academic performance. In addition to the dysfunction in neurodevelopmental domains as listed in the table, the clinician must also consider the possibility of limitations of intellectual and cognitive abilities or associated social and emotional problems.

In **middle school children** the substantial increase in cognitive, academic, and regulatory demands can cause further difficulties for those with existing neurodevelopmental and executive challenges. In reading and writing, middle school children might present with transposition and sequencing errors; might struggle with root words, prefixes, and suffixes; might have difficulty with written expression; and might avoid reading and writing altogether. Challenges completing word problems in math are common. Difficulty with recall of information might also be experienced. Although observable in both lower and more advanced grades, behavioral, emotional, and social difficulties tend to become more salient in middle school children who experience cognitive or academic problems.

High school students can present with deficient reading comprehension, written expression, and slower processing efficiency. Difficulty in answering open-ended questions, dealing with abstract information, and deploying executive control (e.g., self-monitoring, organization, planning, self-starting) is often reported.

Academic Problems

Reading disorders (see Chapter 51) can stem from a number of neurodevelopmental dysfunctions, as described earlier (see Table 49.2). Most often, language and auditory processing weaknesses are present, as evidenced by poor phonologic processing that results in deficiencies at the level of decoding individual words and, consequently, a delay in *automaticity* (e.g., acquiring a repertoire of words readers can identify instantly) that causes reading to be slow, laborious, and frustrating. Deficits in other core neurodevelopmental domains might also be present. Weak WM might make it difficult for a child to hold sounds and symbols in mind while breaking down words into their component sounds, or might cause reading comprehension problems. Some children experience temporal-ordering weaknesses and struggle with reblending phonemes into correct sequences. Memory dysfunction can cause problems with recall and summarization of what was read. Some children with higher-order cognitive deficiencies have trouble understanding what they read because they lack a strong grasp of the concepts in a text. Although rare as a cause of reading difficulty, problems with visual-spatial functions (e.g., visual perception) can cause children difficulty in recognizing letters. It is not unusual for children with reading problems to avoid reading practice, and a delay in reading proficiency becomes increasingly pronounced and difficult to remediate.

Spelling and writing impairments share many related underlying processing deficits with reading, so it is not surprising that the two disorders often occur simultaneously in school-age children (see Table 49.2). Core neurodevelopmental weaknesses that underlie *spelling difficulties* include phonologic and decoding difficulties, orthographic problems (coding letters and words into memory), and morphologic deficits (use of suffixes, prefixes, and root words). Problems in these areas can manifest as phonetically poor, yet visually comparable, approximations to the actual word (*faght* for *fight*), spelling that is phonetically correct but visually incorrect (*fite* for *fight*), and inadequate spelling patterns (*plade* for *played*). Children with memory disorders might misspell words because of coding weaknesses. Others misspell because of poor auditory WM that interferes with their ability to process letters. Sequencing weaknesses often result in transposition errors when spelling.

Writing difficulties have been classified as **disorder of written expression**, or **dysgraphia** (see Table 49.2). Although many of the same dysfunctions described for reading and spelling can contribute to problems with writing, written expression is the most complex of the language arts, requiring synthesis of many neurodevelopmental functions (e.g., auditory, visual-spatial, memory, executive; see Chapter 52.2). Weaknesses in these functions can result in written output that is difficult to comprehend, disjointed, and poorly organized. The child with WM challenges can lose track of what the child intended to write. Attention deficits can make it difficult for a child to mobilize and sustain the mental effort, pacing, and self-monitoring demands necessary for writing. In many cases, writing is laborious because of an underlying *graphomotor dysfunction* (e.g., fluency does not keep pace

with ideation and language production). Thoughts may also be forgotten or underdeveloped during writing because the mechanical effort is so taxing.

Weaknesses in mathematical ability, known as **mathematics disorder** or **dyscalculia**, involve the assimilation of both procedural knowledge (e.g., calculations) and higher-order cognitive processes (e.g., WM) (see Table 49.2). There are many reasons why children struggle with mathematics (see Chapter 52.1). It may be difficult for some to grasp and apply math concepts effectively and systematically; good mathematicians are able to use both verbal and perceptual conceptualization to understand such concepts as fractions, percentages, equations, and proportion. Children with language dysfunctions have difficulty in mathematics because they have trouble understanding their teachers' verbal explanations of quantitative concepts and operations and are likely to experience frustration in solving word problems and in processing the vast network of technical vocabulary in math. Mathematics also relies on visualization. Children who have difficulty forming and recalling visual imagery may be at a disadvantage. They might experience problems writing numbers correctly, placing value locations, and processing geometric shapes or fractions. Children with executive dysfunction may be unable to focus on fine detail (e.g., operational signs), might take an impulsive approach to problem solving, engage in little or no self-monitoring, forget components of the problem, or commit careless errors. When a child's memory system is weak, the child might have difficulty recalling appropriate procedures and automatizing mathematical facts (e.g., multiplication tables). Moreover, children with mathematical disabilities can have superimposed mathematics **phobias**; anxiety over mathematics can be especially debilitating.

Nonacademic Problems

The impulsivity and lack of effective self-monitoring of children with executive dysfunction can lead to unacceptable actions that were unintentional. Children struggling with neurodevelopmental dysfunction can experience excessive performance anxiety, sadness, or clinical depression; declining self-esteem; and chronic fatigue. Some children may lose motivation and feel no need to exert effort and develop future goals. These children may be easily led toward dysfunctional interpersonal relationships, detrimental behaviors (e.g., delinquency, substance abuse), and the development of mental health disorders, such as mood disorders (see Chapter 39) or conduct disorder (see Chapter 42).

ASSESSMENT AND DIAGNOSIS

Pediatricians have a critical role in identifying and treating the child with neurodevelopmental or executive dysfunction (Fig. 49.1). They have knowledge of the child's medical and family history and social-environmental circumstances and have the benefit of longitudinal contact over the course of routine health visits. Focused **surveillance and screening** will facilitate early identification of developmental-behavioral and preacademic difficulties and interventions to facilitate optimal outcomes.

A **family history** of a parent who still struggles with reading or time management or an older sibling who has failed at school should spur an increased level of monitoring. **Risk factors** in the medical history, such as extreme prematurity or chronic medical conditions, should likewise be flagged. Children with low birthweight and those born prematurely who appear to have been spared more serious neurologic problems might only manifest academic problems later in their school career. **Nonspecific physical complaints** or unexpected **changes in behavior** might be presenting symptoms. Warning signs might be subtle or absent, and parents might have concerns about their child's learning progress but may be reluctant to share these with the pediatrician unless prompted, such as through completion of **standardized developmental screening questionnaires** or direct questioning regarding possible concerns. Concerns voiced to parents or caregivers by daycare, preschool, or early elementary teachers might be the first indicators of neurodevelopmental dysfunctions. There should be a low threshold for initiating further school performance screening and assessment if there are any concerns or "red flags" (see "Clinical Manifestations").

In elementary school, review of **school report cards** and teacher comments can provide very useful information. In addition to patterns of grades in the various academic skill areas, it is also important to review ratings of classroom behavior and work habits. Group-administered **standardized tests** provide further information, although interpretation is required because poor scores could result from a learning disorder, ADHD, emotional problems, lack of motivation, or some combination. Conversely, a discrepancy between above-average scores on standardized tests and unsatisfactory classroom performance could signal motivation, adjustment issues, or instructional mismatches. Challenges related to **homework**, such as excessive time to complete, can provide further insight regarding EFs, academic skill, and behavioral factors or factors related to the home environment.

Underlying or associated medical problems should be ruled out. Any suspicion of sensory difficulty should warrant referral for **vision or hearing testing**. The influence of chronic medical problems or potential side effects of medications should be considered. **Sleep deprivation** is increasingly being recognized as a contributor to academic problems, especially in middle and high school. **Substance use** must always be a consideration as well, especially in the adolescent previously achieving well who has shown a rapid decline in academic performance.

The physician should be alert for **dysmorphic physical features**, minor congenital anomalies, or constellations of physical findings (e.g., cardiac and palatal anomalies in 22q11.2 deletion syndrome) and should perform a detailed **neurologic examination**, including an assessment of fine and gross motor coordination and any involuntary movements or soft neurologic signs. Genetic testing is often recommended for children with intellectual disability or autism spectrum disorder; electroencephalogram and brain MRI are generally not indicated in the absence of specific medical findings or a family history.

Early signs of **executive dysfunction** can also be subtle and easily overlooked or misinterpreted. Informal inquiry might include questions about how children complete schoolwork or tasks, how organized or disorganized they are, how much guidance they need, whether they think through problems or respond and react too quickly, what circumstances or individuals affect their ability to employ EFs, how easily they begin tasks and activities, and how well they plan, manage belongings, and control their emotions.

Pediatricians who are interested in performing further assessment before referral, or who are practicing in areas where psychologic testing resources are limited, can use **standardized rating scales and inventories** or brief, individually administered tests to narrow potential diagnoses and guide next steps in diagnosis and treatment. Such instruments, completed by the parents, teachers, and the child (if old enough), can provide information about emotions and behavior, patterns of academic performance, and traits associated with specific neurodevelopmental dysfunctions (see Chapter 32). Screening instruments such as the *Pediatric Symptom Checklist* and behavioral questionnaires such as the *Child Behavior Checklist* (CBCL) and *Behavior Assessment System for Children, Third Edition* (BASC-3) can aid in evaluation.

EFs can be further assessed by instruments such as the *Behavior Rating Inventory of Executive Function, Second Edition* (BRIEF-2), which provides a comprehensive measure of real-world behaviors that are closely tied to executive functioning in children age 5-18 years. Tests that can be directly administered to gauge intellectual and language functioning include the *Kaufman Brief Intelligence Test, Second Edition* (KBIT-2) and *Peabody Picture Vocabulary Test, Fifth Edition* (PPVT 5; assessing receptive vocabulary). A relatively brief test of academic skills is the *Wide Range Achievement Test5* (WRAT5). It should be recognized that these are midlevel tests that can provide descriptive estimates of function but are not diagnostic.

Children who are struggling academically are entitled to evaluations in school. Such assessments are guaranteed in the United States under Public Law 101-476, the **Individuals with Disabilities Education Act (IDEA)**. One increasingly common type of evaluation model supported by IDEA is referred to as a **Response to Intervention (RtI)** model (see Chapter 52.1). In this model, students who are struggling with academic skills are initially provided research-based instruction. If a child does not respond to this instruction, an individualized

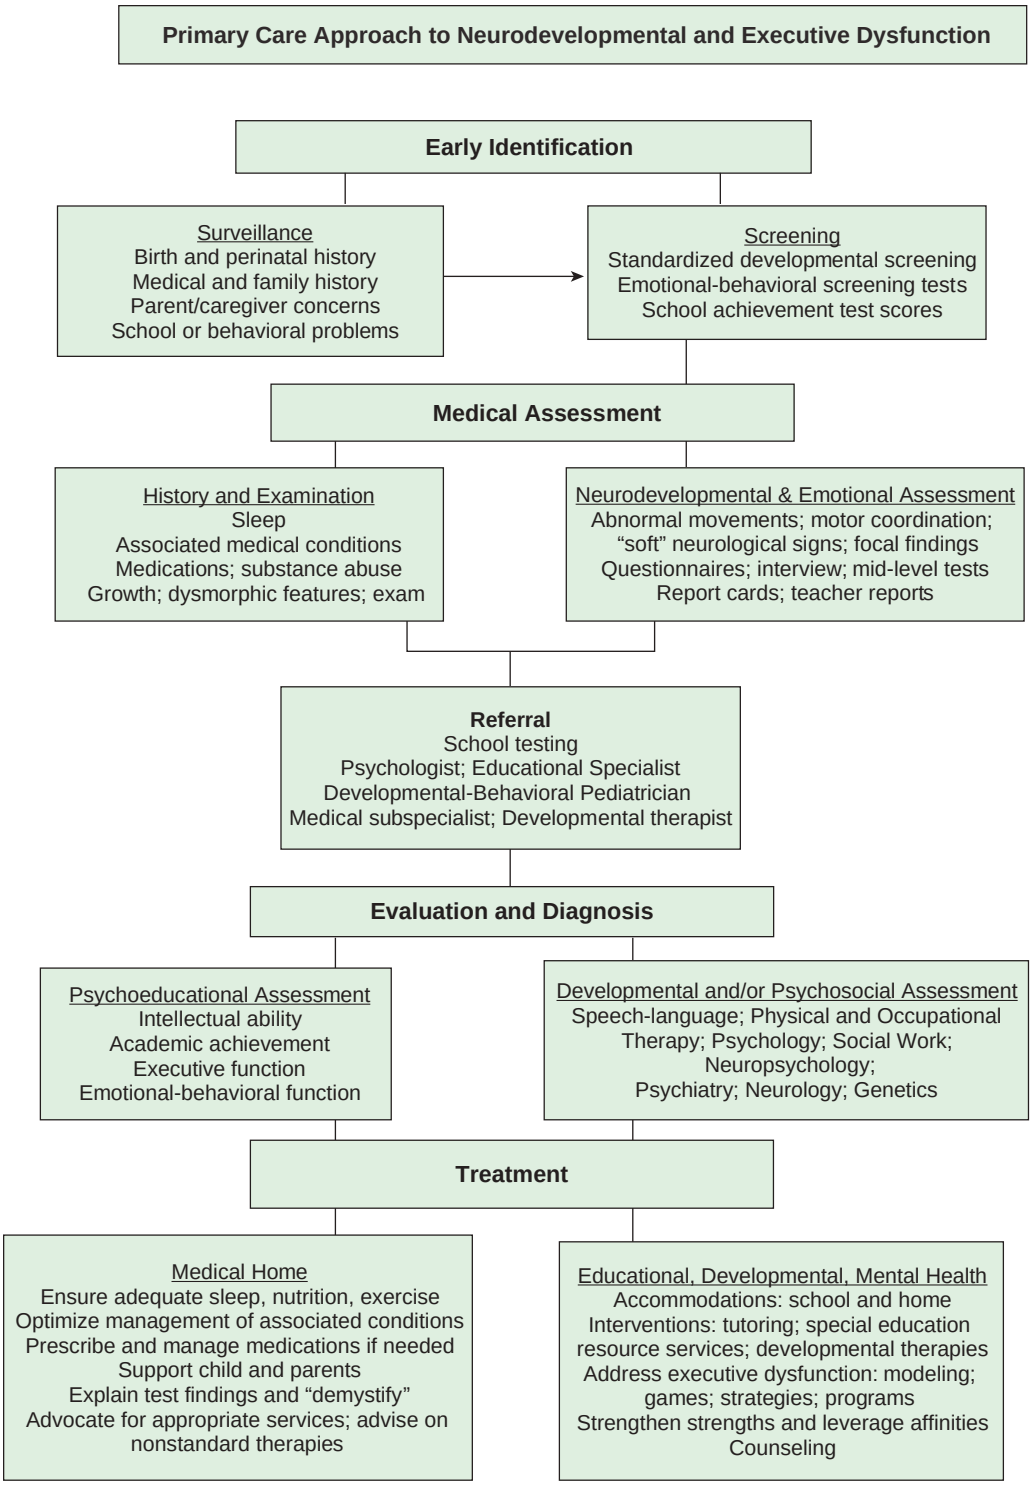

Fig. 49.1 Algorithm showing components of a primary care approach to identification, diagnosis, and comprehensive multidisciplinary management of neurodevelopmental and executive dysfunction.

evaluation by a multidisciplinary team is conducted. Children found to have attentional dysfunction and other disorders might qualify for educational accommodations in the regular classroom under Section 504 of the Rehabilitation Act of 1973 (**504 Plan**) or might qualify for an **individualized education program (IEP)**.

The pediatrician should advise and support parents regarding steps to request evaluations by the school. Multidisciplinary evaluations are focused primarily on determining whether a student meets the eligibility criteria for special education services and to assist in developing an IEP for those eligible for these services. **Independent evaluations** can provide second opinions outside the school setting. The multidisciplinary team should include a psychologist and preferably an educational diagnostician who can undertake a detailed analysis of academic skills and subskills to pinpoint where breakdowns are occurring in the processes of reading, spelling, writing, and mathematics. Other professionals should become involved, as needed, such as a speech-language pathologist, occupational therapist, and social worker. A mental health specialist can be valuable in identifying family-based issues or psychiatric disorders that may be complicating or aggravating neurodevelopmental dysfunctions.

In some cases, more in-depth examination of a child's **neurocognitive status** is warranted. This is particularly true for children who

present with developmental or cognitive difficulties in the presence of a medical condition (e.g., epilepsy, traumatic brain injury, childhood cancers/brain tumors, genetic conditions). A **neuropsychologic evaluation** involves comprehensive assessment to understand brain functions across domains. Neuropsychologic data are often analyzed together with other tests, such as MRI, to look for supporting evidence of any areas of difficulty (e.g., memory weaknesses associated with temporal lobe anomalies). Neuropsychologists can also provide more in-depth evaluation of EFs. Assessment of EFs is typically completed in an examination setting using tools specifically designed to identify any weaknesses in these functions. Although few tools are currently available to assess EF in preschool-age children, the assessment of school-age children is better established. Problems with EFs should be evaluated across measures and in different settings, particularly within the context of the child's daily demands.

TREATMENT

Treatment for neurodevelopmental and executive dysfunction involves a **multimodal, multidisciplinary "cross-sector" approach to foster optimal outcomes.** This process begins with **demystification**, which involves educating the child and family about the nature of the child's delay or dysfunction while also identifying a child's strengths. The explanation of the dysfunction should be provided in nontechnical language, communicating a sense of optimism for improvement with appropriate intervention. Children need to have their affinities, potentials, and talents identified clearly and emphasized as an integral component of the long-term treatment plan. It is as important to **augment strengths** as it is to attempt to **remedy deficiencies**. Athletic skills, artistic inclinations, creative talents, and mechanical abilities are among the potential assets of certain students who are underachieving academically. Parents and school personnel need to create opportunities for such students to build on these assets. These well-developed personal assets can ultimately have implications for the transition into young adulthood, including career or college selection.

In the clinic setting, the pediatrician plays an important role as a **consultant and advocate** in overseeing and monitoring the implementation of a comprehensive multidisciplinary management plan for children with neurodevelopmental dysfunctions. The primary care provider should **identify and treat any underlying or associated medical problems** that might contribute to neurodevelopmental and EF dysfunction, such as iron deficiency, elevated lead levels, and sleep problems, including inadequate sleep related to poor sleep hygiene or poor quality of sleep (e.g., obstructive sleep apnea). Additionally, the pediatrician will need to monitor for **conditions that often co-occur** with neurodevelopmental delays and executive dysfunction or that may develop over time, including anxiety, depression, and substance use disorder.

Bypass Strategies (Accommodations)

Numerous techniques can enable a child to circumvent neurodevelopmental dysfunctions. Such strategies are typically used in the regular classroom and can be incorporated into a 504 Plan or IEP. Accommodations change *how* the child learns, allowing them to access material and meet the same expectations as their peers. Examples of accommodations include using large print for those with visual impairment and using a frequency modulation (FM) system for students with hearing impairment. For children with learning disorders, accommodations may include using a calculator while solving mathematical problems, writing essays with a word processor and use of spellcheck, or presenting oral instead of written reports. Children with executive dysfunction might benefit from being seated near the teacher to minimize distractions and taking tests untimed. These bypass strategies do not cure neurodevelopmental dysfunctions, but they minimize their academic and nonacademic effects and can provide a scaffold for more successful academic achievement.

Curriculum Modifications

Many children with neurodevelopmental dysfunctions require alterations in the school curriculum to succeed, especially as they progress through secondary school. A modification changes *what* the child is taught or expected to learn. Modifications include a student learning different material (e.g., continuing to work on addition and subtraction facts while peers move on to fractions) and instructors assigning grades using a different standard. In high school and college, students with memory weaknesses might need to work with an advisor to select courses that avoid an inordinate cumulative memory load in any single semester. For adolescents with learning disorders, the timing of foreign language learning and the selection of mathematics and science courses are critical to their academic success.

Remediation/Targeted Intervention

Interventions can be implemented at home and in school to strengthen academic skills. **Early identification** is critical so that appropriate instructional interventions can be introduced to minimize the long-term effects of academic disorders. Any interventions should be empirically supported (e.g., phonologically based reading intervention has been shown to significantly improve reading skills in school-age children). **Remediation** may take place in a resource room or learning center at school and is usually limited to children who have met the educational criteria for special education services described earlier. Reading specialists, mathematics tutors, and other professionals can use diagnostic data to select techniques that use a student's neurodevelopmental strengths to improve decoding skills, writing ability, or mathematical computation skills. Remediation need not focus exclusively on specific academic areas. Many students need assistance in acquiring study skills, cognitive strategies, and productive organizational habits.

Speech-language pathologists offer intervention for children with various forms of language disability. **Occupational therapists** focus on sensorimotor skills, including the motor skills of students with writing problems, and **physical therapists** address gross motor incoordination.

Treatment of Executive Dysfunction

Interventions to strengthen EFs can be implemented throughout childhood but are most effective if started at a young age. Preschool-age children first learn EFs by way of the **modeling, boundaries, and rules** observed and put in place by their parents/caregivers, and this modeled behavior must gradually become "internalized" by the child. Early **play** has been shown to be effective in promoting executive skills in younger children with games such as peek-a-boo (WM); pat-a-cake (WM and IC); follow the leader, Simon Says, and "Ring Around the Rosie" (self-control); imitation activities (attention and impulse control); matching and sorting games (organization and attention); and imaginary play (attention, WM, IC, self-monitoring, cognitive flexibility).

In school-age children it is crucial to establish consistent **cognitive and behavioral routines** that foster and maximize independent, goal-oriented problem solving and performance through mechanisms that include modification of the child's environment, modeling and guidance with the child, and positive reinforcement strategies. Interventions should promote **generalization** (teaching executive routines in the context of a problem, not as a separate skill) and should move from the external to the internal (from "external support" with active and directive modeling to an "internal process"). An intervention could proceed from external modeling of multistep problem-solving routines and external guidance in developing and implementing everyday routines, to practicing application and use of routines in everyday situations, to a gradual fading of external support and cueing of internal generation and use of executive skills. Such approaches should make the child a part of intervention planning, should avoid labeling, reward effort not outcomes, make interventions positive, and hold the child responsible for his or her efforts. Studies have consistently shown that a **combination of medication and behavioral treatments** are most effective, although evidence for long-term efficacy is lacking. It is important that any treatment plans aimed at bolstering attention and EF also include interventions that address the specific deficits associated with any comorbid diagnoses.

In addition to behavioral approaches, **cognitive training**, both computerized and noncomputerized, has been shown to strengthen the cognitive skills on which one is trained. Some computerized training

programs show lasting improvements in WM skills in children, though benefits are narrow and limited only to the aspects of WM specifically trained. Recently, game-based digital therapy has been shown to improve attention in children with ADHD-inattentive type and combined type. Noncomputerized cognitive training has shown greater improvements in EF than any type of computerized cognitive training. This may be the result of instructor-trainee interaction. Also evidencing positive outcomes are curriculum-based **classroom programs**, such as the *Tools of the Mind* (Tools) and *Promoting Alternative Thinking Strategies* (PATHS), which have been shown to improve IC.

Emerging evidence suggests **physical activity** can improve EF. Children who are more physically active and have better aerobic fitness have been shown to have better EF than children who are sedentary. Although plain aerobic exercise (e.g., walking, running) has not been found to improve EF, encouraging findings have been noted when an activity involves aerobic exercise and is also cognitively demanding. Basketball and dance, for example, are high in physical exertion while also requiring cognitive engagement through motor coordination and planning. In contrast, resistance training has not been shown to improve EF.

Approaches that use **mindfulness techniques** are also gaining prominence. Mindfulness practices incorporating movement (e.g., tai chi) improve EF better than those performed in a seated position. **Martial arts** such as taekwondo, which stresses discipline and self-regulation, have demonstrated improvements that generalize in many aspects of EFs and attention (e.g., sustained focus).

COUNSELING AND PARENT TRAINING PROGRAMS

The pediatrician is often in a close, trusting relationship with families and is well-positioned to identify adverse home factors that may require additional supports, including counseling and parent training. When academic difficulties are complicated by family problems or identifiable psychiatric disorders, **psychotherapy** may be indicated. Mental health professionals may offer long-term or short-term therapy. Such intervention may involve the child alone or the entire family. **Cognitive-behavioral therapy** is especially effective for mood and anxiety disorders. It is essential that the therapist have a firm understanding of the nature of a child's neurodevelopmental dysfunctions. Formal **parenting interventions** have also demonstrated strong evidence for effectiveness. Four programs that have the most empirical support are the *Triple P, Parent-Child Interaction Therapy* (PCIT), *Incredible Years,* and *New Forest Parenting Programme*.

Table 49.3 outlines interventions to target the specific components of EF. Although interventions may target each component separately, success will be determined by how well treatments can be integrated across settings and generalized to other areas of function. Whenever possible, working with more than one EF simultaneously is encouraged as a means of scaffolding intervention and building on previously mastered skills.

Medication

Psychopharmacologic agents may be helpful in lessening the toll of some neurodevelopmental dysfunctions. Most often, **stimulants** are used in the treatment of children with attention deficits. Although most children with attention deficits have other associated dysfunctions, such as language disorders, memory problems, motor weaknesses, or social skill deficits, medications such as methylphenidate, dextroamphetamine, lisdexamfetamine, and mixed amphetamine salts, as well as nonstimulants such as α_2**-adrenergic agonists** and **atomoxetine**, can be important adjuncts to treatment by helping some children focus more selectively and control their impulsivity. When depression or excessive anxiety is a significant component of the clinical picture,

Table 49.3 Executive Function Categories: Presenting Symptoms, Suggested Dysfunction, and Potential Interventions

SYMPTOM/PRESENTING COMPLAINT	SUSPECTED AREA OF DYSFUNCTION	POSSIBLE "REAL-WORLD" INTERVENTIONS
Acts before thinking Interrupts Poor behavioral and/or emotional control	Inhibitory control	Increase structure in environment to set limits for inhibition problems. Make behavior and work expectations clear and explicit; review with child. Post rules in view; point to them when child breaks rule. Teach response-delay techniques (e.g., counting to 10 before acting).
Cannot follow multistep instructions Forgetful	Working memory	Repeat instructions as needed. Keep instructions clear and concise. Provide concrete references.
Struggles starting assignments/tasks Lacks initiative/motivation Has trouble developing ideas/strategies	Initiation	Increase structure of tasks. Establish and rely on routine. Break tasks into smaller, manageable steps. Place child with partner or group for modeling and cueing from peers.
Does not plan ahead Uses trial-and-error approach	Planning	Practice with tasks with only a few steps first. Teach simple flow charting as a planning tool. Practice with planning tasks (e.g., mazes). Ask child to verbalize plan before beginning work. Ask child to verbalize second plan if first does not work. Ask child to verbalize possible consequences of actions before beginning. Review incidents of poor planning/anticipation with child.
Work/belongings is/are "messy" Random/haphazard problem solving Procrastinates/does not complete tasks	Organization	Increase organization of classroom and activities to serve as model, and help child grasp structure of new information. Present framework of new information to be learned at the outset, and review again at the end of a lesson. Begin with tasks with only a few steps and increase gradually.
Gets "stuck" Trouble transitioning Does not adapt to change	Flexibility/shifting	Increase routine to the day. Make schedule clear and public. Forewarn of any changes in schedule. Give "2-minute warning" of time to change. Make changes from one task to the next or one topic to the next, clear and explicit. Shifting may be a problem of inhibiting, so apply strategies for inhibition problems.

antidepressants or **anxiolytics** may be helpful. Other medications may improve behavioral control (see Chapter 33). Children receiving medication need regular follow-up visits that include a history to check for side effects, a review of current behavioral checklists, a complete physical examination, and appropriate modifications of the medication dose. Periodic trials off medication are recommended to establish whether the medication is still necessary.

Nonstandard Therapies

Pediatricians should be aware of nonstandard therapies that purport to treat neurodevelopmental and executive dysfunction or components therein. A variety of treatment methods for neurodevelopmental dysfunctions have been proposed that currently have little to no known scientific evidence of efficacy. This list includes dietary interventions (vitamins, elimination of food additives or potential allergens), neuromotor programs or medications to address vestibular dysfunction, eye exercises, filters, tinted lenses, and various technologic devices. Parents should be cautioned against expending the excessive amounts of time and financial resources usually demanded by these remedies. In many cases, it is difficult to distinguish the nonspecific beneficial effects of increased support and attention paid to the child from the purported target effects of the interventions.

Chapter 50

Attention-Deficit/ Hyperactivity Disorder

Elizabeth B. Harstad

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common and extensively studied neurobehavioral disorders of childhood and is among the most prevalent chronic health conditions affecting school-age children. ADHD is characterized by inattention, including increased distractibility and difficulty sustaining attention; poor impulse control and decreased self-inhibitory capacity; and motor overactivity and restlessness (Table 50.1, Fig. 50.1). Definitions vary in different countries. In the International Classification of Diseases (ICD) 2022 update from ICD-10 to ICD-11, hyperkinetic disorder was replaced with ADHD, which aligns with *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) terminology. Under ICD-11, the essential features of ADHD are described, but without giving age of onset, duration, or minimum number of symptoms needed for the diagnosis as specified in DSM-5 (Table 50.2). Children with ADHD may experience academic underachievement, problems with interpersonal relationships with family members and peers, and low self-esteem. ADHD often coexists with other emotional, behavioral, language, and learning disorders. Evidence also suggests that for many people, the disorder continues, with varying manifestations across the life cycle, leading to significant underemployment and unemployment, social dysfunction, and increased risk of antisocial behaviors (e.g., substance abuse), difficulty maintaining relationships, encounters with the law, and death from suicide or accidents (Figs. 50.2 and 50.3).

EPIDEMIOLOGY

Studies of the prevalence of ADHD worldwide have generally reported that 5–10% of school-age children are affected, although rates vary considerably by country, perhaps in part because of differing sampling and testing techniques and a varying symptom threshold for diagnosis. ADHD is more common in males than in females (male to female ratio 4:1 for the predominantly hyperactive-impulsive presentation and 2:1 for the predominantly inattentive presentation). Many children with ADHD will have coexisting diagnoses, including learning disabilities, mood disorders, and/or language disorders. Children with high intellectual quotient (IQ) are just as likely to have ADHD as those with average IQ, but children with below-average IQ have increased risk of having coexisting ADHD.

ETIOLOGY

There is no single etiology identified for ADHD; many factors play a role in its development. A genetic contribution to the etiology of ADHD is well established. Twin studies show 70–80% heritability, and there is a 5- to 10-fold increased risk for ADHD among first-degree relatives of those with ADHD. However, there are many ways in which genetic variants contribute to ADHD; it is thought that ADHD is a polygenic disorder in which multiple common genetic variants act together to increase the risk for ADHD.

Structural and functional abnormalities of the brain have been identified in children with ADHD. These include dysregulation of the frontal subcortical circuits; small cortical volumes in this region or more widespread throughout the brain; and abnormalities of the cerebellum, particularly midline/vermian elements. There is a median of a 3-year delay in attainment of peak cortical thickness in prefrontal regions of the brain in those with ADHD. Although neuroimaging studies have advanced knowledge related to ADHD, neuroimaging does not typically have a role in the clinical diagnosis or inform ongoing management.

Brain catecholamine metabolism, specifically for dopamine and norepinephrine, appears to play a role in the pathophysiology of ADHD. Animal studies suggest that an imbalance between these systems (specifically a decrease in inhibitory dopamine activity and increase in norepinephrine activity) contributes to ADHD. These findings are supported by human studies showing that individuals with ADHD have an increase in dopamine transporter density (which clears away dopamine too quickly) compared to non-ADHD controls. Additionally, studies showing that stimulant medications work to treat ADHD by increasing the amount of available dopamine and norepinephrine at the synapse support a role for catecholamine metabolism in the etiology of ADHD.

Some environmental factors also may contribute to the pathogenesis of ADHD. Prenatal exposure to tobacco smoke or alcohol is associated with increased risk for ADHD. Prematurity, including even late-preterm birth, is also associated with increased risk for ADHD. Maternal mental illness increases the risk for ADHD in offspring, and research indicates underlying maternal mental illness itself, rather than treatment of the mental illness, is the associated risk factor. Diet is not thought to play a role in the pathogenesis of ADHD for most children with the condition. A small subset of children with ADHD may be uniquely sensitive to certain foods, sugars, or additives, but this remains controversial, as studies reporting these findings are typically small and often not rigorously designed.

CLINICAL MANIFESTATIONS

Development of the DSM-5 criteria for ADHD has occurred mainly in field trials with children 5-12 years of age (see Table 50.1). The DSM-5 criteria state that the inattentive or hyperactive-impulsive behaviors must be developmentally inappropriate (substantially different from that of other children of the same age and developmental level), must begin before age 12 years, must be present for at least 6 months, must be present in two or more settings, and must not be secondary to another disorder. To meet criteria for ADHD, the symptoms must interfere with social, academic, or occupational functioning.

antidepressants or **anxiolytics** may be helpful. Other medications may improve behavioral control (see Chapter 33). Children receiving medication need regular follow-up visits that include a history to check for side effects, a review of current behavioral checklists, a complete physical examination, and appropriate modifications of the medication dose. Periodic trials off medication are recommended to establish whether the medication is still necessary.

Nonstandard Therapies

Pediatricians should be aware of nonstandard therapies that purport to treat neurodevelopmental and executive dysfunction or components therein. A variety of treatment methods for neurodevelopmental dysfunctions have been proposed that currently have little to no known scientific evidence of efficacy. This list includes dietary interventions (vitamins, elimination of food additives or potential allergens), neuromotor programs or medications to address vestibular dysfunction, eye exercises, filters, tinted lenses, and various technologic devices. Parents should be cautioned against expending the excessive amounts of time and financial resources usually demanded by these remedies. In many cases, it is difficult to distinguish the nonspecific beneficial effects of increased support and attention paid to the child from the purported target effects of the interventions.

Chapter 50

Attention-Deficit/ Hyperactivity Disorder

Elizabeth B. Harstad

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common and extensively studied neurobehavioral disorders of childhood and is among the most prevalent chronic health conditions affecting school-age children. ADHD is characterized by inattention, including increased distractibility and difficulty sustaining attention; poor impulse control and decreased self-inhibitory capacity; and motor overactivity and restlessness (Table 50.1, Fig. 50.1). Definitions vary in different countries. In the International Classification of Diseases (ICD) 2022 update from ICD-10 to ICD-11, hyperkinetic disorder was replaced with ADHD, which aligns with *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) terminology. Under ICD-11, the essential features of ADHD are described, but without giving age of onset, duration, or minimum number of symptoms needed for the diagnosis as specified in DSM-5 (Table 50.2). Children with ADHD may experience academic underachievement, problems with interpersonal relationships with family members and peers, and low self-esteem. ADHD often coexists with other emotional, behavioral, language, and learning disorders. Evidence also suggests that for many people, the disorder continues, with varying manifestations across the life cycle, leading to significant underemployment and unemployment, social dysfunction, and increased risk of antisocial behaviors (e.g., substance abuse), difficulty maintaining relationships, encounters with the law, and death from suicide or accidents (Figs. 50.2 and 50.3).

EPIDEMIOLOGY

Studies of the prevalence of ADHD worldwide have generally reported that 5–10% of school-age children are affected, although rates vary considerably by country, perhaps in part because of differing sampling and testing techniques and a varying symptom threshold for diagnosis. ADHD is more common in males than in females (male to female ratio 4:1 for the predominantly hyperactive-impulsive presentation and 2:1 for the predominantly inattentive presentation). Many children with ADHD will have coexisting diagnoses, including learning disabilities, mood disorders, and/or language disorders. Children with high intellectual quotient (IQ) are just as likely to have ADHD as those with average IQ, but children with below-average IQ have increased risk of having coexisting ADHD.

ETIOLOGY

There is no single etiology identified for ADHD; many factors play a role in its development. A genetic contribution to the etiology of ADHD is well established. Twin studies show 70–80% heritability, and there is a 5- to 10-fold increased risk for ADHD among first-degree relatives of those with ADHD. However, there are many ways in which genetic variants contribute to ADHD; it is thought that ADHD is a polygenic disorder in which multiple common genetic variants act together to increase the risk for ADHD.

Structural and functional abnormalities of the brain have been identified in children with ADHD. These include dysregulation of the frontal subcortical circuits; small cortical volumes in this region or more widespread throughout the brain; and abnormalities of the cerebellum, particularly midline/vermian elements. There is a median of a 3-year delay in attainment of peak cortical thickness in prefrontal regions of the brain in those with ADHD. Although neuroimaging studies have advanced knowledge related to ADHD, neuroimaging does not typically have a role in the clinical diagnosis or inform ongoing management.

Brain catecholamine metabolism, specifically for dopamine and norepinephrine, appears to play a role in the pathophysiology of ADHD. Animal studies suggest that an imbalance between these systems (specifically a decrease in inhibitory dopamine activity and increase in norepinephrine activity) contributes to ADHD. These findings are supported by human studies showing that individuals with ADHD have an increase in dopamine transporter density (which clears away dopamine too quickly) compared to non-ADHD controls. Additionally, studies showing that stimulant medications work to treat ADHD by increasing the amount of available dopamine and norepinephrine at the synapse support a role for catecholamine metabolism in the etiology of ADHD.

Some environmental factors also may contribute to the pathogenesis of ADHD. Prenatal exposure to tobacco smoke or alcohol is associated with increased risk for ADHD. Prematurity, including even late-preterm birth, is also associated with increased risk for ADHD. Maternal mental illness increases the risk for ADHD in offspring, and research indicates underlying maternal mental illness itself, rather than treatment of the mental illness, is the associated risk factor. Diet is not thought to play a role in the pathogenesis of ADHD for most children with the condition. A small subset of children with ADHD may be uniquely sensitive to certain foods, sugars, or additives, but this remains controversial, as studies reporting these findings are typically small and often not rigorously designed.

CLINICAL MANIFESTATIONS

Development of the DSM-5 criteria for ADHD has occurred mainly in field trials with children 5-12 years of age (see Table 50.1). The DSM-5 criteria state that the inattentive or hyperactive-impulsive behaviors must be developmentally inappropriate (substantially different from that of other children of the same age and developmental level), must begin before age 12 years, must be present for at least 6 months, must be present in two or more settings, and must not be secondary to another disorder. To meet criteria for ADHD, the symptoms must interfere with social, academic, or occupational functioning.

Table 50.1 DSM-5 Diagnostic Criteria for ADHD

A. A persistent pattern of inattention and/or hyperactivity/impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. **Inattention:** Six (or more) of the following symptoms of inattention have persisted for ≥6 mo to a degree that is inconsistent with development level and that negatively affects directly on social and academic/occupational activities:
   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
   b. Often has difficulty sustaining attention in tasks or play activities.
   c. Often does not seem to listen when spoken to directly.
   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not the result of oppositional behavior or failure to understand instructions).
   e. Often has difficulty organizing tasks and activities.
   f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork, homework).
   g. Often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, tools).
   h. Is often easily distracted by extraneous stimuli.
   i. Is often forgetful in daily activities.
2. **Hyperactivity/impulsivity:** Six (or more) of the following symptoms of inattention have persisted for ≥6 mo to a degree that is inconsistent with development level and that negatively affects directly on social and academic/occupational activities.
   a. Often fidgets with hands or feet or squirms in seat.
   b. Often leaves seat in classroom or in other situations in which remaining seated is expected.
   c. Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness).
   d. Often has difficulty playing or engaging in leisure activities quietly.
   e. Is often "on the go" or often acts as if "driven by a motor."
   f. Often talks excessively. Impulsivity.
   g. Often blurts out answers before questions have been completed.
   h. Often has difficulty awaiting turn.
   i. Often interrupts or intrudes on others (e.g., butts into conversations or games).

B. Several inattentive or hyperactive/impulsive symptoms were present before 12 yr of age.

C. Several inattentive or hyperactive/impulsive symptoms are present in two or more settings (e.g., at school [or work] or at home) and are documented independently.

D. There is clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. Symptoms do not occur exclusively during the course of schizophrenia, or another psychotic disorder, and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

CODE BASED ON TYPE

314.01 Attention-deficit/hyperactivity disorder, combined presentation: if both Criteria A1 and A2 are met for the past 6 mo.

314.00 Attention-deficit/hyperactivity disorder, predominantly inattentive presentation: if Criterion A1 is met but Criterion A2 is not met for the past 6 mo.

314.01 Attention-deficit/hyperactivity disorder, predominantly hyperactive-impulsive presentation: if Criterion A2 is met but Criterion A1 is not met for the past 6 mo.

Specify if:

Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, and if the symptoms result in no more than minor impairments in social and occupational functioning.

Moderate: Symptoms or functional impairment between "mild" and "severe" are present.

Severe: Many symptoms in excess of those required to make the diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

DSM-5 identifies three presentations of ADHD: the inattentive presentation, hyperactive-impulsive presentation, and combined presentation. Clinical manifestations of ADHD may change with age; thus the specific ADHD presentation for an individual may not be stable over time but describes current symptomatology (see Fig. 50.2). The symptoms may vary from motor restlessness and aggressive and disruptive behavior, which are common in preschool children, to disorganized, distractible, and inattentive symptoms, which are more typical in older adolescents and adults. Although hyperactivity generally decreases in late childhood and adolescence, symptoms of impulsivity and inattention often persist. Females with ADHD are relatively more likely than males to be diagnosed with the inattentive presentation, and this presentation is more commonly associated with internalizing symptoms (anxiety and low mood).

DIAGNOSIS

An evaluation for ADHD should be initiated in any child ≥4 years of age with symptoms of inattention, hyperactivity, and/or impulsivity (Fig. 50.4). This evaluation includes a careful history and clinical interview to rule in ADHD or to identify other causes or contributing factors, completion of behavior rating scales by different observers from at least two settings (e.g., teacher and parent), and a physical examination. It is important to systematically gather and evaluate information from a variety of sources, including the child, parents, teachers, and, when appropriate, other caretakers or professionals involved in the child's care.

The evaluation for ADHD may require several office visits. A thorough assessment should be conducted at the time of initial diagnosis, and reevaluation should occur if there are worsening or new symptoms, given the common occurrence of coexisting conditions.

Clinical Interview and History

The clinical interview allows a comprehensive understanding of whether the symptoms meet the diagnostic criteria for ADHD and to assess for coexisting conditions. The interview should collect information about the history and duration of presenting problems, the child's attainment of developmental milestones, school performance, social skills, mood, sleep, medical illnesses, sensory impairments, or

medication use that might affect the child's functioning. Disruptive social factors, such as family discord, situational stress, and abuse or neglect, can result in hyperactive or anxious behaviors. A family history of first-degree relatives with ADHD, mood or anxiety disorders, learning disability, antisocial disorder, or alcohol or substance abuse might indicate an increased risk of ADHD and coexisting conditions.

Behavior Rating Scales

Behavior rating scales can help to elicit information about ADHD symptoms across contexts (i.e., home and school). The *Vanderbilt ADHD Rating Scale* (which has parent and teacher versions) is a commonly used screening measure for ADHD in primary care. It has specific questions about inattention and hyperactivity/impulsivity that correspond directly with the DSM-5 ADHD diagnostic criteria and questions about overall performance to assess for functional impairment, as well as subscales for some common coexisting conditions (anxiety/depression and oppositional behaviors/conduct disorder). Additional ADHD-specific rating scales include the *Conners 3 ADHD Index* and *ADHD Rating Scale 5*, among others that can be used. Broadband rating scales (such as *Achenbach Child Behavior Checklist* [CBCL] or *Behavioral Assessment Scale for Children* [BASC] or *Conners 3 Full Length Forms*) can be useful in assessing for coexisting conditions. Electronic capture of rating scale information is increasingly available and may facilitate completion and scoring. Rating scales provide information about the type, frequency, and severity of ADHD or other behavioral/mood symptoms, but interpretation requires clinical judgement. Contextual factors (such as triggers for a certain behavior, responses to a behavior that may inadvertently reinforce it) should be considered when interpreting rating scales. When there are discrepancies between results of rating scales for parents and teachers, the context and level of support provided in each setting should be assessed. ADHD rating scales can help with both the initial diagnostic assessment and with monitoring treatment response over time. Although there is no universal standard to use as a criterion for a positive response to treatment in terms of rating scale results, a decrease in ADHD symptom scores by 25% or more is generally considered significant improvement. However, improvement in functional outcomes may be more important to consider than changes in symptom scores. For children on medication, it is important to consider if the medication was "active" when the child was observed (i.e., stimulant medication may work to reduce ADHD symptoms during the school day, but the symptoms may return as the medication wears off in the afternoon/evening when the child is home).

Physical Examination, Laboratory, and Other Assessments

Most children with ADHD will have a normal physical exam, but one should be conducted as part of the diagnostic evaluation. Particular attention should be paid to cardiac and neurologic evaluations, thyroid, hearing and vision, and assessment for dysmorphic features that may signify an underlying condition, such as fetal alcohol syndrome. A child's behavior in the clinic visit may not represent the child's usual behaviors, as some children may be able to remain focused or calm for brief periods and others may exhibit more impulsivity or high activity level when nervous in the context of a clinic visit. Laboratory tests and brain imaging are not routinely recommended as part of an ADHD assessment. The presence of hypertension, ataxia, or asymmetric neurologic examination or symptoms of a sleep, seizure, or thyroid disorder may prompt further diagnostic tests. Lead levels could be considered if there are other factors associated with risk for lead toxicity. The clinician should identify possible vision or hearing problems. Computerized attentional tasks and quantitative electroencephalographic assessments are not needed to make the diagnosis. They are subject to high rates of false-positive and false-negative results and thus are of limited utility in the diagnostic assessment.

Educational testing should be considered if there are concerns about academic progress, as specific learning disabilities in reading,

mathematics, or written expression often coexist with ADHD (see Chapters 51 and 52). If there has been slow attainment of developmental milestones, intelligence or developmental testing should be conducted. If there are concerns about a child's social communication skills combined with restricted, repetitive behaviors or interests, a clinical assessment for autism spectrum disorder may be indicated (see Chapter 58).

Differential Diagnosis and Coexisting Conditions

Given that the symptoms of ADHD can overlap with other conditions, a broad differential diagnosis should be considered. For ease of presentation, the differential diagnosis for ADHD can be grouped into specific categories of developmental, psychiatric, medical, and psychosocial (Table 50.3). Children at either end of the developmental/cognitive level (i.e., with significant cognitive delays or with superior intelligence) can appear inattentive and/or distracted and sometimes also disruptive if the material in school or expectations at home are not appropriate for their developmental level. In differentiating impulsivity and challenging behaviors associated with ADHD versus an externalizing disorder (oppositional defiant disorder [ODD] or conduct disorder), consider whether the child "acts without thinking" and/or is more reactive (easily upset over demands for sustained attention or other small triggers), which would be more consistent with ADHD, versus proactively looks to aggress, fight, and challenge authority, which may be indicative of an externalizing disorder. Tic disorders can both present with some symptoms similar to ADHD (e.g., fidgeting, squirming, making sounds that seem impulsive) and also commonly coexist with ADHD. For cases in which ADHD symptoms are reported in one setting but not another, psychosocial causes should be considered, such as unrealistic classroom expectations, distress at home, or untoward parenting strategies. However, clinicians should be aware that inappropriate parenting strategies may be the result of the child's ADHD, as parents try anything (often unsuccessfully) to help their child. These parents are in need of parenting and behavioral supports, without feeling blamed for their child's symptoms.

Sleep disorders, including those secondary to chronic upper airway obstruction from enlarged tonsils and adenoids, often result in behavioral and emotional symptoms that can resemble or exacerbate ADHD (see Chapter 31). Periodic leg movements of sleep/restless legs syndrome have been associated with symptoms of inattention, and inquiry regarding this should be made during the history. Behavioral and emotional disorders can cause disrupted sleep patterns as well.

Mental health disorders: Depression and anxiety disorders can cause many of the same symptoms as ADHD (inattention, restlessness, inability to focus and concentrate on work, poor organization, forgetfulness) but can also coexist with ADHD (see Chapters 38 and 39). Obsessive-compulsive disorder can mimic ADHD, particularly when recurrent and persistent thoughts, impulses, or images are intrusive, interfering with normal daily activities. Adjustment disorders secondary to major life stresses (death of a close family member, parents' divorce, family violence, parents' substance abuse, or a move) or parent–child relationship disorders involving conflicts over discipline, overt child abuse and/or neglect, or overprotection can result in symptoms similar to those of ADHD.

When considering a new diagnosis in an adolescent patient, there should be an opportunity to interview the adolescent privately, and the adolescent should be specifically asked about mood symptoms and psychosocial stressors; frequent digital media use; and screened for use of alcohol, marijuana, and illicit substances.

Table 50.3 Differential Diagnosis of Attention-Deficit/Hyperactivity Disorder (ADHD)

GENERAL CATEGORY	SPECIFIC CONDITIONS, CAUSES
Developmental	Low developmental level/cognitive abilities Very high cognitive abilities Specific learning disabilities in reading, mathematics, or written expression Communication or language disorder Autism spectrum disorder Fetal alcohol syndrome
Psychiatric	Anxiety/depression Oppositional defiant disorder/conduct disorder Bipolar disorder/disruptive mood dysregulation disorder Substance use disorder Posttraumatic stress disorder/adjustment disorder
Medical	Sleep disorder, obstructive sleep apnea Hearing or vision impairment Specific medications, such as some antiepileptics or high-dose steroids Thyroid disorders Tic disorders Posttraumatic head injury or encephalitis Genetic conditions, such as fragile X, Klinefelter syndrome, Turner syndrome, tuberous sclerosis, and neurofibromatosis
Psychosocial	Response to abuse, neglect Response to distress in home, inappropriate expectations or parenting practices Response to inappropriate classroom setting

TREATMENT

Overall Treatment Approach

ADHD is considered a chronic condition and should be managed as such, with education about ADHD at the time of diagnosis and regular follow-up visits to monitor and treat symptoms. Parent support groups with appropriate professional consultation to such groups can be very helpful. Treatment of ADHD should be multimodal and involve behavioral therapy, school-based supports, and/or medications. The treatment plan should be developed in collaboration with the child (if developmentally appropriate) and family. The recommended initial treatments for ADHD vary by age.

Preschool-age children: For children up until 6 years of age, the recommended first-line treatment is evidence-based parent- and/or teacher-administered behavior therapy. If behavior interventions do not provide significant improvements and there is moderate to severe impairment in the child's functioning as a result of ADHD symptoms, medication should be considered. If behavioral interventions are not available, the risks of medication should be compared with risks of not treating ADHD symptoms.

School-age children and adolescents: For children ages 6 years old and older, ADHD medications should be considered first-line treatment, along with behavior and educational interventions. Organizational skills training, coaching, or cognitive-behavioral therapy may be helpful for adolescents and adults.

Behaviorally Oriented Treatments

Behavioral interventions should be an integral part of the treatment plan for all children with ADHD. Behavioral interventions involve modifying the environment and empowering caregivers with strategies to promote positive behaviors and minimize negative behaviors. Behavioral strategies typically focus on promoting a limited number of well-defined appropriate behaviors, using positive reinforcement with increased adult attention, tangible rewards, or access to privileges. A token economy in which a child earns (or loses) tokens that can be exchanged for rewards may be used. Any rules should be clearly defined and consistently enforced. Behavioral parent training, also known as *parent training in behavioral management,* is a well-established combination of behavioral interventions shown to reduce problematic behaviors and improve adaptive skills for children with ADHD. It involves teaching parents how to use behavior modification strategies to address specific behaviors, with a strong emphasis on positive reinforcement (described earlier) while ignoring or, if necessary, systematically implementing appropriate consequences for maladaptive behaviors. Treatments geared toward behavioral management for ADHD often occur in the time frame of 8-12 sessions but may sometimes require more sessions.

Although there is much less research published on psychosocial treatments for adolescents with ADHD, behavioral parent training can be modified to focus on improving communication between parents and adolescents with ADHD, developing a behavioral contract, and problem-solving around challenging situations. For children and adolescents with ADHD and coexisting anxiety disorders and/or depression, cognitive-behavioral therapy may help address anxiety or low mood.

At least 60 minutes of moderate to vigorous exercise is recommended for the general health of all children ≥6 years old, and some studies indicate exercise may reduce ADHD symptoms in children; thus encouraging regular exercise is reasonable. Interventions including cognitive training, electroencephalogram (EEG) biofeedback, and diet modification do not have the level of evidence needed to recommend them for most children.

Educational Supports and Accommodations

Behavioral classroom management strategies can be used by teachers to implement strategies within the whole classroom that will help children with ADHD. These include clear expectations and consistency in follow-through, positive reinforcement for work completion and on-task behaviors, and appropriate consequences when rules are not followed. Additionally, children with ADHD may benefit from individualized educational supports and accommodations, such as preferential seating near the source of instruction and away from distractions, motor breaks as needed, frequent teacher check-ins, being able to take tests in a less distracting environment, and an individualized positive behavior plan. A daily report card or communication log can be used to facilitate regular communication between the parents and teachers. A daily report card is individually designed for each child to include target problem behaviors in academic and/or social domains in the classroom (e.g., following directions, turning in work, getting along with others). The teacher provides a rating for each behavior on the report card, which is sent home daily, and the child is given home-based rewards for meeting goals set for the ratings from school.

Children with ADHD often need explicit instruction in organization and executive functioning skills and may not develop these skills at the same pace as non-ADHD peers. The use of an agenda book to record assignments, color coding for different classes, and teacher check-ins regularly to help with organization may be helpful for some children, and others may require a higher level of more individualized instruction in the executive functioning domains of staying organized, planning, initiating tasks, shifting gears, and self-monitoring.

Children with ADHD and coexisting learning disorders, communication or developmental delays, significant mental health or oppositional challenges, or autism spectrum disorder often need more specialized educational supports than those that can be provided through accommodations in a general classroom. In the United States, these children would qualify to have an individualized educational plan (IEP) developed through the public school system.

Medications

Before medication initiation, a history and physical examination and an assessment for baseline sleep, eating, and mood should be conducted because these need to be monitored for a child on medication. Children with ADHD and their families should be educated on the benefits, risks, and side effects of medication, with a discussion about goals and expectations for medication treatment. It is common for a child to need to try several trials of different medications or doses to find the optimal ADHD pharmacologic treatment that both reduces core ADHD symptoms and is well tolerated. ADHD rating scales can be used to assess for medication effectiveness and side effects, both at initiation and during medication maintenance, and should be collected from parents and teachers when possible.

The types of medications used to treat ADHD fall into one of the following three categories: stimulants, norepinephrine reuptake inhibitors, and α_2-adrenergic agonists. Stimulants are the most commonly used medications to treat ADHD and have been used to treat this condition since the 1930s. Stimulant medications have a slightly larger treatment effect size (standardized mean difference) than nonstimulants (approximately 1.0 for stimulants versus approximately 0.7 for both norepinephrine reuptake inhibitors and α_2-adrenergic agonists). Although stimulants are generally recommended as the first-line ADHD medication, nonstimulant medications may be considered in the context of active substance use disorder for an adolescent with ADHD or household family member or if there is a strong family desire for a nonstimulant medication. Stimulants have been found to have relatively high rates of adverse effects (particularly moodiness and irritability) in preschool-age children and in children with intellectual disability or autism spectrum disorder, leading some physicians to choose nonstimulant medication in these situations, as described later.

When starting a stimulant, the clinician can select either a methylphenidate-based or an amphetamine-based medication. The decision about which stimulant medication to use for a specific child or adolescent with ADHD is often based on factors such as duration of action (short, intermediate, long acting), preparation (pills, capsules that can be swallowed whole or whose contents can be "sprinkled" into food, chewable tablets, and liquids), and clinician preference or insurance company formularies. Stimulant medications have a rapid onset of action (ranging from about 20 minutes to up to an hour, depending on the formulation), and most leave the system within 3-12 hours, depending on if they are short, intermediate, or long acting. A child who responds poorly to one stimulant medication may do well with a different medication in that class or the other class (methylphenidate versus amphetamine). Stimulant medications should be initiated at the lowest available dose and titrated upward, assessing for both effectiveness and side effects, until reaching a dose that reduces ADHD symptoms and has minimal to no side effects. Common side effects of stimulant medication include decreased appetite, headaches, stomachaches, and difficulty falling asleep. If mood lability occurs, it should be noted whether this is while the stimulant medication is active (which may indicate that a different medication should be tried instead) or as the medication is wearing off (also called *rebound* and may indicate that a short-acting preparation should be replaced by a longer-acting preparation or a low dose of a short-acting preparation should be added about 30 minutes before the onset of the rebound symptoms).

Height, weight, pulse, and blood pressure should be periodically monitored. Stimulants may be associated with a slight reduction in linear growth, although studies of the impact of stimulants on adult height range from findings of a slight impact to no significant difference. Children with decreased appetite from stimulants and difficulty with weight gain can be counseled to increase caloric intake later in the day when the appetite returns. Significant reductions (i.e., crossing two lines on the growth curve) in either height or weight for a child on stimulant medication may prompt changing to a different ADHD medication.

Before starting stimulants, children should be screened for symptoms or signs suggestive of a cardiomyopathy, coronary artery disease, cardiac arrhythmias, or a family history of cardiac arrhythmias or sudden death under 50 years of age, and if these symptoms are present, an electrocardiogram and/or evaluation by a cardiologist to determine if it is safe to start these medications is recommended. Most children with tics can be treated with stimulant medication, but occasionally these medications may exacerbate tics. In these cases, the risks and benefits of continuing versus changing or stopping the medication should be considered.

Treatment of ADHD with stimulant medication is associated with reduced substance use risks. However, stimulant medications themselves are controlled substances with potential for misuse, diversion, and abuse. Therefore clinicians should regularly counsel adolescent patients about this risk, the importance of taking the medication only as prescribed, and about safe medication storage practices (e.g., keeping medication in a secure location).

Two types of selective norepinephrine reuptake inhibitors are approved by the U.S. Food and Drug Administration (FDA) for the treatment of ADHD in children and adolescents: atomoxetine and viloxazine. These medications take up to 4 weeks to achieve effectiveness and should be taken consistently to be effective. Both atomoxetine and viloxazine have common side effects of fatigue, decreased appetite, nausea, vomiting, and irritability and a rare potential for suicidal thinking and behaviors for which the child must be monitored.

α_2-Adrenergic agonist medications include guanfacine and clonidine. Long-acting preparations of both have U.S. FDA approval for the treatment of ADHD in children ≥6 years old either as monotherapy or an adjunctive therapy with stimulant medication. Short-acting preparations are sometimes used off-label to treat young (<6-year-old) children with ADHD (especially those with coexisting autism spectrum disorder or sleep disorders). α_2-Adrenergic agonists may take up to 2 weeks to achieve an initial response. These medications can also treat motor and vocal tics and so may be a reasonable choice in a child with a coexisting tic disorder. Common side effects of α_2-adrenergic agonists can include sedation, headaches, and hypotension, and they should be stopped gradually because abrupt discontinuation could result in rapid increase in blood pressure.

Medication alone may not be sufficient to treat ADHD in children, particularly when children have additional psychiatric disorders, developmental disabilities, or significant psychosocial challenges. When children do not respond to medication, it may be appropriate to refer them to a mental health specialist. Consultation with a child psychiatrist, developmental-behavioral pediatrician, or psychologist can be beneficial to determine the next steps for treatment, including adding other components and supports to the overall treatment program. Evidence suggests that children who receive careful medication management, accompanied by frequent treatment follow-up, all within the context of an educational, supportive relationship with the primary care provider, are likely to experience behavioral gains.

PROGNOSIS

More than half of individuals with a childhood diagnosis of ADHD will manifest a mental health condition (e.g., anxiety, depression, substance use disorders) in adulthood. Approximately one third to two thirds of those diagnosed with ADHD in childhood will continue to manifest significant symptoms of ADHD in adulthood. In children with ADHD, a reduction in hyperactive behavior often occurs with age. Other symptoms associated with ADHD can become more prominent with age, such as inattention, impulsivity, and disorganization, and these exact a heavy toll on adolescent and young adult functioning. Adolescents and young adults with ADHD have an increased likelihood of risk-taking behaviors (early sexual activity, delinquent behaviors, motor vehicle accidents, substance use), seizures, psychosis, educational underachievement or employment difficulties, and relationship difficulties. With proper treatment, the risks associated with ADHD, including injuries, can be significantly reduced. Consistent treatment with medication and adjuvant therapies appears to lower the risk of adverse outcomes, such as substance abuse.

SECONDARY PREVENTION

Parent training can lead to significant improvements in ADHD symptoms and oppositional behaviors in preschool and school-age children with ADHD. To the extent that parents, teachers, physicians, and policymakers support efforts for earlier detection, diagnosis, and treatment, prevention of long-term adverse effects of ADHD on affected children's functioning can be considered within the lens of secondary prevention of the long-term effects of untreated or ineffectively treated ADHD on children and youth.

Chapter 51

Dyslexia

Sally E. Shaywitz and Bennett A. Shaywitz

DEFINITION

Dyslexia has always been defined as an unexpected difficulty in reading, which has been codified in U.S. Federal law (First Step Act of 2018, PL: 115–391) as the most up-to-date, evidence-based definition of dyslexia: "The term *dyslexia* means an unexpected difficulty in reading for an individual who has the intelligence to be a much better reader, most commonly caused by a difficulty in the phonological processing (the appreciation of the individual sounds of spoken language), which affects the ability of an individual to speak, read, and spell." In typical readers, development of reading and intelligence quotient (IQ) are dynamically linked over time. In dyslexic readers, however, a developmental uncoupling occurs between reading and IQ (Fig. 51.1), such that reading achievement is significantly below what would be expected given the individual's IQ.

The uncoupling between reading achievement and IQ provides the long-sought empirical evidence for the seeming paradox between cognition and reading in individuals with developmental dyslexia, and this discrepancy is recognized in the federal definition as unexpected difficulty in reading. However, clinicians may see other approaches to diagnosis. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) describes specific learning disorder with impairment in reading for children with reading skills significantly below those expected for the child's age where the deficits are not explained by intellectual disability, sensory deficits, neurologic disorders, or psychosocial adversity. This definition can be problematic in failing to differentiate primary problems with reading comprehension from the reading problems experienced by children with dyslexia despite strong evidence that the two are distinct. Further, excluding children with psychosocial adversity is concerning because children who struggle with reading due to psychosocial adversity suffer similar adverse long-term consequences and have been shown to benefit from interventions designed to help children with dyslexia.

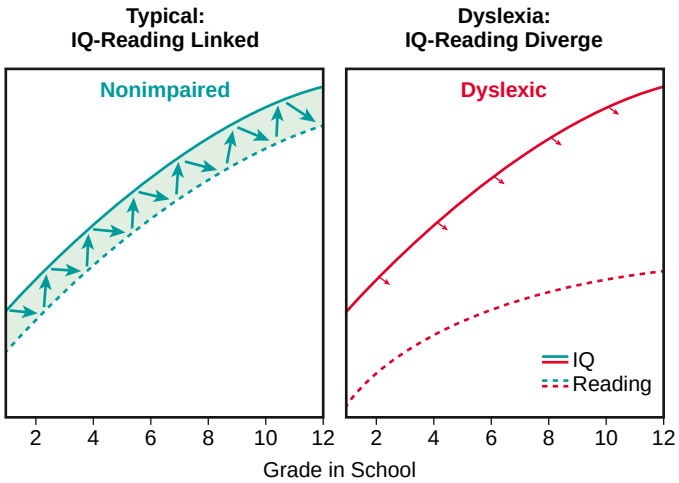

Fig. 51.1 Uncoupling of reading and IQ over time: empirical evidence for a definition of dyslexia. *Left,* In typical readers, reading and IQ development are dynamically linked over time. *Right,* In contrast, reading and IQ development are dissociated in dyslexic readers, and one does not influence the other. *(Copyright Sally Shaywitz, MD. Adapted from Shaywitz S, Shaywitz J. Overcoming Dyslexia, 2nd ed. New York: Vintage Books;2020: 103.)*

EPIDEMIOLOGY

Dyslexia is the most common of the learning disabilities, affecting 80–90% of children identified as having a learning disability. Dyslexia may be the most common neurobehavioral disorder affecting children, with prevalence rates ranging from 20% in unselected population-based samples to much lower rates in school-identified samples. The low prevalence rate in school-identified samples may reflect the reluctance of schools to screen, assess, and identify dyslexia. Dyslexia occurs with equal frequency in males and females in survey samples in which *all* children are assessed. Despite such well-documented findings, schools continue to identify more males than females, probably reflecting the more rambunctious behavior of males who come to the teacher's attention because of misbehavior, whereas females with reading difficulty, who are less likely to be misbehaving, are also less likely to be noticed and identified by the schools. Dyslexia fits a dimensional model in which reading ability and disability occur along a *continuum*.

PATHOGENESIS

Evidence from a number of lines of investigation indicates that dyslexia reflects deficits within the language system, and more specifically, within the **phonologic component** of the language system engaged in processing the sounds of speech. Individuals with dyslexia have difficulty developing an awareness that spoken words can be segmented into smaller elemental units of sound (phonemes), an essential ability given that reading requires that the reader map or link printed symbols to their sounds. Increasing evidence indicates that disruption of attentional mechanisms may also play an important role in reading difficulties.

Functional brain imaging in both children and adults with dyslexia demonstrates an inefficient functioning of left hemisphere posterior brain systems, a pattern referred to as the *neural signature of dyslexia* (Fig. 51.2). These differences can be observed before the start of formal reading instruction, suggesting they represent a biologic predisposition to reading difficulties as opposed to a result of inadequate instruction. Although functional magnetic resonance imaging (fMRI) consistently demonstrates differences between *groups* of dyslexic compared to typical readers, brain imaging is not able to reliably differentiate an *individual* case of a dyslexic reader from a typical reader and thus is not useful in diagnosing dyslexia.

CLINICAL MANIFESTATIONS

Reflecting the underlying phonologic weakness, children and adults with dyslexia manifest problems in both spoken and written language. Spoken language difficulties are typically manifest by mispronunciations, lack of glibness, speech that lacks fluency with many pauses or hesitations and "ums," word-finding difficulties with the need for time to summon an oral response, and the inability to come up with a verbal response quickly when questioned; these reflect *sound-based,* not semantic or knowledge-based, difficulties.

Struggles in decoding and word recognition can vary according to age and developmental level. The cardinal signs of dyslexia observed in school-age children and adults are a labored, effortful approach to reading involving decoding, word recognition, and text reading. Listening comprehension is typically robust. Older children improve reading accuracy over time, but without commensurate gains in reading fluency; they remain slow readers. Difficulties in spelling typically reflect the phonologically based difficulties observed in oral reading. Handwriting is often affected as well.

History often reveals early subtle language difficulties in dyslexic children. During the preschool and kindergarten years, at-risk children display difficulties playing rhyming games and learning the names for letters and numbers. Kindergarten assessments of these language skills can help identify children at risk for dyslexia. Although a dyslexic child enjoys and benefits from being read to, the child might avoid reading aloud to the parent or reading independently.

Dyslexia may coexist with attention-deficit/hyperactivity disorder (see Chapter 50); this comorbidity has been documented in both referred samples (40% comorbidity) and nonreferred samples (15% comorbidity).

DIAGNOSIS

A large achievement gap between typical and dyslexic readers is evident as early as first grade and persists (Fig. 51.3). These findings provide strong evidence and impetus for early screening and identification of and early intervention for young children at risk for dyslexia. One source of potentially powerful and highly accessible screening information is their teacher's judgment about the child's reading and reading-related skills. Evidence-based screening can be carried out as early as kindergarten, and also in grades 1-3, by the child's teacher. Their teachers' responses to a small set of questions (10-12 questions) predict a pool of children who are at risk for dyslexia with a high degree of accuracy. This evidence-based screening takes less than 10 minutes, is completed on a tablet, and is extremely efficient and economical. Children

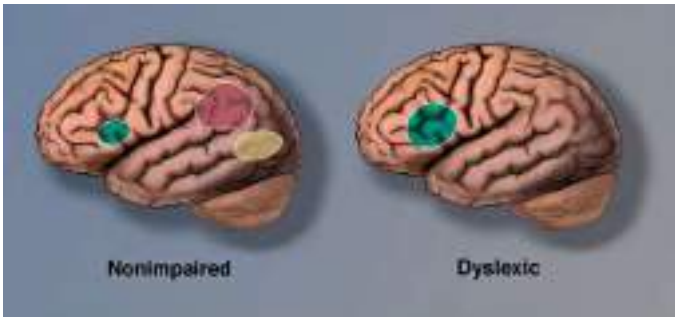

Fig. 51.2 A neural signature for dyslexia. Image on left shows left hemisphere brain systems in typical (nonimpaired) readers. The three systems for reading are an anterior system in the region of the inferior frontal gyrus (Broca's area), serving articulation and word analysis, and two posterior systems: one in the occipitotemporal region serving word analysis and a second in the occipitotemporal region (the word-form area) serving the rapid, automatic, fluent identification of words. In dyslexic readers (*right* image), the two posterior systems are functioning inefficiently and appear underactivated. This pattern of underactivation in left posterior reading systems is referred to as the neural signature for dyslexia. *(Copyright Sally Shaywitz, MD. Adapted from Shaywitz S. Shaywitz J. Overcoming Dyslexia, 2nd ed. New York: Vintage Books;2020: 78.)*

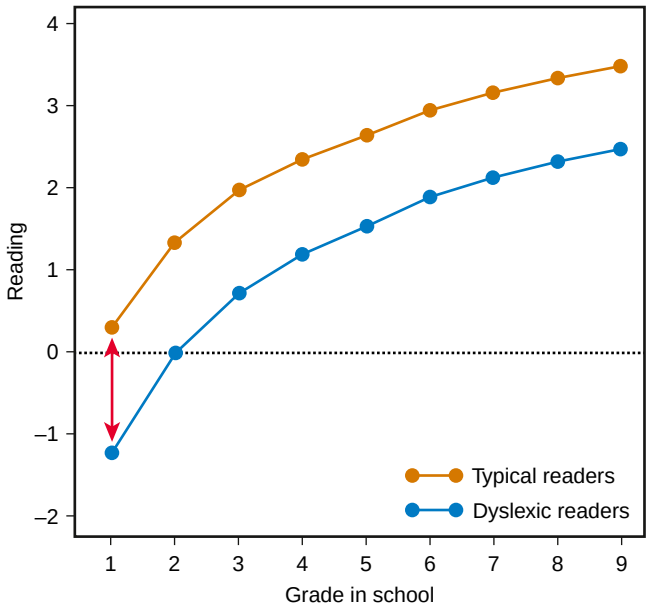

Fig. 51.3 Reading from grades 1 through 9 in typical and dyslexic readers. The achievement gap between typical and dyslexic readers is evident as early as first grade and persists through adolescence. *(Copyright Sally Shaywitz, MD. Adapted from Shaywitz S. Shaywitz J. Overcoming Dyslexia, 2nd ed. New York: Vintage Books;2020: 56.)*

found to be at risk will then have further assessment and, if diagnosed as dyslexic, should receive evidence-based intervention.

Dyslexia is a clinical diagnosis, and history is especially critical. The clinician seeks to determine through history, observation, and psychometric assessment if there are unexpected difficulties in reading (based on the person's intelligence, chronologic/grade, level of education, or professional status) and associated linguistic problems at the level of phonologic processing. No single test score is pathognomonic of dyslexia. The diagnosis of dyslexia should reflect a thoughtful synthesis of all clinical data available.

Dyslexia is distinguished from other disorders that can prominently feature reading difficulties by the unique, circumscribed nature of the *phonologic deficit,* one that does not intrude into other linguistic or cognitive domains. A core assessment for the diagnosis of dyslexia in children includes tests of language, particularly phonology; reading, including real and pseudowords; reading fluency; spelling; and tests of intellectual ability. Additional tests of memory, general language skills, and mathematics may be administered as part of a more comprehensive evaluation of cognitive, linguistic, and academic function.

For informal screening, in addition to a careful history, the primary care physician in an office setting can listen to the child read aloud from the child's own grade-level reader. Keeping a set of graded readers available in the office serves the same purpose and eliminates the need for the child to bring in schoolbooks. **Oral reading** is a sensitive measure of reading accuracy and fluency. The most consistent and telling sign of a reading disability in an accomplished young adult is slow and laborious reading and writing. In attempting to read aloud, most children and adults with dyslexia display an effortful approach to decoding and recognizing single words, an approach in children characterized by hesitations, mispronunciations, and repeated attempts to sound out unfamiliar words. In contrast to the difficulties they experience in decoding single words, persons with dyslexia typically possess the vocabulary, syntax, and other higher-level abilities involved in comprehension.

Fluency forms the bridge between decoding, that is, reading a word accurately, and comprehension, understanding what is read. Fluent reading is reading accurately and rapidly, with good intonation (prosody) indicating an understanding of the text. The failure either to recognize or to measure the lack of fluency in reading is perhaps the most common error in the diagnosis of dyslexia, especially in older children and accomplished young adults. Simple word identification tasks will not detect dyslexia in a person who is accomplished enough to be in honors high school classes or to graduate from college or obtain a graduate degree. Tests relying on the accuracy of word identification alone are inappropriate to use to diagnose dyslexia because they show little to nothing of the *struggle* to read. Because they assess reading accuracy but not automaticity or prosody, the types of reading tests used for school-age children might provide misleading data on bright adolescents and young adults. Among the most critical tests are those that are *timed;* they are the most sensitive in detecting dyslexia in a bright adult. Few standardized tests for young adult readers are administered under timed and untimed conditions; the *Nelson-Denny Reading Test* is an exception. The helpful *Test of Word Reading Efficiency* (TOWRE) examines simple word reading under timed conditions, and the Achievement Improvement Monitoring System (AIMSweb) and Dynamic Indicators of Basic Early Literacy Skills (DIBELS) measure reading connected text under timed conditions. Any scores obtained on testing must be considered relative to peers with the same degree of education or professional training.

IS FAMILY HISTORY HELPFUL IN DIAGNOSING DYSLEXIA?

Although dyslexia is familial, family history is not effective as a screening measure for dyslexia and does not improve the classification accuracy provided by an evidence-based early screening measure.

Genome-wide association studies (GWASs) in children with dyslexia have demonstrated that a large number of genes are involved, each producing a small effect. Complex traits such as reading are the work of thousands of genetic variants working in concert (see Chapter 103). Thus pediatricians should be wary of recommending any genetic test to their patients that purports to diagnose dyslexia in infancy or before language and reading have even emerged. It is unlikely that a single gene or even a few genes will reliably identify people with dyslexia. Rather, dyslexia is best explained by multiple genes, each contributing a small amount toward the expression of dyslexia.

MANAGEMENT

The management of dyslexia demands a life-span perspective. Early in life the focus is on **remediation** of the reading problem. Applying knowledge of the importance of early language, including phonologic skills and vocabulary, leads to significant improvements in children's reading accuracy, even in predisposed children. As a child matures and enters the more time-demanding setting of middle and then high school, the emphasis shifts to the important role of providing accommodations. Based on the work of the National Reading Panel, evidence-based reading intervention methods and programs are identified. Effective intervention programs provide systematic instruction in five key areas: phonemic awareness, phonics, fluency, vocabulary, and comprehension strategies. These programs also provide ample opportunities for writing, reading, and discussing literature.

Taking each component of the reading process in turn, effective interventions improve phonemic awareness: the ability to focus on and manipulate phonemes (speech sounds) in spoken syllables and words. The elements found to be most effective in enhancing **phonemic awareness**, reading, and spelling skills include teaching children to manipulate phonemes with letters, focusing the instruction on one or two types of phoneme manipulations rather than multiple types, and teaching children in small groups. Providing instruction in phonemic awareness is necessary, but not sufficient, to teach children to read. Effective intervention programs include teaching **phonics**, or making sure that the beginning reader understands how letters are linked to sounds (phonemes) to form letter-sound correspondences and spelling patterns. The instruction should be explicit and systematic; phonics instruction enhances children's success in learning to read, and systematic phonics instruction is more effective than instruction that teaches little or no phonics or that teaches phonics casually or haphazardly. Important but often overlooked is starting children on reading connected text early on, optimally at or near the beginning of reading instruction. Reading connected text is critical in building vocabulary and increasing background knowledge—both important in improving reading comprehension.

Fluency is of critical importance because it allows the automatic, rapid recognition of words. Although it is generally recognized that fluency is an important component of skilled reading, it is often overlooked in teaching. One approach is to have a child practice oral reading with a teacher or parent providing positive and helpful feedback. Here practice is critical. Interventions for vocabulary development and reading comprehension are not as well established. The most effective methods to teach reading comprehension involve teaching vocabulary and strategies that encourage active interaction between the reader and the text. Emerging science indicates that it is not only teacher content knowledge but the teacher's skill in engaging the student and focusing the student's attention on the reading task at hand that is required for effective instruction.

The interventions described here can be provided in multiple settings, but specialized schools for children with dyslexia that provide intensive intervention over 4 years or more have been very effective. Typically, these schools are costly, although increasingly offering scholarships. Some school districts are considering developing public schools specializing in educating children with dyslexia.

For those in high school, college, and graduate school, provision of **accommodations** most often represents a highly effective approach to dyslexia. Imaging studies now provide neurobiologic evidence of the need for extra time for dyslexic students; accordingly, college students with a childhood history of dyslexia require extra time in reading and writing assignments and in examinations. Many adolescent and adult students have been able to improve their reading accuracy, but without commensurate gains in reading speed. The accommodation of extra time reconciles the individual's often high cognitive ability and slow reading, so that the exam is a measure of that person's ability rather than disability. Another important accommodation is helping the student access text-to-speech programs. Excellent text-to-speech programs and apps are available for Apple and Android systems and the PC and include Voice Dream Reader, Immersive Reader (available for free in all Microsoft Office programs, including Word, OneNote, and PowerPoint), Kurzweil Firefly, Read & Write Gold, Read: OutLoud, and Natural Reader. Voice-to-text programs are also helpful, often part of the suite of programs, as well as the popular Dragon Dictate. Voice-to-text is found on many smartphones. Other helpful accommodations include the use of laptop computers with spelling checkers, access to lecture notes, tutorial services, and a separate quiet room for taking tests.

In addition, the impact of the primary phonologic weakness in dyslexia mandates special consideration during oral examinations so that students are not graded on their lack of glibness or speech hesitancies, but on their content knowledge. Unfortunately, speech hesitancies or difficulties in word retrieval often are wrongly confused with insecure content knowledge. The major difficulty in dyslexia—reflecting problems accessing the sound system of spoken language—causes great difficulty learning a second language. As a result, an often-necessary accommodation is a waiver or partial waiver of the foreign language requirement; the dyslexic student may enroll in a course taught in English on the history or culture of a non–English-speaking country.

PROGNOSIS

Application of evidence-based methods to young children, when provided with sufficient intensity and duration, can result in improvements in reading accuracy and, to a much lesser extent, fluency. Improvements in fluency can be effected with frequent practice in reading aloud with the helpful input of a teacher or parent. As noted earlier, accommodations are critical in allowing the dyslexic child to demonstrate his or her knowledge.

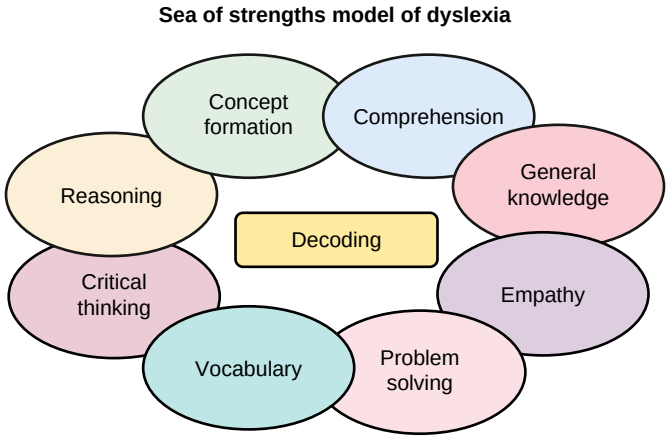

Fig. 51.4 Sea of strengths model of dyslexia. In dyslexia, a circumscribed, encapsulated weakness in decoding is surrounded by a sea of strengths in higher-level thinking and reasoning. The weakness in decoding masks what are often excellent thinking and comprehension skills. *(Copyright Sally Shaywitz, MD. Adapted from Shaywitz S. Shaywitz J. Overcoming Dyslexia, 2nd ed. New York: Vintage Books;2020: 141.)*

A person who is dyslexic experiences through life aligns with our Sea of Strengths model of dyslexia (Fig. 51.4). This model indicates that in dyslexia there is a weakness in decoding reflecting the difficulties connecting letters to sounds, a weakness that is very visible early on when learning to read. At the same, this weakness is surrounded by a sea of strengths in higher-level cognitive, big-picture thinking, including reasoning, problem solving, vocabulary, empathy, concept formation, and critical thinking. It is this sea of strengths that comes to the fore and supports a positive future as a person with dyslexia matures. The sea of strengths was very "visible" in a recent report examining the academic and social experiences in college and outcomes in the workplace 5 or more years after graduation in Yale graduates with dyslexia compared with a matched group of Yale graduates who were typical readers. Dyslexic college graduates did not differ from typical graduates either in college or in the workplace. Parents of dyslexic children often ask about their child's future. These findings should reassure those pediatricians and parents that dyslexic students can succeed all along the developmental pathway throughout school, and now through college and the workplace. With proper support, dyslexic children can succeed in a range of future occupations that might seem out of their reach, including medicine, law, journalism, and writing.

Chapter 52
Math and Writing Disabilities

52.1 Math Disabilities

Kenneth L. Grizzle and Brittany J. Bice-Urbach

Data from the U.S. National Center for Educational Statistics for 2009 showed that 69% of U.S. high school graduates had taken algebra 1, 88% geometry, 76% algebra 2/trigonometry, and 35% precalculus. These percentages are considerably higher than those from 20 years earlier. However, concerns remain about the limited mathematics literacy level for children, adolescents, and those entering the workforce; poor math skills predict numerous social, employment, and emotional challenges. The need for number and math literacy extends beyond the workplace and into daily lives, and weaknesses can negatively affect daily functioning. Research into the etiology and treatment of **math disabilities** falls behind the study of reading disabilities (see Chapter 51), and yet the database needed to effectively identify, treat, and minimize the impact of math challenges on daily functioning and education is growing.

MATH LEARNING DISABILITY DEFINED

Understanding learning challenges associated with mathematics requires a basic appreciation of domain-specific terminology and operations. The *Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition* (DSM-5) has published diagnostic criteria for learning disorders. Specific types of learning challenges are subsumed under the broad term of **specific learning disorder (SLD)**. The DSM-5 identifies

the following features of a SLD with an **impairment in math**: difficulties mastering number sense, number facts, or fluent calculation and difficulties with math reasoning. Symptoms must be present for a minimum of 6 months and persist despite interventions to address the learning challenges. **Number sense** refers to a basic understanding of quantity, number, and operations and is represented as nonverbal and symbolic. Examples of number sense include an understanding that each number is 1 more or 1 less than the previous or following number, knowledge of number words and symbols, and the ability to compare the relative magnitude of numbers and perform simple arithmetic calculations.

The DSM-5 definition can be contrasted with an **education-defined learning disability in mathematics**. Two math-related areas are identified as part of the **Individuals with Disabilities Education Act (IDEA)**: mathematics calculation and mathematics problem solving. Operationally, this is reflected in age-level competency in arithmetic and math calculation, word problems, interpreting graphs, understanding money and time concepts, and applying math concepts to solve quantitative problems. The federal government allows states to choose the way a *learning disability* (LD) is identified if the procedure is "research based." Referred to specifically in the IDEA as methods for identifying an LD are a **discrepancy model** and "use of a process based on the child's response to scientific, research-based intervention." The former refers to identifying an LD based on a pronounced discrepancy between intellectual functioning and academic achievement. The latter, referred to as a **response to intervention (RtI)** model, requires school systems to screen for a disability, intervene using evidence-based treatments for the identified disability, closely monitor progress, and make necessary adjustments to the intervention as needed. If a child is not responding adequately, a multidisciplinary team is created, and an evaluation is then completed to determine whether the child qualifies for special education programming. Not responding to the interventions alone does not result in automatic qualification for services outside of regular education. Rather, it is a three-step process: lack of adequate progress to the interventions, an evaluation of the area(s) of concern, and then determination by the team if an **individualized educational plan (IEP)** is needed. The IEP team typically consists of teachers, special education teacher, school psychologist, school district representative, parents, and, depending on their age, the student.

It is important that primary care providers understand the RtI process because many states require or encourage this approach to identifying LDs. Confusion can be avoided by helping concerned parents understand that a school may review their child's records, screen the skills of concern, and provide intervention with close progress monitoring before initiating the process for an IEP. Traditional psychoeducation testing (IQ and achievement) may only be completed if a child has not responded well to specific interventions. The RtI approach is a valuable, empirically supported way to approach and identify a potential LD but is very different from a medical approach to diagnosis and treatment. First and foremost, this allows for early intervention, which has been shown repeatedly to decrease the likelihood of a later identified LD. Intervening early also allows educators to avoid the "wait to fail" model that all too often waited for children to enter third or fourth grade before receiving needed services.

Terminology

The term **dyscalculia**, often used in medicine and research but seldom used by educators, is reserved for children with a SLD in math when there is a pattern of deficits in learning arithmetic facts and accurate, fluent calculations. The term **math learning disability (MLD)** is used generically here, with dyscalculia used when limiting the discussion to children with deficient math calculation skills. A distinction is also made between children with a MLD and those who are **low achieving (LA) in math**; both groups have received considerable research focus. Although not included in either definition provided earlier, research into math deficits often require that individuals identified with MLD have math achievement scores below the 10th percentile across multiple grade levels. These children start out poorly in math and continue poor performance across grades, despite interventions. LA math students consistently score below the 25th percentile on math achievement tests across grades, often showing the same weak math-related characteristics as those with MLD but with less severity. Complicating the identification of MLD and its differentiation from LA math students is the variability in relative complexity of math concepts that may result in short-lived math difficulties.

EPIDEMIOLOGY

Prevalence

Depending on how MLD is defined and assessed, the prevalence varies. Based on findings from multiple studies, approximately 7% of children will show a MLD profile before high school graduation. An additional 10% of students will be identified as LA. Because research in the area typically requires that individuals show deficits for consecutive years, the respective prevalence estimates are lower than the 10th percentile cutoff for being identified as having an MLD or the 25th percentile cutoff for being identified as LA. It is not unusual for children to score below the criterion one year and then above the criterion in subsequent years. Males are at greater risk to experience MLD.

Risk Factors

Genetics

The heritability of math skills is estimated to be approximately 0.50. The heritability or genetic influence on math skills is consistent across the continuum from high to low math skills. This research emphasizes that although math skills are learned across time, the stability of math performance is the result of genetic influences. Math heritability appears to be the product of multiple genetic markers, each having a small effect.

Medical/Genetic Conditions

Numerous genetic syndromes are associated with math problems. Although most children with **fragile X syndrome** have an *intellectual disability* (ID), approximately 50% of females with the condition do not. Of those without an ID, ≥75% have a math disability by the end of third grade and are already scoring below average in mathematics in kindergarten and first grade. For females with fragile X MLD, weak working memory seems to play an important role. The frequency of MLD in **Turner syndrome (TS)** is the same as that found in females with fragile X syndrome. A consistent finding is females with TS complete math calculations at significantly slower speed than typically developing students. Although females with TS have weak calculation skills, their ability to complete math problems not requiring explicit calculation is similar to that of their peers. The percentage of children with **22q11.2 deletion syndrome** (22q11.2ds) with MLD is not clear. Younger children with this genetic condition (6-10 years old) showed similar number sense and calculation skills as typically developing children but weaker math problem solving. Older children with 22q11.2ds showed slower speed in their general number sense and calculations, but accuracy was maintained. Weak counting skills and magnitude comparison have been found in this group of children, suggesting weak visual-spatial processing. Children with **myelomeningocele** are at greater risk for math difficulties than their unaffected peers. Almost 30% of these children have MLD without an additional diagnosed learning disorder, and >50% have both math and reading learning disorders. Although broad, deficits are most pronounced in speed of math calculation and written computation.

Comorbidities

It is estimated that 30–70% of those with MLD will also have a reading disability. This is especially important because children with MLD are less likely to be referred for additional educational assistance and intervention than students with reading problems. Unfortunately, children identified with both learning challenges perform poorer across psychosocial and academic measures than children with MLD alone. Having a MLD places a child at greater risk for not only other learning challenges but also psychiatric disorders, including attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, conduct disorder, generalized anxiety disorder, and major depressive disorder.

Individuals with MLD have been found to have increased social isolation and difficulties developing social relationships in general.

CAUSES OF MATH LEARNING DISABILITY

There is a consensus that individuals with MLD are a heterogeneous group, with multiple potential broad and specific deficits contributing to their learning difficulties. Research into the causes of MLD has focused on math-specific processes and broad cognitive deficits, with an appreciation that these two factors are not always independent.

Broad Cognitive Processes

Intelligence

Intelligence affects learning, but if intellectual functioning were the primary driver of poor math performance, the math skills of low-IQ children would be similar or worse than individuals with MLD. On the contrary, children with MLD have significantly poorer math achievement than children with low IQ. Children with MLD have severe deficits in math not accounted for by their cognitive functioning. Individuals with lower cognition may have difficulty learning mathematics, but their math skills are likely to be commensurate with their intelligence.

Memory

Working memory (WM) refers to the ability to keep information in mind while using the information in other mental processes. WM is composed of three core systems: the central executive, the language-related phonologic loop, and the visual-based sketch pad. The central executive coordinates the functioning of the other two systems. All three play a role in various aspects of learning and in the development and application of math skills in particular; children with MLD have shown deficits in each area.

Committing math facts to and/or retrieving facts from memory has consistently been found to be problematic for children with MLD. This is not necessarily limited to inaccurate retrieval of facts but also speed of retrieval, independent of broader speed of processing deficits. Unfortunately, unlike some typically developing peers who may be slower but accurate in their fact retrieval, students with MLD are often slow and inaccurate. Weak fact encoding or retrieval alone do not determine an MLD diagnosis. Many math curricula in the United States do not include development of math facts as a part of the instructional process, resulting in children not knowing basic facts.

Processing Speed

Individuals with MLD are often slower to complete math problems than their typically developing peers, a result in part of their poor fact retrieval rather than broader speed of processing deficits. However, young children later identified with a MLD when beginning school have numerical-processing speed that is considerably slower than same-age same-grade peers. This is reflected in the time required to recognize numbers, correctly order fractions, and complete word problems.

Problem Solving

Not only do children with MLD struggle to quickly and accurately engage in numerical-related activities, in part because of these difficulties, they commonly rely on less efficient and laborious problem-solving practices. This is seen in children relying on finger counting beyond second grade, use of repeated adding for multiplication facts, pronounced difficulty moving beyond reliance on manipulatives, and drawing objects to help with calculation. Difficulties with math processes across multiple levels can result in math being a time-intensive and time-consuming process for kids with MLD.

Executive Skills

Difficulties with executive functioning (EF) can lead to challenges in multiple areas of a child's life, academic and nonacademic (see Chapter 49). Performance in math is but one example. EF refers to skills including but not limited to sustained attention, managing impulses, cognitive and behavioral flexibility, and WM. Anyone who has worked with children diagnosed with ADHD, a group of kids notorious for having EF challenges, can appreciate the impact these behaviors could potentially have on math. Deficits in WM, auditory and visual, can negatively affect a child's development of math skills. A child approaching a word problem exemplifies the impact of various executive skills on math. The child must keep in memory the content read and integrate it with what they know about the topic and possible operation to apply, all the while not responding to the irrelevant information contained within the passage. Creating a mental representation of the problem requires use of the visual sketch pad (visual WM).

Math-Specific Processes

Number Sense

The term *number sense* has been defined in different ways, though the general agreement is that the concept refers to an intuitive preverbal ability to identify an approximation of items within a set that precedes formal math instruction. This is seen in the ability to recognize and manipulate nonsymbolic properties without having to apply a name to the process—for example, recognizing that a box of three dots is fewer than a box containing five dots. Unlike their peers, children with MLD are more likely to count the number of items within the comparison rather than recognizing the apparent difference.

Math is a symbolic process and cannot be efficiently learned and mastered without understanding this numerical skill. There is considerable evidence that young children who struggle to develop symbolic numerical representation, in contrast to number sense, are at considerable risk to have difficulty developing higher-level math skills. Examples of symbolic representations range from recognizing that the numeral 4 and word *four* reflect a quantity and quickly recognizing the larger (or smaller) of two numbers, all the way to understanding fractions and more complex notations.

Procedural Errors

The type of errors made by children with a, MLD are typical for any child, the difference being that children with a LD show a 2- to 3-year lag in understanding the concept. An example of a common error a first-grade child with a, MLD might make when "counting on" is to undercount: "6 + 2= ?"; "6, 7" rather than starting at 6 and counting an additional two numbers. As children with math deficits get older, it is common to subtract a larger number from a smaller number. For example, in the problem "63 − 29 = 46," the child makes the mistake of subtracting 3 from 9. Another common error is not decreasing the number in the 10s column when borrowing: "64 − 39 = 35." For both adding and subtracting, there is a lack of understanding of the commutative property of numbers and a tendency to use repeated addition rather than fact retrieval. It is not that children with an MLD do not develop these skills, it is that they develop them much later than their peers, thereby making the transition to complicated math concepts much more challenging.

Unlike dyslexia, in which deficits have been isolated and identified as causal (see Chapter 51), factors involved in the development of a MLD are much more heterogeneous. Alone, none of the processes previously outlined fully account for MLD, although all have been implicated as problematic for those struggling with math.

TREATMENT AND INTERVENTIONS

The most effective interventions for MLD are those that include explicit instruction on solving specific types of problems and that take place over several weeks to several months. Skill-based instruction is a critical component; general math problem solving will not carry over across various math skills unless the skill is part of a more complex math concept. Clear, comprehensive guidelines for effective interventions for students struggling with math have been provided by the U.S. Department of Education in the form of a *Practice Guide* released through the What Works Clearinghouse. This document gives excellent direction in the identification and treatment of children with math difficulties in the educational system. Although not intended for medical personnel or parents, the guide is available free of charge and can be helpful for parents when talking to teachers about their child's learning. Table 52.1 lists additional resources for parents concerned about their young child's development of math facts.

Table 52.2 Risk Factors for a Specific Learning Disability Involving Mathematics

The child is at or below the 20th percentile in any math area, as reflected by standardized testing or ongoing measures of progress monitoring.

The teacher expresses concerns about the child's ability to "take the next step" in math.

There is a positive family history for math learning disability (this alone will not initiate an intervention).

Parents think they have to "reteach" math concepts to their child.

Awareness that most public school systems have implemented some form of an RtI model to identify LDs allows the primary care physician to encourage parents to return to the school seeking an intervention to address their child's concern. Receiving special education services in the form of an IEP may be necessary for some children. However, the current approach to identifying children with an LD allows school systems to intervene earlier, when problems arise, and potentially avoid the need for an IEP. Pediatricians with patients whose parents have received feedback from school with any of the risk factors outlined in Table 52.2 should encourage the parents to discuss an intervention plan with the child's teacher.

52.2 Writing Disabilities

Kenneth L. Grizzle and Brittany J. Bice-Urbach

Oral language is a complex process that typically develops in the absence of formal instruction. In contrast, *written language* requires instruction in acquisition (word reading), understanding (reading comprehension), and expression (spelling and composition). Unfortunately, despite reasonable pedagogy, a subset of children struggle with development in one or several of these areas. The disordered output of written language is currently referred to within the *Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition* (DSM-5) as a **specific learning disorder with impairment in written expression** (Table 52.3).

Various terminology has been used when referring to individuals with writing deficits; this subchapter uses the term **impairment in written expression (IWE)** rather than "writing disorder" or "disorder of written expression." **Dysgraphia** is often used when referring to children with writing problems, sometimes synonymously with IWE, though the two are related but distinct conditions. Dysgraphia is primarily a deficit in motor output (paper/pencil skills), and IWE is a conceptual weakness in developing, organizing, and elaborating on ideas in writing.

The diagnoses of IWE and dysgraphia are made largely based on phenotypical presentation; spelling, punctuation, grammar, clarity, and organization are factors to consider with IWE concerns. Aside from these potentially weak writing characteristics, however, no other guidelines are offered. Based on clinical experience and research into the features of writing samples of children with disordered writing skills, one would expect to see limited output, poor organization, repetition of content, and weak sentence structure and spelling despite the child taking considerable time to produce a small amount of content. For those with comorbid dysgraphia, the legibility of their writing product will also be poor, sometimes illegible.

Table 52.3 DSM-5 Diagnostic Criteria for Specific Learning Disability with Impairment in Written Expression

A. Difficulties learning and using academic skills that have persisted for at least 6 months, despite the provision of interventions that target those difficulties.
Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity).

B. The affected academic skills are substantially and quantifiably below those expected for the individual's chronologic age and cause significant interference with academic or occupational performance or with activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals age 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment.

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads).

D. The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurologic disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

315.2 (F81.81) With impairment in written expression:
Spelling accuracy
Grammar and punctuation accuracy
Clarity or organization of written expression
Specify current severity:

Mild: Some difficulties learning skills in one or two academic domains, but of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

Moderate: Marked difficulties learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, in the workplace, or at home may be needed to complete activities accurately and efficiently.

Severe: Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, at school, or in the workplace, the individual may not be able to complete all activities efficiently.

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Washington, DC: American Psychiatric Association; 2013:66–67.

EPIDEMIOLOGY

The incidence of IWE is estimated at 6.9–14.7%, with the relative risk for IWE ~2.5 times higher for males than for females. The risk for writing problems is much greater among select populations; >50% of children with oral language disorders reportedly have IWE. The relationship between attention-deficit/hyperactivity disorder (ADHD) and learning disorders in general is well established, including IWE estimates in the 60% range for the combined and inattentive presentations of ADHD. Because of the importance of working memory (WM) and other executive functions in the writing process, any child with weakness in these areas will likely find the writing process difficult (see Chapter 49).

SKILL DEFICITS ASSOCIATED WITH IMPAIRED WRITING

Written language, much like reading, occurs along a developmental trajectory that can be seamless as children master skills critical to the next step in the process. Mastery of motor control that allows a child to produce letters and letter sequences frees up cognitive energy to devote to spelling words and eventually stringing words into sentences, paragraphs, and complex composition. Early in the development of each individual skill, considerable cognitive effort is required, although ideally the lower-level skills of motor production, spelling, punctuation, and capitalization (referred to as **writing mechanics** or **writing conventions**) will gradually become automatic and require progressively less mental effort. This effort can then be devoted to higher-level skills, such as planning, organization, application of knowledge, and use of varied vocabulary. For children with writing deficits, breakdowns can occur at one, some, or every stage.

Transcription

Among preschool and primary grade children, there is a wide range of what is considered "developmentally typical" as it relates to letter production and spelling. However, evidence indicates that poor writers in later grades are slow to produce letters and write their name in preschool and kindergarten. Weak early spelling and reading skills (letter identification and phonologic awareness; see Chapter 51) and weak oral language have also been found to predict weak writing skills in later elementary grades. Children struggling to master early **transcription** skills tend to write slowly, or when writing at reasonable speed, the legibility of their writing degrades. Output in quantity and variety is limited, and vocabulary use in poor spellers is often restricted to words they can spell.

As children progress into upper elementary school and beyond, a new set of challenges arises. They are now expected to have mastered lower-level transcription skills, and the focus turns to the application of these skills to more complex text generation. In addition to transcription, this next step requires the integration of additional cognitive skills that have yet to be tapped by young learners.

Oral Language

Language, though not speech, has been found to be related to writing skills. Writing difficulties are associated with deficits in both expression and comprehension of oral language. Writing characteristics of children with **specific language impairment (SLI)** can differ from their unimpaired peers early in the school experience and persist through high school (see Chapter 53). In preschool and kindergarten, as a group, children with language disorders show poorer letter production and ability to print their name. Poor spelling and weak vocabulary also contribute to the poor writing skills. Beyond primary grades, the written narratives of SLI children tend to be evaluated as "lower quality with poor organization" and weaker use of varied vocabulary.

Pragmatic language and higher-level language deficits also negatively affect writing skills. **Pragmatic language** refers to the social use of language, including though not limited to greeting and making requests, adjustments to language used to meet the need of the situation or listener, and following conversation rules verbally and nonverbally. Higher-level language goes beyond basic vocabulary, word form, and grammatical skills and includes making inferences, understanding and appropriately using figurative language, and making cause-and-effect judgments. Weaknesses in these areas, with or without intact foundational language, can present challenges for students in all academic areas that require writing. For example, whether producing an analytic or narrative piece, the writer must understand the extent of the reader's background knowledge and in turn what information to include and omit, make an argument for a cause-and-effect relationship, and use content-specific vocabulary or vocabulary rich in imagery and nonliteral interpretation.

Executive Functions

Writing is a complicated process and, when done well, requires the effective integration of multiple processes. Executive functions (EFs) are a set of skills that include planning, problem solving, monitoring, and adjusting as needed (see Chapter 49). Three recursive processes have consistently been reported as involved in the writing process: *translation* of thought into written output, *planning,* and *reviewing.* Coming up with ideas, although challenging for many, is simply the first step when writing a narrative (story). Once an idea has emerged, the concept must be developed to include a plot, characters, and storyline and then coordinated into a coherent whole that is well organized and flows from beginning to end. Even if one develops ideas and begins to write them down, *persistence* is required to complete the task, which requires *self-regulation.* Effective writers rely heavily on EFs, and children with IWE struggle with this set of skills. Poor writers seldom engage in the necessary planning and struggle to self-monitor and revise effectively.

Working Memory

WM refers to the ability to hold, manipulate, and store information for short periods. The more space available, the more memory can be devoted to problem solving and thinking tasks. Nevertheless, there is limited space in which information can be held, and the more effort devoted to one task, the less space is available to devote to other tasks. WM has consistently been shown to play an important role in the writing process, because weak WM limits the

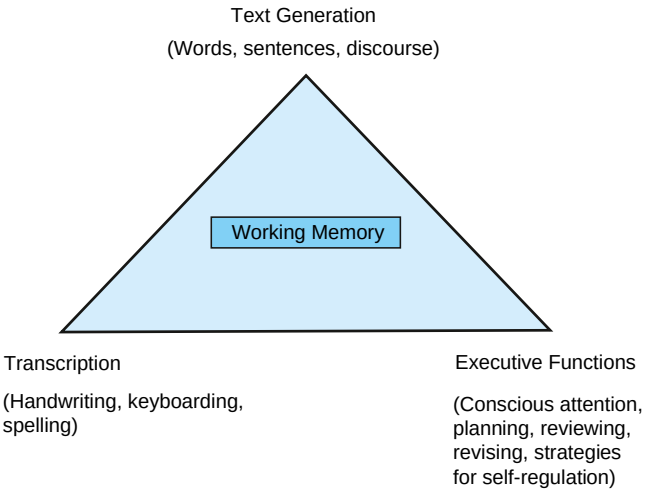

Fig. 52.1 Simple view of writing. *(From Berninger VW. Preventing written expression disabilities through early and continuing assessment and intervention for handwriting and/or spelling problems: Research into practice. In: Swanson HL, Harris KR, Graham S [eds]. Handbook of Learning Disabilities. New York: The Guilford Press;2003.)*

space available. Further, when writing skills that are expected to be *automatic* continue to require effort, precious memory is required, taking away what would otherwise be available for higher-level language.

The **Simple View of Writing** is an approach that integrates each of the four ideas just outlined to describe the writing process (Fig. 52.1). At the base of the triangle are transcription and EFs, which support, within WM, the ability to produce text. Breakdowns in any of these areas can lead to poor writing, and identifying where the deficit(s) are occurring is essential when deciding to treat the writing problem. For example, children with weak **graphomotor** skills (e.g., dysgraphia) must devote considerable effort to the accurate production of written language, thereby increasing WM use devoted to lower-level transcription and limiting memory that can be used for developing discourse. The result might be painfully slow production of a legible story or a passage that is largely illegible. If, on the other hand, a child's penmanship and spelling have developed well but their ability to persist with challenging tasks or to organize their thoughts and develop a coordinated plan for their paper is limited, one might see very little information written on the paper despite considerable time devoted to the task. Lastly, even when skills residing at the base of this triangle are in place, students with a language disorder will likely produce text that is more consistent with their language functioning than their chronologic grade or age.

TREATMENT

Poor writing skills can improve with effective treatment. Weak graphomotor skills may not necessarily require intervention from an **occupational therapist (OT)**, although *Handwriting Without Tears* is a curriculum frequently used by OTs when working with children with poor penmanship. An empirically supported writing program has been developed by Berninger, but it is not widely used inside or outside school systems *(PAL Research-Based Reading and Writing Lessons)*. Her research suggests that for children with dysgraphia, lower-level transcription skills should be emphasized to the point of becoming automatic. The connection between transcription skills and composition should be included in the instructional process; that is, children need to see how their work at letter production is related to broader components of writing. Further, because of WM constraints that frequently affect the instructional process for students with learning disorders, all components of writing should be taught within the same lesson. Building upon Berninger's sequencing of skills, Otaiba, Gillespie-Rouse, and Baker summarized features of effective handwriting instruction for kids who struggle: direct instruction on letter formation that is modeled and followed using verbal and visual instruction; retrieving letters from memory using such strategies as a child viewing the letter, covering, and reproducing the letter; children identifying their own errors; newly learned letters are integrated into word and sentence context and then into a child's own writing product; integration of multisensory strategies; and handwriting interventions included practice, occurred regularly, and were relatively brief but meaningful (children learned that writing had a purpose beyond accurately producing letters).

Explicit instruction of writing composition strategies combined with implementation and coaching in self-regulation will likely produce the greatest gains for students with writing deficits beyond transcription. Emphasis will vary depending on the deficit specific to the child. A well-researched and well-supported intervention for poor writers is **self-regulated strategy development (SRSD)**. The six stages in this model include developing and activating a child's background knowledge, introducing and discussing the strategy that is being taught, modeling the strategy for the student, assisting the child in memorization of the strategy, supporting the child's use of the strategy during implementation, and independent use of the strategy. SRSD can be applied across various writing situations and is supported until the student has developed mastery. The model can emphasize the areas most needed by the child.

An additional excellent resource is entitled *Teaching Elementary School Students to Be Effective Writers* and is found within the What Works Clearinghouse maintained by the U.S. Department of Education's Institute of Education Science.

Educational Resources

Children with identified learning disorders can potentially qualify for formal education programming through special education or a Section 504 plan. **Special education** is guided on a federal level by the **Individual with Disabilities Education Act (IDEA)** and includes development of an **individual education plan** (IEP) (see Chapter 49). The processes involved in pursuing an IEP are somewhat complex and outlined in the chapter on math learning disability (MLD). A **504 plan** provides accommodations to help children succeed in the regular classroom. Accommodations that might be provided to a child with IWE, through an IEP or a 504 plan, include dictation to a scribe when confronted with lengthy writing tasks; additional time to complete exams that require writing; and use of technology such as keyboarding, speech-to-text software, and writing devices that record teacher instruction.

Speech-to-text capability is available on most smartphones, which can be helpful for students from a functional standpoint. Educational resources that can be accessed inside and outside the classroom are often readily available for all children but may need to be included as an accommodation for a child with dysgraphia. Examples of easily available software include Voice Dictation in Google Docs and Dictation in Microsoft Word, both available at no cost. More sophisticated apps that can be purchased include Co:Writer for Chrome, Read & Write, and Kurzweil 3000. Kurzweil 3000 is a comprehensive assistive technology device that, in addition to speech-to-text and text-to-speech, offers multiple valuable resources for students with any type of literacy-based learning disability. Editing is a critical component of the writing process and, for children struggling with written expression, can present quite a challenge. Microsoft Word has built-in spelling and grammar correction suggestions, as do other word processing programs such as Pages and Google Docs. Apps for use when using the internet are also available to help with spelling, grammar, and writing mechanics. One example—though there are others—is Grammarly. When recommending that parents pursue assistive technology for their child as a potential accommodation, the physician should emphasize the importance of instruction to mastery of the device being used. Learning to use technology effectively requires considerable time and is initially likely to require additional effort, which can result in frustration and avoidance.

Chapter 53

Language Development and Communication Disorders

Janet Y. Bang and Heidi M. Feldman

There are over 6,000 languages in the world, each with a distinct set of symbols, defined as words or signs that signify objects, actions, ideas, or relationships. By combining symbols in novel ways, humans can create an infinite number of meanings. Human communication (Table 53.1) encompasses language, speech, nonverbal gestures, and written language. Typically developing children learn language skills seemingly without effort or explicit education early in the course of development. However, there is wide variation in how and when children learn and use language, speech, and communication. Globally, families differ in the specific languages and number of languages they speak and in the ways in which they communicate to convey their beliefs, values, and circumstances. Children vary in their rates of learning language and the highest level of skills they attain. Milestones within each domain (language, speech, communication) signify the unfolding steps by which new structures and skills come into children's language abilities (Table 53.2 and Fig. 53.1). Some children require explicit education or clinical support to learn language or to make their speech easily interpretable.

TYPICAL DEVELOPMENT

Development of Phonology

Every language is made up of an inventory of **speech sounds** or **phonemes** (see Table 53.1), and the number of speech sounds varies across languages (e.g., Hawaiian = 13, Cantonese = more than 36, English = 46). **Speech perception** depends on the physical structures of the ear and the auditory processing system. Fetuses detect sound as early as 28 weeks' gestation, and within 5 days after birth, infants can demonstrate the ability to discriminate vowel sounds (i.e., English vs Swedish) and show preferences for their own prenatal monolingual or bilingual language environments (i.e., English vs Tagalog-English). Infants develop their speech sound perception, built on the ability to track the statistical probabilities of sound combinations (e.g., *b* + *a* is more prevalent in language than *b* + *d*), segment sounds and words from a stream of speech, and become attuned to the speech sounds in their respective language or languages. Older children or adults learning a new language need to learn a new speech sound inventory.

Speech production involves activating the physical structures of the respiratory tract and oral cavity, such as the lips, tongue, and vocal cords, all of which work in concert. Infants begin producing nonspeech **cooing** sounds at 4-6 weeks. By 6-8 months, many infants engage in canonical **babbling** (e.g., *bababa*) followed by variegated babbling (e.g., *badadeda*). Infants who are exposed to **sign language** from birth demonstrate manual babbles at around the same time as hearing infants begin vocal babbles. These skills lay the stage for infants' first words and subsequent word combinations. Speech production continues to develop throughout early childhood, with easier consonant sounds maturing early, around age 3 (e.g., in English *p, b, m, h, w*) and difficult sounds (e.g., in English *l, s, r, v, ch, th*) maturing late, typically by around age 7.

Development of the Lexicon, Morphology, and Syntax

It is difficult to pinpoint when in development children typically understand their first word, but many children may say their first words by around 1 year; English-speaking families in the United States report first words appearing as young as 7 and as late as 15 months. Children's first words mark their expressive skills in their **lexicon** (see Table 53.1), and first words may come from a variety of categories (e.g., people, objects, and greetings). Many children recognize their own name between 7 and 15 months old. Initial word learning is typically very slow, but the rate of acquisition of new words gradually accelerates. Expressive lexical errors are common at this age and can include overextensions (e.g., all edible objects are "*apples*") or underextensions (e.g., only one specific spoon is labeled "*spoon*"). Between 1 and 2 years, children build a lexicon of over 50 words. The **vocabulary spurt** is rapid acceleration in word learning, usually after children reach 50 words in expressive language and coincident with the beginning of two-word phrases.

By approximately 2 years, children begin to demonstrate their developing understanding of **morphology** and **syntax** (see Table 53.1). Morphology and syntax rules differ by language. Children's receptive syntax skills are evident when they can follow simple directions or answer *wh-* questions. Notable expressive morphologic milestones in English include the use of the present progressive tense (e.g., "*go-ing*") and the plural -s (e.g., *dog-s*). Expressive syntax skills are evident via children's early creative word combinations, starting with two-word combinations, which are likely to vary from adult models (e.g., in English "*me down!*" or "*ick eggs!*"). By 3 years, children begin to produce sentences as long as five words and with increasingly complex grammar, such as negation (e.g., in English "*I no want to*") and questions (e.g., "*What he do?*"). As in these examples, lexical, morphologic, and/or syntax errors in understanding and production are common during this early phase of syntactic development. Morphologic or syntax errors in production may consist of overgeneralizations (e.g., in English, generalizing the "*-ed*" ending to all verbs such as "*runned*" rather than "*ran*"; in Spanish, Italian, or French, using the masculine articles with feminine nouns). By 4-5 years, children are able to use sentences with adult-like grammar (e.g., in English "*I fell because I was running too fast.*"), although they may still make mistakes (e.g., in English "*I gots 1 game and he got 3 games.*"). Children also engage in longer, coherent, connected discourse, such as telling or retelling stories and recounting the steps of a familiar activity, such as taking a bath.

Development of Pragmatics

Pragmatic skills begin in infancy. The ability to attend to and follow another's **eye gaze** develops as early as 3-4 months old. As young as 3 months old, children can engage in **protoconversations**, turn-taking patterns with caregivers that resemble early conversations. Responsive, contingent interactions between caregivers and children provide infants the opportunity to experience, imitate, and practice the timing, rhythm, and rate of nonverbal pragmatic skills, such as facial expressions, body language, and intonation. By 6 months, many infants can passively follow the adult's line of visual regard, resulting in a joint reference to the same objects and events in the environment. The ability to share the same experience is critical to the development of further language, social, and cognitive skills as infants "map" specific meanings onto their experiences. By 10-13 months, many infants can actively show, give, and point to objects. Children vary widely in when these skills first appear; English-speaking families have reported pointing skills as early as 6 months and as late as 16 months.

An important facet of typical communication development and a building block of conversational turn-taking skills includes establishing a **joint focus of attention**, a sharing of the topic of conversation with a communicative partner, both in comprehension (e.g., infants turn their heads to the object an adult is pointing at) and in production (e.g., a child saying "look at that dog over there," then looking back at their caregiver and expressing a desire for a dog). Conversation skills are important for forming relationships and especially strong social bonds and friendships. As children reach school age and adolescence, they develop **nonliteral** or **figurative language skills** (see Table 53.1), including hints, idioms, metaphors, hyperbole, humor, and sarcasm. In lexical development, understanding often occurs before production; in children's humor development, children's production may precede full understanding of their meaning. Another notable milestone of

Table 53.1 Definitions of Basic Terms in Communication, Language, and Speech

TERM	DEFINITION	EXAMPLES
Communication	• Broad umbrella term that encompasses understanding and producing language, speech, nonverbal communicative gestures, and written language	• Humans share ideas using verbal or signed speech and language • Nonverbal communicative gestures include nodding one's head up and down to convey "yes" in some cultures
Language	• Verbal, signed, written, or other systems that use arbitrary but conventional, rule-governed symbols to communicate about objects, events, and ideas in the past, present, and future	• Verbal symbols include words (e.g., *apple* in English or *manzana* in Spanish, both of which represent a red, tasty fruit) • Signed symbols include the word *apple* in American Sign Language, produced by the twist of the knuckle of the index finger on the cheek
Speech	• Perception of the meaningful units of sounds that comprise verbal language and production of these sounds by coordinating the mouth, tongue, airflow, and vibration of the vocal folds	• Speech sounds or phonemes make a difference in meaning (e.g., *b, p, a, i,* and *t* affect the meaning of *bat, bit, pat,* and *pit*) • Speech does not include all vocal sounds, such as coughs or throat clearing • Phonemes in sign language are based on spatial, temporal features, such as hand shape
Receptive language	• Hearing and understanding verbal or sign language	• Recognizing own name • Following two-step directions
Expressive language	• Speaking using verbal or sign language	• Speaking first words or signs in a sign language • Telling stories
Phonology	• The system of relationships among speech sounds or phonemes that constitute a fundamental component of language	• Understanding *seetheredball* can be segmented into *see the red ball* • Babbling, consonant-vowel combinations that use phonemes
Lexicon	• All of the words or vocabulary of a person or a language	• The lexicon of the mathematician may vary from the lexicon of the lawyer
Morphology	• Units of meaning that can be combined to form vocabulary	• In English *dogs* is made of two morphemes, *dog* and the plural *-s; untie* is made of *un-* and *tie*
Syntax	• Grammar and word order to make sentences	• In English word order, *the dog chases the cat,* while in Hindi word order, *the cat the dog chases*
Pragmatics	• Verbal and nonverbal communication skills that govern how language and communication are used in context • Includes intonation, facial expression, and body language	• Use of eye contact and gestures to make a point forcefully • The timing and responsiveness between communication partners (e.g., engaging, responding, and maintaining reciprocal exchanges)
Nonliteral or figurative language skill	• Meaning of a word or phrase that is not literal but understood in context	• Hints (e.g., a teacher saying, "*I think I hear children talking*") • Idioms (e.g., "*Give me a hand*") • Metaphor (e.g., "*You are my sunshine*") • Hyperbole (e.g., "*That's the biggest thing I've ever seen!*")
Advanced language skills	• Ability to listen, speak, read, write, and reason using language	• Academic language • Ability to debate and deliver speeches
Literacy skills	• Skills required for reading and writing	• Reading an alphabetic language requires awareness of the sounds of language, print, and the relationship between letters and sounds • Spelling is a literacy skill
Bilingualism and multilingualism	• Ability to speak and/or sign two or more languages	• Ability to communicate verbally in Chinese and English • Ability to communicate verbally in English and to use American Sign Language • Ability to use Chinese, English, and American Sign Language
Biliteracy and multiliteracy	• Ability to read and write in two or more languages	• Ability to read and write Chinese, Spanish, and English
Phonologic processes	• Errors in speech production that affect more than a single sound and are based on violations of predictable, rule-based features	• Fronting, when a sound that should be made in the back of the mouth (cat) is made in the front of the mouth (tat) • Cluster reduction, when a consonant cluster (as in stop) is reduced to a single consonant (top)

Table 53.2 Speech, Language, and Communication Milestones from Birth to 5 Years, Based on Typically Developing Children Acquiring a Single Verbal Language

HEARING AND UNDERSTANDING	SPEAKING
BIRTH TO 3 MO	
• Startles at loud sounds • Recognizes voices and quiets if crying • Turns head toward sounds • Watches faces • Quiets or smiles when spoken to	• Makes pleasure sounds (cooing, gooing) • Cries differently for different needs
4-6 MO	
• Moves eyes in direction of sounds • Responds to changes in tone of voice • Notices music and sounds • Recognizes familiar people and things at a distance	• Vocalizes differently to show excitement, being tired, or in pain • Makes sounds when alone and when playing • Makes babbling sounds that are speechlike and uses consonant sounds, such as *p, b,* and *m* • Reaches for toys or objects • Engages in turn-taking and protoconversations
7-12 MO	
• Listens when spoken to • Turns and looks in direction of sounds • Enjoys social games, such as peek-a-boo and pat-a-cake • Responds to own name • Recognizes words for common items, such as *cup, shoe,* and *juice* • Begins to respond to simple requests *(Come here; Want more?)* or *No* • Looks when an adult points at something	• Uses speech sounds or gestures to get and keep attention and to respond to others • Imitates different speech sounds and gestures • Babbles with long and short groups of sounds, such as *bababa upup bibi,* and mixes different syllables, such as *badadeda* • Says one or two words *(bye-bye, dada, mama)* • Points to or shows things to spontaneously share interest with familiar people • Uses gestures such as waving for *hi* and *bye* or shaking head for *no*
1-2 YR	
• Listens to simple stories, songs, and rhymes • Follows simple commands and understands simple questions *(Roll the ball; Kiss the baby; Where's your shoe?)* • Points to things when asked or when named such as body parts and objects	• Learns to say more words every month • Uses some one- and two-word questions *(Where kitty? Go bye-bye? What's that?)* • Combines two words in their own ways *(more cookie, no juice, mommy book)* • Uses consonant sounds such as *p, b, m, h,* and *w* in English
2-3 YR	
• Understands differences in meaning (e.g., go–stop, in–on, big–little, up–down) • Follows two-step requests *(Get the book and put it on the table.)*	• Often asks for or directs attention to objects by naming them • Has a word for almost everything • Uses prepositions like *in, on,* and *under* • Often uses two- to three-word "sentences" • Speech is mostly understood by familiar listeners • Uses consonant sounds such as *k, g, f, t, d,* and *n* in English
3-4 YR	
• Understands simple *who, what, where,* and *why* questions • Understands words for colors like *red, blue,* or *green* and shapes like *circle* or *square* • Responds when you call from another room	• Uses pronouns like *I, you, me, we,* and *they* • Uses sentences that have four or more words with more complex grammar such as negative *(I no want to)* and questions • Talks about activities outside the home • Usually understood by people outside the family
4-5 YR	
• Hears and understands most of what is said at home and in school • Pays attention to a short story and answers simple questions about it • Understands words for time like *yesterday, today,* and *tomorrow* • Understands words for order like *first, next,* and *last* • Follows longer directions such as *(Find an animal you like, draw a circle around it, and bring the paper to me)*	• Uses sentences that include details (I like to read my books) and different action words like jump or play; may still make some grammar mistakes (I gots one game and he got three games) • Tells simple stories using mostly full sentences • Communicates easily with other children and adults • Says most sounds correctly except a few that are harder to say, such as *l, s, r, v, z, ch, sh,* and *th* in English

Milestones may not apply to bilingual children, children exposed to sign languages, children learning a second language, and children with language and learning disorders

Adapted from the American Speech-Language-Hearing Association (2021), the American Academy of Pediatrics (2009), and the Centers for Disease Control and Prevention Milestones checklist (2021).

pragmatic skills is the ability to adapt how to narrate events or stories for different audiences (e.g., friends vs teachers).

Advanced Language Skills

Once children enter school, they continue to develop new vocabulary and use increasingly complex sentence constructions to communicate about abstract, hypothetical, and imaginary topics. By adolescence, many students in Westernized school systems are required to deliver expository speeches or to debate. Formal schooling also affords new situations to communicate with a broader network of individuals, including teachers, coaches, and supervisors. The diversity of the situations requires nuanced attention to social rules and conventions and increases exposure to diverse forms of nonliteral language use, though proficiency in the use of nonliteral language varies by the language and culture of the speaker and addressee. Finally, the introduction of formal schooling presents children with the demands of acquiring

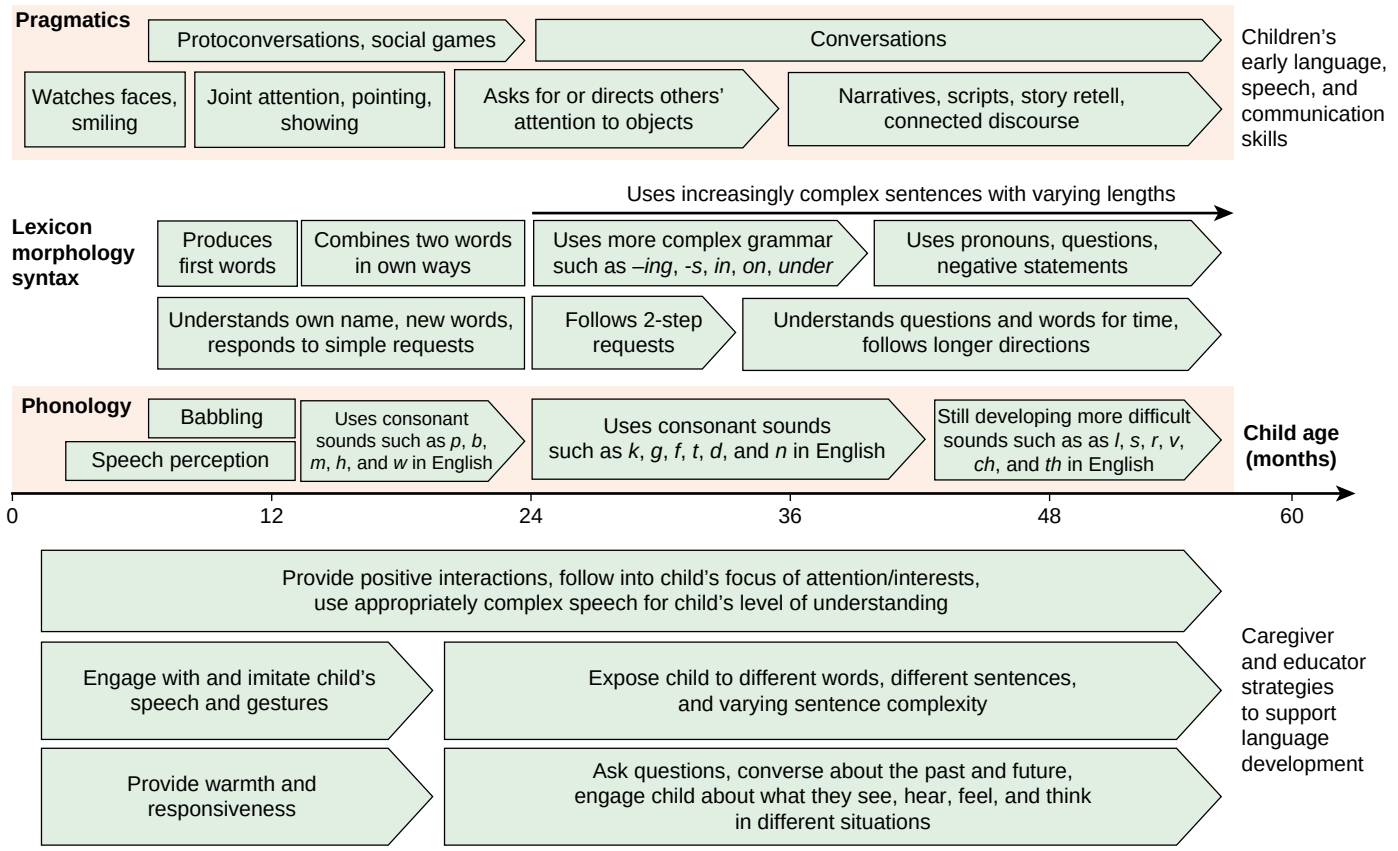

Fig. 53.1 Timeline of children's early language, speech, and communication skills and caregivers' and educators' strategies to support that development. The timing and width of boxes for the child skills are adapted from milestones from the American Speech-Language-Hearing Association, The American Academy of Pediatrics, and the Centers for Disease Control and Prevention. More information on milestones can also be seen in Table 53.1. Caregivers and educators should be encouraged to engage with the child using the language with which they are most comfortable because children, even children with delays, are capable of becoming bilingual. Specific child skills and caregiver/educator strategies may vary according to language and cultural practices.

literacy skills (see Table 53.1), those skills required for reading and writing. Early oral language skills are a robust predictor of children's early reading skills, and early oral language and reading skills are in turn predictors of children's writing skills (see Chapters 51 and 52.2). Language skills become critical to support high-level school- and work-related literacy skills.

BILINGUALISM AND MULTILINGUALISM

Worldwide, learning more than one language is more common than learning just one; many regions and countries in the world are home to individuals who routinely speak two or more languages. The timing of exposure, balance between languages, and level of skill in each language in dual-language or multilanguage learners varies across situations. **Simultaneous bilinguals** refers to those regularly exposed to both languages prenatally or from birth. **Sequential bilinguals** refers to those exposed to the second language after the first language, often when they enter school, though the timing of when the second language is introduced varies. Once children learn two languages, the balance in skill level between them may vary. For example, a child who was born in Nigeria, exposed to Igbo, and then immigrated to Greece at age 5 years will initially be more proficient in Igbo than in Greek. As the child attends school in Greece, Greek proficiency will improve (likely also supported through the introduction of reading and writing in a Greek monolingual school environment), and thus the balance will shift and the child may become more proficient in Greek over Igbo. A high level of skill across all domains of phonology, lexicon, syntax, and pragmatics is considered an ideal picture of bilingualism, but this ideal is not always the case or necessary for many bilingual learners. Bilingual learners often demonstrate **code-switching**, that is, alternating between languages, or **code-mixing**, mixing their languages together, especially when speaking with other bilingual speakers. A distinction between **conversational** and **academic** language skills may be made in reference to bilinguals. Bilingual speakers may master conversational language, the language used to communicate casually with family or friends, but remain less skilled in academic language, the complex, technical, and specialized vocabulary and syntax required in academic or work settings, particularly when school is presented in a language different from the language of the home. Some bilingual learners may experience **language attrition**, a reduction in the proficiency in one language over time. Factors within the child, family (e.g., one caregiver/one language, caregivers speaking both languages), community (e.g., availability of bilingual schooling, minority vs majority language of the community, perceived prestige of a language), and policy (e.g., national acknowledgement of multiple languages or requirements of accessibility of documents in school or business sectors) contribute to proficiency in both languages.

Bilingualism or multilingualism is typical language development for many children and not an adequate explanation for language delays as long as the child's skills in both languages are assessed. Even children with language and developmental disorders, such as intellectual disability and autism spectrum disorder, may be successful bilingual or multilanguage learners. It is difficult to predict developmental trajectories in bilingual development because of the wide variety of factors associated with the level of skill in different domains. *Children in homes with two or more languages who show delays in language development (considering the accumulated accomplishments in all languages) should be promptly referred for evaluation.*

DRIVERS OF VARIATION IN TYPICAL LANGUAGE DEVELOPMENT

Genetic

Similarities in language abilities across members of the same family suggest that genetic factors contribute to individual differences in language abilities. Genetic factors have been studied more often in the context of disorders of language learning than in the context of normal variation (see below).

Environment

Interactions between young children and their caregivers that are positive, responsive, and warm allow children to practice their early word learning (e.g., social games, routines). Living in stable home environments is better for language development than living in an unstable condition. The Bucharest Early Intervention Project conducted a randomized controlled trial to examine the role of being raised in a home (foster care) versus in institutionalized care in Romanian orphanages that were providing infants with low levels of responsive interactions. Children taken from the orphanages and placed in foster care by age 15 months had language skills that were similar to typically developing peers at 30 and 42 months in the same Romanian community living with their biologic families; children placed in foster care after 24 months had persistent expressive language delays.

The role of caregivers specifically is one of the few levers available to influence language outcomes in clinical practice and public programs. Positive links have been found between variability in socioeconomic backgrounds and children's later language skills; caregivers have been shown to mediate this link. Caregivers' **child-directed speech** refers to changes to caregivers' prosody (intonation patterns), phonology, grammar, and lexicon when engaging with young children. This child-directed speech has been measured across a wide variety of features, which can be broadly categorized into measures of quantity (e.g., total number of words spoken), quality (e.g., number of different words spoken), and interaction (e.g., warmth and responsiveness). Taken together, these factors constitute **language nutrition**, which, like dietary nutrition, is associated with rates of growth. However, the causal links between caregivers' child-directed speech and children's language outcomes are still unclear in children with typical development or language delays or disorders. Meta-analyses of interventions targeting improved language nutrition to date have generally reported either null effects or small to moderate positive effects on children's language skills. The specific role of book-sharing interventions to support children's language development is also mixed among different meta-analyses. Wide heterogeneity across intervention studies, including the method of delivery (e.g., one-on-one coaching vs caregiver groups), intensity (e.g., 1 hour per week for 12 weeks vs two 45-minute visits), measures of caregiver-child interaction, and child language outcomes, may contribute to differences in results. Caregivers' mental health has been found to be an important mediator of child outcomes; higher caregiver depression has been linked to poorer children's language outcomes.

Greater amounts of screen time and early age of screen time are negatively related to children's early language skills. However, high-quality screen-time practices (e.g., co-viewing, educational programs) are positively related to children's language skills; effect sizes are small to moderate.

Misattributions of Language Delay

Several common conditions have been erroneously implicated as an adequate explanation for language delays and disorders. Typically developing twins learn to talk at the same age as typically developing single-born children. Birth-order effects on language development have not been consistently found. **Ankyloglossia** (tongue-tie), an extremely tight lingual frenulum, does not prevent the acquisition of speech, but ankyloglossia may be the result of abnormalities associated with disorders of speech, such as neural injury and cerebral palsy. Frequent ear infections and serous otitis media in early childhood *do not* result in persisting language disorder. Prompt placement of tympanostomy tubes for chronic serous otitis media *does not* lead to better skills than watchful waiting. Biologic sex differences have been found in many studies of language development. Though males are generally slower to develop than females, the differences do not usually rise to the level of being clinically apparent. However, males are more likely to develop language disorders than females. Based on these findings, *children with moderate to severe delays in the development of language and speech deserve a prompt evaluation, even if they are males, non–first born children, twins, tongue-tied toddlers, and/or children with chronic otitis media.*

LANGUAGE, SPEECH, AND COMMUNICATION DISORDERS

Impairment in language, speech, and communication may occur in isolation or may be associated with other conditions.

Isolated Language Disorders with or Without Accompanying Speech Disorders

Clinical Presentation

Primary disorders of speech and language development are significant difficulties found in the absence of major cognitive, sensory, or motor dysfunction. The literature uses the term **specific language impairment** (SLI) or **language impairment**, the term we use here, also called *developmental language disorder* or *developmental dysphasia.* Children with language impairment typically perform >1.25-1.5 standard deviations below the mean on standardized language assessments. The *Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition* (DSM-5) criteria for a language disorder are provided in Table 53.3. Many children with language impairment eventually become competent language users, though they may show persistent and subtle difficulties with skills related to phonology, lexicon, and/or syntax. As adolescents and adults, compared to peers, they are generally less proficient at producing stories, descriptions, and scripts of everyday events, collectively known as **oral narratives**. Their narratives tend to be shorter, including fewer prepositions, main story ideas, and devices fostering cohesion. Children with language impairment may have significant difficulty in higher-level language skills (see Table 53.1), reasoning skills (e.g., drawing correct inferences and conclusions), the ability to take another person's perspective, and the ability to paraphrase and rephrase. Some children with language impairment show difficulties with social interaction because social interactions are often mediated by verbal language. Young children with language impairment may interact more successfully with older children or adults, who can adapt their communication to match the child's level of function, than with peers.

Epidemiology

Over 15% of 2-year-olds may not produce a vocabulary of 50 words or two-word utterances; estimates may vary for children exposed to two or more languages. Almost half of preschool-age children, age 3-5 years old, who qualify for special education meet eligibility based only on speech-language impairment. By age 5, approximately 6% of children are identified as having a speech impairment alone, 5% as having both speech and language impairment, and 8% as having language impairment alone. Males are nearly twice as likely to have an identified speech or language impairment as females.

Etiology

Genetic factors appear to play a major role in influencing how children learn to talk. A family history may identify current or past speech or language problems in up to 30% of first-degree relatives of proband children. Concordance rate for low language test scores and/or a history of speech therapy within twin pairs is about 50% in dizygotic pairs and 90% in monozygotic pairs. Consistent pathogenic genetic variations have not been identified. Instead, multiple genetic regions and epigenetic changes may result in heterogeneous genetic pathways causing language disorders. Several single-nucleotide polymorphisms (SNPs) involving noncoding regulatory genes, including *CNTNAP2* (contactin-associated-protein-like-2) and *KIAA0319,* are strongly associated with early language acquisition and are also thought to

affect early neuronal structural development. Several chromosomal **copy number variants** (see Chapter 96) have also been associated with abnormalities of language and speech; these variants may be associated with distinctive physical features (e.g., tall stature in Klinefelter syndrome) or neurobehavioral conditions (e.g., autistic features). Environmental, hormonal, and nutritional factors may exert **epigenetic** influences by dysregulating gene expression. These forces result in aberrant sequencing of the onset, growth, and timing of language development.

All of the family, community, and sociopolitical factors that appear to contribute to variation in typical language learning may contribute to the rate of learning in children with disorders. Improving the quality of the verbal environment, and in particular the quantity and quality of child-directed speech (see above), may moderate the impact of genetic and epigenetic factors.

Pathogenesis

Language functioning is widely distributed across the brain through interconnected neural networks. Frank neurologic injury is typically absent in children with language impairment. Language disorders have been attributed to a fundamental difficulty in the brain's capacity to process complex information rapidly. Limitations in the amount of information that can be stored in verbal working memory (see Chapter 49) may also limit the rate at which language information is processed. Electrophysiologic studies show abnormal latency in the early phase of auditory processing in children with language impairment. Neuroimaging studies identify an array of anatomic abnormalities, implicated in language processing. MRI scans in children with language impairment may reveal white matter lesions and volume loss, ventricular enlargement, focal gray matter heterotopia within the right and left parietotemporal white matter, abnormal morphology of the inferior frontal gyrus, atypical patterns of asymmetry of language cortex, or increased thickness of the corpus callosum in a minority of affected children. Postmortem studies of children with language disorders found evidence of atypical symmetry in the plana temporale and cortical dysplasia in the region of the sylvian fissure. A high rate of atypical perisylvian asymmetries has been documented in the parents of children with language impairment.

Language Disorders Associated with Cognitive Impairment and Intellectual Disability

Speech and language impairment may be the first indication of a global neurodevelopmental disorder. **Global developmental delay** or **early developmental impairment** is defined as delays in two or more domains. Children with substantial delays in adaptive function and scores 2 or more standard deviations below the mean on intelligence testing may meet criteria for **intellectual disability** (see Chapter 56). Most children with a mild intellectual disability learn to communicate adequately, though they are likely to encounter difficulties with higher-level language skills (see Table 53.1). Children with an IQ as low as 25 may eventually acquire a small lexicon and ability to combine words. Specific genetic syndromes have distinctive language profiles: in Down syndrome, verbal skills are more impaired than nonverbal skills; in William syndrome, language skills may be relatively preserved compared to nonverbal skills; in fragile X syndrome, unusual word or sound repetition may be present.

Autism Spectrum Disorder

A disordered pattern of language, speech, and communication development characterizes autism spectrum disorder (ASD) (see Chapter 58). The core characteristics of ASD are persistent difficulties in social communication and social interaction relative to age expectations and restricted, repetitive patterns of behavior, interests, or activities. Children with ASD show a wide range of language and communication abilities. At the severe end, language and speech may be extremely limited (nonverbal). Approximately 30–50% of children with ASD also meet criteria for intellectual disability, which contributes to the challenges of developing communication skills. Parents report regression in language and social skills (**autistic regression**) in approximately 20–25% of children with ASD, usually between 12 and 36 months of age. The cause of the regression is not known; it is associated with an increased risk for intellectual disability and severe ASD. Individuals with ASD who are high functioning may have large vocabularies and use grammatically correct sentences but have unusual or impaired social-pragmatic features, such as odd intonation patterns, off-topic comments, and atypical conversational skills. For example, they may engage in long monologues about a topic of special interest, without considering the interest of their conversational partner. Some individuals with ASD have highly specialized, isolated, "savant" skills, such as calendar calculations or **hyperlexia** (the precocious ability to recognize written words beyond expectation based on general intellectual ability).

DSM-5 identified **social (pragmatic) communication disorder (SPCD)** as a category of communication disorder distinct from ASD (see Table 53.3). Symptoms of SPCD include extreme literalness and inappropriate verbal and social interactions. Socially appropriate use and understanding of figurative language (see Table 53.1) depends on correct interpretation of the meaning and the context of language and the ability to draw proper inferences, skills limited in SPCD. SPCD has been recognized as a symptom of a wide range of disorders, including right-hemisphere brain injury and nonverbal learning disabilities.

Hearing Impairment

Hearing loss may be caused by a sensorineural loss, a conductive loss, or a mixed picture in one or both ears. Although it is not possible to accurately predict the impact of hearing loss on a child's verbal language development, the type, degree, and laterality of hearing loss; the age of onset; and the duration of the auditory impairment before amplification play important roles (see Chapter 55). Newborn screening programs are designed to identify congenital hearing loss but fail to identify children with progressive or acquired hearing loss or deafness after birth. *Any child who shows a speech or language problem should have a hearing assessment by an audiologist, even if they passed their newborn hearing screen.*

Conductive hearing loss occurs when sounds cannot get through the outer and middle ear to stimulate the auditory nerve. In children, the most common cause of conductive hearing loss is **acute** or **chronic serous otitis media**. Otitis media is typically transient and may increase the sound threshold at which children can detect tones or understand language. Persistent fluid in the middle ear may be treated with **tympanostomy or ventilation tubes**. However, treatment of chronic serous otitis media with tympanostomy tubes does not improve outcomes in the domains of speech and language, cognition, academic skills, or psychosocial functioning from preschool years through middle childhood.

Neurologic Conditions

Epilepsy Syndromes

Children with Landau-Kleffner syndrome or verbal auditory agnosia have a history of typical language development until they experience a regression in their ability to comprehend spoken language—verbal auditory agnosia—along with the development of seizures, usually between 3 and 7 years of age. Expressive language skills also typically deteriorate. An electroencephalogram (EEG) may show a distinct pattern of status epilepticus in sleep (continuous spike wave in slow-wave sleep), and up to 80% of children with Landau-Kleffner syndrome eventually exhibit clinical seizures. Use of antiepileptic medication, corticosteroids, and intravenous gamma globulin has led to varying results. The prognosis for return of typical language ability is uncertain, even if seizures resolve.

Epileptic interictal discharges are more frequently found on EEGs of children with language impairments than EEGs of otherwise typically developing children. The discharges are likely a manifestation of an underlying disorder of brain, distinct from the language impairment. Only when seizure symptoms or regression in language ability is present is a routine EEG recommended in the evaluation for a child with speech and/or language impairment.

Table 53.3 DSM-5 Diagnostic Criteria for Communication Disorders

LANGUAGE DISORDER

A. Persistent difficulties in the acquisition and use of language across modalities (i.e., spoken, written, sign language, or other) due to deficits in comprehension or production that include the following:
   1. Reduced vocabulary (word knowledge and use).
   2. Limited sentence structure (ability to put words and word endings together to form sentences based on the rules of grammar and morphology).
   3. Impairments in discourse (ability to use vocabulary and connect sentences to explain or describe a topic or series of events or have a conversation).
B. Language abilities are substantially and quantifiably below those expected for age, resulting in functional limitations in effective communication, social participation, academic achievement, or occupational performance, individually or in any combination.
C. Onset of symptoms is in the early developmental period.
D. The difficulties are not attributable to hearing or other sensory impairment, motor dysfunction, or another medical or neurologic condition and are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay.

SPEECH SOUND DISORDER

A. Persistent difficulty with speech sound production that interferes with speech intelligibility or prevents verbal communication of messages.
B. The disturbance causes limitations in effective communication that interfere with social participation, academic achievement, or occupational performance, individually or in any combination.
C. Onset of symptoms is in the early developmental period.
D. The difficulties are not attributable to congenital or acquired conditions, such as cerebral palsy, cleft palate, deafness or hearing loss, traumatic brain injury, or other medical or neurologic conditions.

SOCIAL (PRAGMATIC) COMMUNICATION DISORDER

A. Persistent difficulties in the social use of verbal and nonverbal communication as manifested by all of the following:
   1. Deficits in using communication for social purposes, such as greeting and sharing information, in a manner that is appropriate for the social context.
   2. Impairment of the ability to change communication to match context or the needs of the listener, such as speaking differently in a classroom than on a playground, talking differently to a child than to an adult, and avoiding use of overly formal language.
   3. Difficulties following rules for conversation and storytelling, such as taking turns in conversation, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate interaction.
   4. Difficulties understanding what is not explicitly stated (e.g., making inferences) and nonliteral or ambiguous meanings of language (e.g., idioms, humor, metaphors, multiple meanings that depend on the context for interpretation).
B. The deficits result in functional limitations in effective communication, social participation, social relationships, academic achievement, or occupational performance, individually or in combination.
C. The onset of the symptoms is in the early developmental period (but deficits may not become fully manifest until social communication demands exceed limited capacities).
D. The symptoms are not attributable to another medical or neurologic condition or to low abilities in the domains of word structure and grammar and are not better explained by autism spectrum disorder, intellectual disability (intellectual developmental disorder), global developmental delay, or another mental disorder.

From the *Diagnostic and Statistical Manual of Mental Disorders, 5th ed.* Washington, DC: American Psychiatric Association; 2013:42, 44, 47–48.

Cerebellar Mutism Syndrome

In the aftermath of operations for tumors in the posterior fossa, such as **medulloblastoma**, many children lose the ability to speak. Fortunately, though the presentation is initially profound, most children recover the ability to use language. **Cerebellar mutism syndrome** demonstrates that the cerebellum probably plays a fundamental role in language and communication. The syndrome is thought to result from damage to the superior cerebellar peduncle that connects the cerebellum to language centers in the frontal lobes.

Stroke

Strokes in childhood can occur prenatally, in the perinatal period, or at any time in childhood. As in adults, a brain territory frequently affected is supplied by the middle cerebral artery resulting in damage to the **left frontal and temporal lobes** that are associated with language function in adults. However, young children with stroke show greater plasticity of language function than do adults with similar brain injuries. Many children with left hemisphere stroke go on to demonstrate typical or near-typical language functions. Functional imaging studies document that these children activate uninjured regions of the left hemisphere around the stroke or homologous regions in the right hemisphere. This demonstrates that though under usual circumstances the left hemisphere serves language, alternative networks can substitute in the case of early injury. The quality of the home language environment is strongly associated with the language skills of children with strokes.

Metabolic and Neurodegenerative Disorders (see Part IX and Chapter 639)

Regression of language development may accompany loss of neuromotor function at the outset of a number of metabolic diseases, including lysosomal storage disorders (metachromatic leukodystrophy), peroxisomal disorders (adrenal leukodystrophy), ceroid lipofuscinosis (Batten disease), and mucopolysaccharidosis (Hunter disease, Hurler disease). A creatine transporter deficiency was identified as an X-linked disorder that manifests with language delay in males and with mild learning disability in female carriers.

Hydrocephalus (see Chapter 631.11)

Children with hydrocephalus may be described as having cocktail-party syndrome. In this syndrome, children may use sophisticated words, but their comprehension of abstract concepts is limited, pragmatic conversational skills are weak, their analyses are superficial, and/or they appear to be carrying on a monologue.

Language in the Context of Psychologic or Mental Health Conditions

Selective Mutism

In **selective mutism**, children do not speak in specific social situations, such as school or other settings outside the home, though they speak normally in certain settings, such as within their home or when they are alone with their parents. Other symptoms include excessive shyness, withdrawal, dependency on parents, and oppositional behavior. Most cases of selective mutism are the manifestation of a chronic pattern of **anxiety**. Children with selective mutism often report that they want to speak in social settings but are too afraid, worried, or distressed to do so. The family history is often positive for anxiety symptoms. Children with selective mutism may also have a language or speech impairment, contributing to their sense of distress in speaking. Treatment of selective mutism generally uses evidence-based approaches to reducing general anxiety, including cognitive-behavioral therapy and/or selective serotonin reuptake inhibitors in conjunction with speech-language therapy.

Schizophrenia

A characteristic of schizophrenia is abnormal communication, including highly disorganized language that is difficult to follow and frequent changes in topic (see Chapter 47.1). This communication challenge accompanies the thought disturbance that is the hallmark of schizophrenia. Schizophrenia usually presents in individuals in adolescence or young adulthood. The communication disorder is linked to other features of schizophrenia, including slower processing speed, poorer cognitive control, and weaker working memory relative to typically developing peers.

Adverse Psychosocial Conditions

Orphanages

An estimated 8 million children worldwide are living in residential care or orphanages, despite recognition of the severe adverse impacts of institutionalization on children's health and development. Children in orphanages have poor receptive and expressive language skills, most likely the result of limited language exposure and lack of consistent warm relationships with caring adults. Children from orphanages may be adopted. In an international adoption, the children typically face a new challenge: learning a different language (see Chapter 9). Outcomes for internationally adopted children are mixed; meta-analyses suggest trends for stronger language outcomes when children are adopted before the age of 1 year than after 1 year. However, findings were not statistically significant, likely because of the wide variety of challenges that the children face and difficulty identifying appropriate comparison groups.

Foster Care

Approximately 30–75% of the children 6 years of age or younger in foster care are delayed, and therefore **assessing language skills for them is imperative** (see Chapter 10). An important contribution to the language delay in many children in foster care, like that of children in orphanages, is the lack of consistently warm, responsive parenting that is fundamental to language nutrition. Encouraging foster parents to increase language nutrition may positively affect the language skills of children in foster care.

High-Stress, Low-Verbal Environments

Children from homes where they may experience stressors, such as food insecurity, housing insecurity, poor childcare facilities, and high levels of community violence, are at risk for slower language development relative to peers in stable environments. All of these factors may contribute to initial delays in physical and cognitive development, with language development being one of the most noticeable to track developmental progress. If language delays persist, the chances that the children will catch up with others from more resourced environments, even if their circumstance change, are limited. Thus, what begins as a delay may end up as a disorder. Referral of children from stressed, low-verbal environments to public and community-based prevention programs designed to provide stability and to enhance language input may improve the children's outcomes.

SPEECH DISORDERS

Structural Anomalies of the Organs of Speech

Cleft Lip and Palate

Cleft lip is a split in the formation of the lip. **Cleft palate** is a split in the hard and/or soft palate (see Chapter 356). These conditions often occur together but may occur separately. Cleft lip or palate is the most common structural abnormality at birth in the United States. The cleft is often easy to see but may be subtle if isolated to the soft palate. A child with isolated cleft lip may have minimal speech problems. A child with cleft palate is likely to have speech difficulties, including **hypernasal speech** in which air escapes through the nose, making it difficult to produce consonants that need pressure to build in the mouth for proper execution (e.g., *b, k,* and *s*). In addition, children with cleft palate may have severe and persistent serous otitis media, leading to moderate to severe conductive hearing loss beyond the frequency and complications of children with an intact palate. Therefore most children with cleft palate need long-term therapy with a speech-language pathologist (SLP). Cleft palate may occur in isolation, called **nonsyndromic cleft palate**, or in conjunction with other malformations, called **syndromic cleft palate**. **Velocardiofacial syndrome (VCFS)** is an autosomal dominant condition that results from a deletion on the long arm of chromosome 22 (deletion22q11) and may include cleft palate. Many different phenotypes are associated with this deletion, demonstrating the complex relationship of genes, anatomic structure, and function. The prognosis for speech and language in such cases is dependent on the specific syndrome associated with the cleft palate.

Velopharyngeal Insufficiency

Velopharyngeal insufficiency (**VPI**) is an abnormality of the soft palate, such that the soft palate cannot regulate the flow of air between the mouth and nose in speech. It may occur as part of cleft palate or may be an isolated finding. VPI may not be apparent in early development when the adenoids are large and bolster the soft palate. As the adenoids regress, it may become clear that the soft palate is not closing off the passage to the nose, creating hypernasal speech. Evaluation of the intactness of the soft palate is important before adenoidectomy because removal of the adenoids can bring on VPI suddenly. Surgery or use of prosthetic devices may be required for individuals who cannot be helped by speech therapy.

Speech Sound Disorders

Speech sound disorders is an umbrella term that refers to difficulties with perception, motor production, or phonologic representation of speech sounds and/or speech segments (see Table 53.3). Speech sound disorders may be organic in origin, including neurologic conditions, structural conditions, or sensory conditions. Speech sound disorders are considered **functional** when no known cause can be identified. Speech sound disorders may be accompanied by subtle difficulties in speech perception.

Phonologic Disorders

Phonologic disorders are functional speech sound disorders that affect linguistic aspects of speech. **Phonologic processes** (see Table 53.1) are errors in speech production based on violations of predictable, rule-based features of speech. These phonologic processes are typical at young ages and resolve at specific ages. Phonologic processes become disorders when they persist to older ages and impair intelligibility.

Articulation Disorders

Articulation disorders focus on errors (such as distortions and substitutions) in production of individual speech sounds regardless of where in a word or phrase the sound occurs. Articulation errors are not the result of neuromotor impairment, but rather seem to reflect an inability to correctly process the words they hear. As a result, they lack understanding of how to fit sounds together properly to create words. Children with articulation or other speech sound disorders are at risk for later reading and learning disability.

Childhood Apraxia of Speech

In childhood apraxia of speech (CAS), difficulty in planning and coordinating movements for speech sound production results in inconsistent distortions or errors of speech sounds, even vowel sounds. The same word may be pronounced differently each time, making intelligibility poor. Intelligibility also tends to decline as the length and complexity of the child's speech increase. Consonants may be deleted and sounds transposed. As they try to talk spontaneously or imitate others' speech, children with CAS may display oral groping or struggling. Children with CAS frequently have a history of early feeding difficulty, limited sound production as infants, and/or delayed onset of spoken words. They may point, grunt, or develop an elaborate gestural communication system in an attempt to overcome their verbal difficulty. Apraxia may be limited to verbal motor skills, may extend to oral-motor function, or may be a more generalized problem affecting fine and/or gross motor coordination. Childhood apraxia of speech may co-occur with disorders of language and learning.

Dysarthria

This motor speech disorder often originates from neuromotor disorders, such as cerebral palsy, muscular dystrophy, myopathy, and facial palsy. Dysarthria is characterized by lack of strength and muscular control and manifests as slurring of words and distorting vowels. Speech patterns are often slow and labored. Feeding difficulty, drooling, open-mouth posture, and protruding tongue may accompany the dysarthric speech.

Disorders of Fluency, Voice, and Resonance

Stuttering

Under normal circumstances, most people do not speak smoothly all the time, but rather repeat words or sounds, hesitate to find a word, pause, add "uh" or "you know" to the flow of speech, or repeat a sound or word more than once. These disruptions are called **dysfluencies** and are discussed further in Chapter 53.1. **Stuttering** in children over age 4 that lasts longer than 6 months, includes repetition of individual sounds, and/or creates emotional distress should be evaluated by a speech and language pathologist.

Voice

A **voice disorder** is an abnormality in voice quality, pitch, and loudness that is unexpected or inappropriate for an individual's age, gender, cultural background, or geographic location. Voice disorders can be subdivided into organic and functional. **Organic voice disorders** are physiologic in nature and result from alterations in respiratory, laryngeal, or vocal tract mechanisms. **Aerodigestive disorders** cover congenital or acquired conditions of the aerodigestive tract; they include abnormalities of the **airway** (pharynx and larynx), **pulmonary tract** (trachea, bronchi, and lungs), and **upper digestive tract** (esophagus). These structural problems may affect respiratory and swallowing functions and speech, especially voice. **Functional voice** disorders result from improper or inefficient use of the vocal mechanism in the context of normal physical structure. Psychologic stress can also lead to habitual and maladaptive voice quality, known as **psychogenic voice disorders**. These categories may overlap. Vocal nodules result from behavioral voice misuse that leads to repeated trauma to the vocal folds and structural changes to the vocal fold tissue.

ASSESSMENT OF LANGUAGE AND SPEECH DISORDERS

Screening

Developmental surveillance at each well-child visit should include specific questions about typical language developmental milestones and observations of the child's behavior. Clinical judgment, defined as eliciting and responding to parents' concerns, can detect many children with speech and language challenges. The American Academy of Pediatricians (AAP) recommends clinicians employ standardized developmental screening questionnaires and observation checklists at select well-child visits (see Chapter 28). However, the U.S. Preventive Services Task Force reviewed screening for language impairment in young children in primary care settings and found inadequate evidence to support screening in the absence of parental or clinician concern about children's speech, language, hearing, or development. At present, when parents, other caregivers, or physicians are concerned about speech or language development, the child should be referred for a diagnostic evaluation and intervention.

Diagnostic Evaluation

A developmental delay indicates abnormally slow timing relative to same-age peers in the development of the skill. A language delay becomes a language disorder when it persists to school age; is functionally impactful in terms of communication, social skills, or learning and cognition; or is qualitatively different from normal patterns or sequences of development. Language and communication skills should be interpreted within the context of that child's overall cognitive, social, and physical abilities. A multidisciplinary evaluation of a child with language delay or disorder is often warranted. At a minimum, the diagnostic evaluation should include psychologic or neurodevelopmental evaluation, including an assessment of social skills, a speech-language evaluation, an audiologic assessment, and a pediatric examination.

Psychologic or Neurodevelopmental Evaluation

The two main goals for the psychologic evaluation of a young child with a communication disorder are to assess nonverbal cognitive ability and social skills. A broad-based cognitive assessment is important to determine the breadth and severity of developmental difficulties. At a minimum, the child should have an assessment of both verbal and nonverbal skills. As children reach school age, they may be assessed with an intelligence test and an assessment of adaptive function to determine if they meet criteria for intellectual disability (see Chapter 56). If the child has findings of global developmental delay or intellectually disability, their language and speech skills should be evaluated within that context. Language and speech disorders may coexist with other conditions, so that the psychologic evaluation at all ages should consider mental health conditions, such as anxiety, mood disorder, and attention-deficit/hyperactivity disorder (ADHD) and, at older ages, learning challenges.

A child's social behaviors must be assessed to determine whether the child meets diagnostic criteria for ASD (see Chapter 58). Children with language impairment may display an interest in social interaction, even if they may have difficulty socializing because of limitations in communication skills, such as difficulties initiating conversation or taking turns. Children with ASD do not display social interest in typical ways. However, the distinction may be challenging in the context of a clinical evaluation when the child needs to interact only with professional adults and not with peers. Observational tests include specific maneuvers, such as calling the child's name, making exaggerated gestures, and attempting to engage the child in a reciprocal interaction around blowing bubbles, to make this distinction.

Speech and Language Evaluation

A certified SLP should perform a speech and language evaluation on a child with delays or difficulties in language and speech. A typical evaluation includes assessment of language, speech, and the physical mechanisms associated with speech production. Both expressive and receptive language (see Table 53.1) are assessed, using a combination of standardized measures, informal interactions, and pertinent observations. All components of language are assessed, including phonology, lexicon, morphology, syntax, and pragmatics (see Table 53.1). Speech assessment similarly uses a combination of standardized measures and informal observations and includes assessment of speech sounds, fluency, voice, and resonance. Assessment of physical structures includes oral structures and function, respiratory function, and vocal quality.

Audiologic Assessment (see Chapter 677)

In many settings, an SLP works in conjunction with an audiologist, who can do an appropriate hearing evaluation of the child. If an audiologist is not available in that setting, a separate referral should be made. No child is too young for a hearing evaluation. Passive methods can be used in children who are young or unable to cooperate with testing. Repeat assessment with an active assessment can be accomplished at older ages. A referral for full hearing evaluation is appropriate whenever there is suspicion of language or speech impairment.

Pediatric Evaluation

History and physical examination should focus on the identification of potential contributors to the child's language and communication difficulties. A family history of delay in talking, need for speech and language therapy, or academic difficulty can suggest a genetic predisposition to language disorders. Pregnancy history might reveal risk factors for prenatal developmental anomalies, such as polyhydramnios or decreased fetal movement patterns. Small size for gestational age at birth, symptoms of neonatal encephalopathy, or early and persistent oral-motor feeding difficulty may presage speech and language difficulty. Developmental history should focus on the age when various language skills were mastered and the sequences and patterns of milestone acquisition. *Regression or loss of acquired skills should raise immediate concern.*

Physical examination should include measurement of height (length), weight, and head circumference, even in children over age 2 years. The skin should be examined for lesions consistent with phakomatosis (see Chapter 636). Anomalies of the head and neck, such as white forelock and hypertelorism (Waardenburg syndrome), ear malformations (Goldenhar syndrome), facial and cardiac anomalies (Williams syndrome, VCFS), retrognathism of the chin (Pierre Robin anomaly), or cleft lip/palate, are associated with hearing and speech abnormalities. Neurologic examination might reveal muscular hypertonia or hypotonia, both of which can affect neuromuscular control of speech. Generalized muscular hypotonia, with increased range of motion of the joints, is frequently seen in children with language impairment. The reason for this association is not clear, but it might account for the fine and gross motor clumsiness often seen in these children. However, mild hypotonia is not a sufficient explanation for the impairment of receptive and expressive language. Language impairment may be a component of a syndrome or other recognizable condition. The physical examination gathers information to make other diagnoses.

No routine diagnostic studies are indicated for isolated language disorders with the exception of the hearing assessment. When language delay is a part of a generalized cognitive or physical disorder, referral for further genetic evaluation, genetic testing (e.g., fragile X testing, microarray, whole exome or whole genome sequencing), neuroimaging studies, and EEG should be considered.

Treatment of Language and Speech Disorders

Disorders of language and speech are often treated by SLPs working alone or as part of a multidisciplinary team with others, such as early intervention specialists or occupational therapists. SLPs may work in hospital in-patient and out-patient settings. More commonly, they work in schools and early intervention programs. The nature and intensity of treatment are predicated on the nature and cause of the language or speech disorder and the explicit objectives of treatment. **Childhood apraxia of speech** typically requires that the child participate in four or five short sessions per week to achieve intelligible speech, whereas language impairment disorder may require once- or twice-weekly therapy in a peer-group setting to increase communicative attempts. Speech-language therapy for young children is typically play-based. Even drills are couched in naturally occurring, enjoyable, or fun activities. Group therapy with other young children is often well suited to children with language and communication disorders because children practice their emerging skills with peers in naturalistic settings. A strong family component to therapy is important to leverage the limited time that therapists can spend with children. Caregivers can be taught to use effective techniques designed to meet the objectives of the treatment program. For children who do not develop useful verbal language, the SLP may consider the use of assistive and augmentative communication (AAC; see Chapter 54), which may use high-technology devices, such as voice-generating computer programs, or low-technology solutions, such as sign language or picture exchanges. The use of AAC allows the nonverbal child to communicate within the human community. Several systematic reviews and meta-analyses provide compelling data that speech-language therapy is effective for improving many aspects of language and speech. Therefore a timely referral for treatment with an SLP is recommended over watchful waiting for many children with delays and disorders of language and speech.

53.1 Childhood-Onset Fluency Disorder

Kenneth L. Grizzle and Karolyn Mirasola

Dysfluent speech describes speech, language, and voice behaviors that interrupt the production and fluency of sounds, words, and thoughts. All speakers produce dysfluent speech, but not all dysfluent speech is stuttering. The words *stuttering, stammering,* and *dysfluency* are often used interchangeably. *Stutter* is used informally, particularly in the United States, to describe when an individual is struggling to express themself and may speak in a halting manner. *Stammering* is used in the United Kingdom in place of stuttering (Table 53.4). It is important for clinicians to have a general understanding about what stuttering is and when to counsel and refer families to speech-language pathologists (SLPs). It is important to distinguish between stuttered and nonstuttered dysfluencies and other fluency disorders and to identify concomitant symptoms.

DIAGNOSIS

In the *Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition* (DSM-5), the term *stuttering* has been removed from the diagnostic classification, and the disorder is referred to as **childhood-onset fluency disorder** (Table 53.5). Note that impact on functional behavior is a component of the psychiatric diagnosis. In contrast, communication disorder specialists would consider anxiety and avoidance of various activities as concomitant symptoms, but not necessarily a requirement for the diagnosis of stuttering.

Child-onset stuttering (formerly known as developmental stuttering) is a speech disorder that often begins in the preschool period

Table 53.4 Terminology Related to Childhood-Onset Fluency Disorder

TERM	DEFINITION
Stuttering	A speech disorder manifested through abnormal speech patterns referred to as *dysfluencies*
Childhood-onset fluency disorder	Term used in DSM-5 that is synonymous with *stuttering*
Stammering	The clinical term used in the United Kingdom rather than stuttering; stammering also used informally to describe halting speech
Cluttering	A speech disorder characterized by an excessively rapid and irregular rate of speech
Dysfluency	Speech disruptions that can occur in normal or disordered speech

Table 53.5 DSM-5 Diagnostic Criteria for Childhood-Onset Fluency Disorder

A. Disturbances in the normal fluency and time patterning of speech that are inappropriate for the individual's age and language skills, persist over time, and are characterized by frequent and marked occurrences of one (or more) of the following:
   1. Sound and syllable repetitions.
   2. Sound prolongations of consonants and vowels.
   3. Broken words (e.g., pauses within a word).
   4. Audible or silent blocking (filled or unfilled pauses in speech).
   5. Circumlocutions (word substitutions to avoid problematic words).
   6. Words produced with an excess of physical tension.
   7. Monosyllabic whole-word repetitions (e.g., "I-I-I-I see him").

B. The disturbance causes anxiety about speaking or limitations in effective communication, social participation, or academic or occupational performance, individually or in any combination.

C. The onset of symptoms is in the early developmental period.
Note: Later-onset cases are diagnosed as 307.0 [F98.5] adult-onset fluency disorder.

D. The disturbance is not attributable to a speech-motor or sensory deficit, dysfluency associated with neurologic insult (e.g., stroke, tumor, trauma), or another medical condition and is not better explained by another mental disorder.

From the *Diagnostic and Statistical Manual of Mental Disorders. 5th ed.* Washington, DC: American Psychiatric Association; 2013:45–46.

and is not associated with stroke, traumatic brain injury, or other possible medical conditions. Stuttering behaviors can occur in typically developing children who do not have a speech disorder and in this situation are more accurately referred to as *developmental dysfluencies*. During the toddler and preschool years, children often produce repetition of sounds, syllables, or words, particularly at the beginning of sentences (normal dysfluencies). These developmental dysfluencies occur between the ages of 2.5 and 4 years old when the language, motor, and emotional systems are developing. These dysfluencies may occur as the child struggles to try to express more complex ideas in a rapid and precise manner.

Child-onset stuttering disorder also typically begins between 2 and 4 years of age. Onset of symptoms varies from pronounced stuttering within a few days to gradual worsening of symptoms across months. Symptoms may ebb and flow, including disappearing for weeks before returning, especially among young children. From 40% to 75% of young children who stutter will stop spontaneously, typically within months of starting. Although predicting which child will stop stuttering is difficult, risk factors for persisting include stuttering for >1 year, continued stuttering after age 6 years, and experiencing other speech or language problems. Additionally, certain types of dysfluencies are typically seen only in child-onset stuttering disorder.

Types of Dysfluencies

Dysfluencies interrupt the normal flow of speech through repeated or prolonged sounds, syllables, or words. Types of dysfluency that are *not* exclusive to children who stutter include *interjections* ("well, uhh, umm"), hesitations (pause), *revisions* ("I thought . . . I mean"), and *phrase repetitions* ("Did you say—Did you say"). In addition, the perspective of the speaker and cause of the dysfluency differ between true stuttering disorders and other types of dysfluency. The dysfluencies might sound the same but occur for different reasons. For example, a typically developing child with dysfluency may talk around a word or use a completely different word because of issues with word retrieval, complex thought formulation, or distractibility. But for children who stutter, they may talk around a word or retrieve a completely different word because even though they know exactly what they want to say, they are unable to produce or "get" the sounds out. This highlights the notion that stuttering is about more than what the listener observes. The "moment of stuttering" is different because something occurs that only the person who stutters can perceive.

Dysfluencies that occur in child-onset stuttering vary in type, frequency, and longevity. Specifically, children who stutter show greater part-word repetition ("b-b-b-b-but"), single-syllable word repetition ("My, my, my"), sound prolongation ("MMMMMM-an"), and in more severe cases, blocking. Blocking is a dysfluent behavior that is identified by a fleeting or sometimes lengthy blockage of the flow of air at the level of the vocal folds or articulators (tongue, teeth, and lips). Typically, the child has initiated an articulatory posture (tongue is in the position to produce "k"), but she is unable to release any air and/or phonation (i.e., voice). Often in response to this inability to produce sounds or words, the child will develop secondary behaviors that recruit movement from other parts of the body that the child feels they have more "control" over.

These types of behaviors and movements exist only within child-onset stuttering disorder. They are referred to as *secondary characteristics,* or physical concomitants that often occur as a response to stuttering. Common secondary characteristics include movements of the head (head turning or jerking), face (eye blinking/squinting, grimacing, opening or tightly closing the jaw), neck (tightening), and limbs (stomping feet, slapping hand); an increase in body tension; and irregular patterns of inhalations and exhalations.

Emotional Symptoms and Stuttering

Fear and anxiety are **emotional symptoms** associated with stuttering. Many people experience some level of fear and anxiety related to speaking in front of a group, but children who stutter often experience high levels of fear and anxiety related to all speaking situations, especially ones that occur with newer or unfamiliar people (e.g., ordering at a restaurant, calling a store to ask about store hours, introducing oneself). Along with their own feelings interfering with speech production, the reactions of those around them may also increase the anxiety of children who stutter. Negative interactions or comments may inhibit a child's future attempts to interact verbally with another person or in a group setting. Consider also the potential **social challenges** associated with entering a classroom for the first time, transitioning to middle/high school/college, beginning a job, dating, and so on. Not surprisingly, just as avoiding production of a perceived sound or word is common, *avoidance* of situations and people is a common way of coping with the anxiety created by the fear of stuttering. These avoidance behaviors indicate a need for intervention.

Differential Diagnosis

Although many dysfluencies are often referred to as stuttering, it is important to recognize that there are different types of fluency disorders. Cluttering is a fluency disorder that may occur with or separate from stuttering but is different in form and cause. Stuttering and cluttering have been identified to exist on a continuum. Unlike stuttering, for which distinct episodes can be identified and even counted, **cluttering** affects the entire speech output and is often diagnosed around age 7 years or later. In addition to elevated repetitions of partial words (as in stuttering), whole words, and phrases, those who clutter show speech bursts that are often choppy, and articulation can be slurred and imprecise. In addition, there is often an increase in disorganization of their language, unusual prosody, and listener perception of a fast rate of talking. The level of awareness of how their speech affects those listening, unlike children who stutter, is minimal for those who clutter. In fact, children with a cluttering disorder often experience a decrease in their dysfluent behaviors when they are speaking in front of a group because of an increased focus on their speech, whereas the impact for children who stutter is exactly the opposite.

In addition to cluttering, neurogenic (result of a stroke, head trauma, or other neurologic damage) and psychogenic (associated with psychologic trauma) stuttering also exist, though they rarely occur in childhood. Stuttering can also be confused with dysfluent speech that occurs for other neurologic reasons (e.g., Tourette syndrome, cerebral palsy, spasmodic dysphonia).

Epidemiology

Approximately 5% of children experience stuttering, with the highest rates among young children. Seldom does a child begin stuttering before 2 years of age or after 12 years; in fact, the mean age of onset is 2-4 years, and most children stop stuttering within 4 years of onset. Symptoms will disappear within 4 weeks for a minority of children. Stuttering is more common in males than in females, and the magnitude of the difference increases as children get older. The ratio among children <5 years is approximately 2:1 and jumps to 4:1 among adolescents and young adults.

Genetics

There is convergent evidence of a genetic link for childhood-onset fluency disorder. Concordance rates among monozygotic twins range from 20% to 83%, and for dizygotic twins, 4–19%. Family aggregation studies suggest increased incidence of approximately 15% among first-degree relatives of those affected, three times higher than the 5% rate for the general population. The variance in risk for stuttering attributed to genetic effects is high, ranging from 70% to 85%. Although evidence is limited, stuttering appears to be a polygenic condition, and several genes increase susceptibility.

Brain Structure and Function

Brain structure and function abnormalities found among individuals who stutter include deficits in white matter in the left hemisphere, overactivity in the right cortical region, and underactivity in the auditory cortex. Abnormal basal ganglia activation has also been identified.

EVALUATION

Comorbidities

Despite the widely held belief in a high degree of comorbidity between childhood-onset fluency disorder and other communication disorders, research to date does not necessarily support this association. SLPs consistently report high rates of comorbidity, although this would be expected in clinical samples. Speech sound (phonologic) disorders are the most commonly reported comorbidities, occurring in 30–40% of children seen by SLPs. However, studies have not found greater incidence of phonologic disorders among those who stutter compared to a control group. Similarly, SLPs report a much higher percentage of children with language disorders among their patients who stutter than the approximately 7% expected in the population at large, yet studies find the language functioning among individuals who stutter is no different than in the general population. The same pattern holds for learning disorders (LDs).

Children who stutter seem to experience more anxiety than their nonstuttering peers, although research is limited. The frequency of reported anxiety increases with age. Social anxiety and generalized anxiety disorder are common among adolescents who stutter. Although one should not assume that an individual who stutters will have an increased risk for any specific psychiatric disorder, assessing for anxiety is important, as children who stutter frequently avoid situations that demand speaking, as discussed earlier in the chapter.

Children who stutter have consistently been found to be bullied more than peers. In one study, these children were almost four times more likely to be bullied than their nonstuttering counterparts. About 45% of children who stuttered reported having been the victim of bullying.

Referral to Speech and Language Pathology

In deciding who to refer to an SLP, it is important to distinguish developmental dysfluencies from stuttering. In addition to the risks noted in Table 52.5, indications for referral include three or more dysfluencies per 100 syllables (b-b-but; th-th-the; you, you, you), secondary characteristics denoting escape or avoidance behaviors (pauses, head nod, blinking), discomfort or anxiety while speaking, family history of stuttering or other speech-language disorders, and suspicion of an associated neurologic or psychotic disorder. Most children with persistent stuttering after age 4 years should be evaluated by an SLP.

As a part of the evaluation, the SLPs will be able to address the many pressing concerns and worries of a parent whose child is stuttering. The outcome of a speech-language evaluation for stuttering should accomplish the following:

1. Obtain a strong family history related to the existence of speech and language disorders in general and more specifically related to stuttering and dysfluencies.
2. Interview the parent or child about the child's stress when speaking in various situations.
3. Record a speech sample to analyze the type, frequency, and complexity of the dysfluent behaviors and secondary characteristics that the child is producing.
4. Differentiate between developmental dysfluency behaviors, other causes of dysfluent behaviors, and a child-onset dysfluency disorder (aka stuttering).
5. Develop a plan with the family that involves a combination of direct and indirect speech and language therapy, parent education, and home programming.

TREATMENT

A true stuttering disorder is a lifelong condition. To date, no evidence supports the use of a pharmacologic agent to treat stuttering in children and adolescents, and there is no cure for stuttering. However, treatment in preschool-age children has been shown to improve stuttering. In fact, speech-language therapy is most effective when initiated during the preschool period. The broad focus of therapy allows for minimizing the adverse effects of the condition.

Based on the child's age, types and frequency of stuttered behaviors, severity of secondary characteristics, and impact on the child's qualify of life, the SLP will decide if a less direct or more direct therapeutic intervention is recommended.

Less direct therapy focuses on manipulating the situation and environment while allowing the child to experience increased fluency. Most preschool children respond to interventions taught by SLPs that are accompanied by behavioral feedback strategies implemented by parents and teachers. It is important to recognize that parental pressure or speaking pressure does not cause stuttering. A less direct therapy approach involves working with the caregiver to accomplish the following:

1. Limit situations and expectations that cause increased dysfluencies and stress
2. Demonstrate and model how to adjust speaking rate and complexity of language rather than reprimanding children for their speech errors or asking them to slow down
3. Increase opportunities for the child to experience fluent communication

More direct therapy is recommended and implemented when less direct therapy did not have an impact on the stuttering behaviors, the child has increasing worries related to stuttering, the child has a high risk of continuing to stutter, or the child is older and has been stuttering for some time. One of the overarching goals of the therapy implemented by an SLP is to help the child experience increased fluency and strategies to learn how to "stutter" better.

Therapy that is more direct adds the following elements:

1. Awareness and education: Recognizing and accepting that their speech is different, identifying and naming types of speech, nonjudgmentally noting episodes of stuttering using selected words and phrases (which are often accompanied by pictures) that were developed with and practiced by the child ("That was a bit bumpy"), appreciating others' reaction to the child when stuttering, managing secondary behaviors, admitting they are a person who stutters, and addressing avoidance behaviors as a result of the stress and anxiety they are experiencing.
2. Fluency-shaping behaviors: Regulating rate of speech and breathing and helping the child gradually progress from the fluent production of syllables to more complex sentences. The child should be involved in opportunities to identify speech disfluencies, implement self-correction, and respond to requests ("Can you say that again?").

Because stuttering rarely disappears, the thrust of therapy is often to "improve" the type of stuttering, decrease the occurrences of stuttering, and develop strategies for coping with the fear and anxiety that will continue to occur in various speaking opportunities.

Appreciating that dysfluency is a broad term and stuttering can be one of the causes for this behavior allows pediatricians to have a more accurate understanding of the symptoms, causes, and treatments associated with dysfluencies. Being armed with this information allows the provider to include in their referral to an SLP an accurate description of symptomology, which will be beneficial in the planning and execution of their initial evaluation.

Chapter 54

Augmentative and Alternative Communication

Michelle M. Macias

Children must develop communicative competence to interact with others, to influence their environment, and to participate fully in society. If children are not able to effectively communicate, they will have minimal means to express what they need, exchange information with others, and develop social skills and relationships. Some children are unable to communicate effectively through natural means, including speech, gestures, or writing (see Chapter 53). These children with **complex communication needs (CCNs)** have more independent function through **augmentative and alternative communication (AAC)** methods to meet their communication needs and to avoid significant restrictions on their participation in all aspects of life.

AAC interventions have been helpful for individuals with no speech, limited speech, and those at risk for speech-language disorders; this includes individuals who rely on speech but need augmentation to enhance speech, those recovering from a traumatic brain injury, and those who may have temporary conditions affecting communication. AAC has changed from an emphasis on providing the means to express needs and wants to the recognition that communication must also foster exchange of information, development of social relationships, and participation in social routines. In addition, there is recognition that communication needs extend beyond face-to-face interactions and also include written communication in the school setting and even social media in peer communities.

DEFINITIONS

According to the American Speech-Language-Hearing Association (ASHA), AAC is "an area of clinical practice that addresses the needs of individuals with significant and complex communication disorders characterized by impairments in speech-language production and/or comprehension, including spoken and written modes of communication." AAC encompasses the communication methods used to supplement or replace speech or writing for those with impairments in the production or comprehension of spoken or written language. In pediatrics, AAC is used by youth with a wide range of speech and language impairments, including cerebral palsy (CP), traumatic brain injury, intellectual disabilities, autism spectrum disorder (ASD), and apraxia of speech. In addition, children and adolescents hospitalized in intensive care units can benefit from AAC.

AAC is **augmentative** when used to supplement existing speech and **alternative** when used in place of speech that is absent or not functional. AAC uses a wide variety of electronic and nonelectronic techniques from low technology to high technology, including manual signs, gestures, tangible objects, line drawings, picture communication boards and letter boards, and speech-generating devices. The term **assistive technology (AT)** is a more general term describing systems and devices that alleviate the effects of a disability and improve function, for example, bracing for a child with a neuromotor impairment as well as AAC.

Prevalence

Across countries, the overall prevalence of AAC use ranges from approximately 1.2% to 1.5% of the population; worldwide up to 0.6% of the school-age population has a severe speech impairment. A national survey of U.S. special educators reported that approximately 18% of students served in special education use a form of AAC for communication, with 7% using gestural modes, 6.5% using pictorial supports, and 4.8% using a speech-generating device (SGD). However, not all U.S. children with developmental disabilities or children with special healthcare needs have their communication needs met. The more severe a child's communication deficit, the more likely the child would benefit from AAC support.

Across particular pediatric populations, it has been estimated that 25–50% of children with ASD have limited speech and would benefit from AAC. Up to 45% of children with CP use AAC either exclusively or to supplement speech. Several studies have found that in intensive care units ~30% of patients had communication breakdowns and met AAC candidacy criteria, although alternative communication modes were rarely used.

Goals of Communicative Interactions and AAC Interventions

The ultimate goal of AAC is to enable individuals to effectively engage in interactions and participate in activities of their choosing. Broadly speaking, the goals of AAC interventions are to assist individuals with meeting their current communication needs and prepare them to meet their future communication needs. Communicative interactions can be said to fulfill four purposes: (1) communicate needs/wants, (2) transfer information, (3) social closeness, and (4) social etiquette. It is important to remember that adequacy of communication depends on the personal goals of the person using AAC, and the definition of success may vary by the professionals involved.

Most children with complex communication needs demonstrate some ability to communicate using speech, although some are entirely nonverbal. The effectiveness of natural speech for communication can be divided into 10 levels (Meaningful Use of Speech Scale; Robbins & Osberger):

1. Makes vocal sounds in communicative exchanges
2. Gets another person's attention using speech
3. Uses various vocal sounds depending on the intention and content of messages

Uses speech for communication about:

1. Known topics with familiar people
2. Known topics with unfamiliar people
3. New topics with familiar people
4. New topics with unfamiliar people
5. Messages that are understood by familiar people
6. Messages that are understood by unfamiliar people
7. Clarification messages as needed when communication breakdown occurs

AAC Systems

An "**AAC system**" refers to the integrated group of components used to support and enhance communication. These components include the specific forms of AAC, selection techniques, and strategies for use.

Individuals with complex communication needs must have access to a wide range of means to enhance their communication and participate fully within social and educational contexts. This may include **unaided AAC**, which does not require an external tool and requires some degree of motor control (e.g., gestures, sign language, finger spelling, speech approximations), or **aided AAC**, which requires either an electronic or a nonelectronic tool. Nonelectronic aided forms are referred to as **low-tech aided AAC** and include options such as communication boards/books, picture-exchange communication systems (PE or PECS, pictures, photographs), or visual schedules. Electronic forms are referred to as **mid-tech or high-tech AAC** systems and include traditional speech-generating devices (SGDs) or voice output communication aids (VOCAs), recordable devices, and computer/tablet options and applications ("apps"). SGDs/VOCAs include multiple options. **Single-level devices** have pictures/words on a single-level display, whereas **multilevel devices** can have vocabulary programmed on more than one level. **Static display devices** keep the same display, and the user can sequence symbols or words to generate a message. **Dynamic display devices** are usually those with a touch screen for the display in which pages can change using navigation keys and link buttons. **Text-to-speech devices** enable the user to spell messages that convert to synthesized speech. Some dynamic display devices include text-to-speech

Table 54.1 Types of Augmentative and Alternative Communication

	LOW TECH	MID-HIGH TECH
Unaided	• Sign language • Gestures	—
Aided	• Communication boards/books • Picture exchange systems • Visual schedules • Eye-gaze picture board • Simple single-message speech output devices	• Voice output communication aids (VOCAs)/speech-generating devices (SGDs) with prestored recordings of natural speech or computer-generated speech • Specialized software on electronic tablet, smartphone • Spelling and/or symbol systems to represent language

Unaided systems: Do not require special materials or equipment; rely on user's body to covey messages.
Aided systems: Require the use of tools or equipment; can require power or no power.

and use symbols as well as text. Table 54.1 provides examples of the range of AAC systems.

Mobile technology (e.g., iPad) and greater use of social media tools have increased acceptance of AAC and reduced attitudinal barriers to AAC use. However, the increased diversity of communication tools also means increased operational demands, given that each tool is designed with different representations, organizations, and layouts of information as well as different access techniques (e.g., swiping, tapping). Each design may reflect different motor, cognitive, perceptual, and linguistic learning demands. A combination of gestures/signs, low-technology systems, mobile technology devices, and SGDs can provide AAC users with the most effective communication options to suit their needs.

AAC Teams

AAC teams serving individuals with CCNs are the groups of people that guide the AAC intervention decision-making process and implement communication supports. Team members include the children and adolescents with CCN themselves, parents/caregivers, and professionals playing a variety of roles.

Children with CCN. The most important member of the team is the individual relying on AAC techniques. The role may change in response to the individual's maturation and capability, but to the extent possible, the child or adolescent should participate in the decision-making process regarding goals, social relationships, and support options related to the AAC system and interventions.

AAC facilitators. The term *facilitator* refers to parents/family members, friends, professionals, and frequent communication partners who assume some responsibility for keeping the AAC system operational and/or supporting the person with CCN to use it effectively. They support communication interactions by coaching, serving as interpreters, and/or helping resolve communication breakdowns. Importantly, the role of facilitator is to support independent communication by the individual with CCN, not to communicate *for* the individual.

AAC specialists. AAC specialists provide direct AAC intervention services by instructing and educating about AAC and designing and implementing AAC interventions. AAC specialists work with clinicians and educators, such as speech-language pathologists, occupational therapists, teachers, and pediatric healthcare providers who provide clinical and educational services to youth with CCN.

AAC Assessment

AAC assessment involves gathering information so that informed decisions can be made about the adequacy of current communication, the communication needs, the AAC techniques that are most appropriate, how to provide instruction in AAC techniques, and how to evaluate outcomes. Proper evaluation and support for the use of AAC devices are of paramount importance.

Studies comparing acquisition of communication skills reveal few differences in terms of how quickly many children can learn to use some of the available AAC options. For example, PEC and sign language comparison studies vary—some show PECs were acquired more easily than signing, and others suggest both PECs and signing were acquired at an equal pace. Studies comparing PECs with SGDs similarly vary in terms of effectiveness of device use.

Physicians, therapists, and other professionals who prescribe AAC must make sure the child (and family) receives training and monitoring for using the device and that the device is accessible across settings in which the child functions (e.g., home, school, community activities). A substantial number of AAC devices are abandoned shortly after implementation without support for their use. AAC assessment and intervention is a dynamic process, and usually ongoing, as often the children and adolescents requiring the AAC system are unable to speak or write because of physical, cognitive, language, and/or sensory impairments. Assessment generally consists of four phases as outlined here:

Phase 1: Referral. The "finder" role is an important role for pediatric healthcare providers. They may be the impetus for recognizing that a child has a CCN and that an AAC intervention may be helpful. They then assist the patient and their family by initiating a referral to an appropriate resource. The pediatric provider can support the AAC funding application by certifying a medical diagnosis and signing a prescription for the recommended service. Although the role is episodic, it is nonetheless a key role in the AAC assessment and treatment process.

Phase 2: Initial Assessment. The goal of this phase is to gather information to design an AAC intervention to match the child's existing needs and capabilities. The AAC specialist(s) assesses the child's current communication interaction needs and his or her physical, cognitive, language, and sensory abilities. This typically focuses on enabling communicative interactions between the child and familiar AAC facilitators. The intervention is refined as the child learns about the operational requirements of the AAC system and the AAC team gathers information on how well the system works for the child. Demonstrations and simulators are available to help with training before the actual equipment is ordered.

Phase 3: Assessment for Other Settings. The goal is to develop a solid communication system that supports the child with CCN in a variety of environments, including home, school, and recreational environments. A child must have access to a system that allows educational and social participation.

Phase 4: Follow-Up Assessment. This involves maintaining a comprehensive AAC system that accommodates the child's changing capabilities. The communication equipment must be examined regularly to assess the needs of new communication partners, detect replacement/repair needs, and reassess the child's capabilities as they change.

Specific Assessment Details

Assess Current Communication. The initial step is to assess the effectiveness of the child's current communication system. The assessment of communication access focuses on the operational and social aspects of communicative competence. A child with spastic quadriplegia, for example, may be unable to use eye gaze consistently and therefore operationally unable to use an eye-gaze AAC system. On the other hand, a minimally verbal adolescent with ASD may be able to operate an electronic AAC device but never use it to initiate a social interaction.

Some questions to ask regarding current communication behaviors in children with CCN include the following:

- What are the various methods your child uses to communicate? Examples: words/speech, vocalizations, gestures, signing, communication board, eye gaze, typing, and so on.
- What body part is used for each technique (e.g., left/right hand, eyes)?
- On a scale of 1 to 5, how accurately and efficiently is your child able to use this technique?
- On a scale of 1 to 5, how well is your child able to use this technique in an interactive, socially appropriate manner?

Screening Tools. Various screening instruments exist that help document communication behaviors. These include the Communication Matrix; the Inventory of Potential Communicative Acts (IPCA); and the Social Communication, Emotional Regulation, Transactional Support (SCERTS) Model Assessment, among others. The Communication Matrix focuses on individuals using any form of communication (presymbolic or AAC), and the IPCA focuses primarily on presymbolic communicators with physical and/or developmental disabilities. The SCERTS Model Assessment focuses on communication and social regulation behaviors in verbal and nonverbal children with ASD.

Assess Potential to Use or Increase Speech. A key issue in AAC assessment for children with CCN is whether AAC is needed to augment insufficient speech or serve as a replacement for speech. Parents are often concerned that using an AAC device will negatively affect speech development, as the child will have access to an "easier" alternative. The use of AAC techniques does not inhibit natural speech; conversely, AAC may enhance spoken language by supporting the development of communicative competence and language skills.

Assess Potential for Environmental Adaptations. Modifications of physical spaces or structures may be relatively straightforward or more complex, depending on the specific situation. For example, at home, furniture rearrangement or renovations to adapt the home to accommodate AAC devices may be necessary. In the school, desks/tables may need to be raised/lowered or a vertical workspace may need to be created with a slanted board.

Specific Issues Regarding AAC for Children with Disabilities

Cerebral Palsy

Communication impairments are commonly seen in children with CP, both related to impaired (motor) speech intelligibility and language disorders (see Chapter 638.1). The incidence of dysarthria varies depending on the type of CP and degree of motor impairment. Language impairments are associated with intellectual functioning and hearing loss, if present.

More than any other disability, communication interventions for children with CP require a multidisciplinary team approach. The wide variety of motor impairments entails the involvement of occupational and physical therapists, orthotics specialists, rehabilitation engineers, and speech-language pathologists. Positioning and seating adaptations may need to be developed for optimum stability and to allow efficient movement to access the AAC system. The team must consider the wide range of options available and what is necessary to optimally match the child with the system being used. Although up to half of children with CP may be able to access the AAC device through use of a finger, others will need alternative access techniques, including chin pointers, joysticks, optical indicators, or switches.

Emphasis on AAC needs to be balanced with other developmental interventions, including speech-language therapy, motor development training, and academic instruction. Some will require extensive motor training to be able to use alternative access methods such as eye tracker, head mouse, or a switch for scanning. Although speech, gestures, and facial expressions may be affected as a result of motor impairment, patients should still be encouraged in using these natural modes for communication. A balanced approach supports the use of multimodal systems, which can vary according to the situation. A child with CP may be able to communicate effectively with family members using natural speech and gestures but may need to rely on AAC techniques with unfamiliar partners.

Long-term planning for adulthood is essential, given the need to rely on AAC devices and techniques that can accommodate the range of demands that are communicative in nature, including interpersonal, academic, and employment demands. Without advance planning, AAC systems are unlikely to meet all these demands, or the individual will not have all the skills required to use the systems.

Intellectual Disability

As defined by the American Association on Intellectual and Developmental Disabilities (AAIDD), intellectual disability (ID; see Chapter 57) is characterized by "significant limitations both in intellectual functioning and adaptive behavior as expressed in conceptual, social, and practical skills." Appropriate supports, including AAC supports, can have a significant impact on the ability of individuals with ID to live and learn successfully in inclusive environments typical of their same-age peers. At least 30% of school-age individuals requiring AAC supports have an ID. One of the main barriers that exists for children with ID is simply recognizing that the use of AAC can be beneficial and that AAC use should be generalized across settings and not just used in highly structured settings such as school.

Although most youth with ID do not engage in socially inappropriate behaviors, problem behaviors occur more frequently in this population compared to those without ID. Many individuals with ID do not use speech as their primary mode of communication, and problem behaviors can be exacerbated by difficulty communicating. Many of the strategies used to support individuals with ID involve AAC strategies such as visual schedules or those used to teach choice making and functional communication training.

The nature of interventions directed at both natural speech development and AAC varies considerably given the diversity of syndromes and conditions that result in ID. Many individuals with ID may have multiple diagnoses that affect the nature of their intervention needs.

Autism Spectrum Disorder

ASD (see Chapter 58) is a highly variable disorder; individuals with ASD experience a wide range of complex issues related to language and communication, which presents challenges regarding speech-based and AAC interventions. Individuals with ASD *and* ID may require more extensive educational, behavioral, and community supports compared with those without ID, but those without ID still require supports in the core area of social communication. **Language forms** are the language structures and vocabulary (e.g., grammar, syntax). **Language function** refers to what individuals do with language as they engage and interact with others. Because ASD affects the nature of communication as a social mediator, it is important that AAC interventions emphasize the function, or pragmatic aspects of communication, as well as the communication aspects related to the form of language.

Interventions must start at the individual's level of social, communicative, and cognitive development and build skills in a natural developmental progression. The development of dynamic, interactive communication is critical, and the child with ASD needs to learn to use communication skills related to functional activities in daily life. The developmental profiles of youth with ASD are often characterized by an uneven distribution of skills. Children with ASD often perform much better with object permanence and tool use (causality) than those areas requiring interpersonal interaction, such as gestural or vocal imitation, symbolic understanding, or language comprehension. Therefore AAC interventions must be geared to the child's social and linguistic abilities rather than the child's object abilities (e.g., fine motor skills or object manipulation skills). Manual sign or pictorial systems (PECS) are often recommended for nonverbal children with ASD. This often presumes that the problem is only one of output and that communicative intent is intact; however, the child may not have the language or the social base on which communication must be built. Therefore interventions should initially build imitation, joint attention, and natural gestural communication skills before initiating formal language-based AAC or speech approaches.

SGDs and other speech-output technologies can be used effectively in children with ASD to teach both communication and literacy skills. SGDs can act as a "social bridge" to familiar and unfamiliar communicative partners. They can be programmed with whole messages (e.g., "do you want to play") in addition to single words and phrases and thereby increase communicative efficiency and decrease potential communication breakdowns. These output devices are available via touch-screen tablet and mobile devices.

Childhood Apraxia of Speech

ASHA defines childhood apraxia of speech (CAS) as a neurologic speech-sound disorder "in which the precision and consistency of movements underlying speech are impaired in the absence of neuromuscular deficits." Given consensus on diagnostic criteria is lacking, ASHA recommends that the term "suspected CAS" be used. There is consensus on motor speech behaviors in three areas: (1) inconsistent errors on consonants and vowels in repeated syllables or words; (2) lengthened, disrupted transitions between sounds and syllables; and (3) inappropriate prosody of speech (see Chapter 53).

Given CAS is primarily a motor speech disorder, AAC is usually a secondary intervention, with the primary intervention focused on improving natural speech production. Because children with CAS often evidence significant language delays related to the inability to practice language, it is important to provide them with AAC modalities early on. The use of AAC will not inhibit speech development and production, and generally use of AAC supports result in increased mean length of utterances for the child.

Children with suspected CAS who benefit from traditional AAC are those who primarily speak in single words, have largely unintelligible speech, and are not able to effectively communicate with family members, peers, and teachers. The children benefit from a wide range of AAC, from unaided techniques including gestures and signs and aided techniques such as PECS communication books and/or SGD. It is important that the AAC device facilitates both language development and social competence. The AAC system should be designed so that the child learns to create longer and more complex messages that are grammatically accurate.

Children with suspected CAS who can produce single-word utterances but struggle with multiword speech often benefit from AAC speech supplementation. This supplementation may be in the form of key symbol supplementation, in which they point to key symbols in conjunction with speech. This can help with topic setting—when the child introduces a new topic of conversation, they point to a symbol, which helps narrow the range of possibilities for the communication partner. Often children with suspected CAS prefer to use natural speech and unaided approaches, using aided AAC techniques only when communication breakdown occurs.

Special Considerations

Reimbursement and Funding. The AAC specialist (usually a speech-language pathologist) should be familiar with public and private funding options. Funding can come from schools, third-party payers (private or public insurance companies), or philanthropic sources. Low-tech AAC systems are usually developed by a speech-language pathologist and do not usually require additional funding. SGDs are considered durable medical equipment (DME), and funding can vary immensely. Coverage will need to be verified based on the patient's specific needs and insurance. Pediatric care providers are often asked to sign prescriptions and/or write letters of medical necessity for an AAC device. This should be done only after conferring with the AAC team members, especially the speech-language pathologist. The letter should include that the pediatric provider received the evaluation reports, reviewed the recommendations, and agrees that the recommended AAC devices are medically necessary for treatment of the child's CCN associated with the specific diagnosis. SGD vendors are often able to assist with funding questions.

The Assistive Technology Act. The Assistive Technology Act of 2004 provides all U.S. states and territories with federal funding to increase access to AT devices and services. This information can be found at the National Assistive Technology Act Technical Assistance and training (AT3) Center (https://www.at3center.net/stateprogram).

Chapter 55

Outcomes Among Infants and Children Who Are Deaf/Hard of Hearing

Susan E. Wiley and Rachel D. St. John

See also Chapter 677.

Approximately 3 in every 1,000 infants in the United States are *born* deaf or hard of hearing (D/HH). Additionally, for infants who pass the newborn hearing screening, there are a number of risk factors for developing *delayed-onset* hearing loss at any time during infancy and childhood. Given that the large majority of deaf infants are born to hearing parents, there is the potential for a developmental crisis when an infant or child does not have an accessible shared language in common with their parents.

Acquisition of one's first language is a phenomenon of early development (see Chapter 53). The first months and years of a child's life are critical to developing an intact native language. When the process of language acquisition is delayed or fragmented, as can happen with an infant who is D/HH, it can have a significant and permanent effect on overall lifetime cognitive development. Timely identification and support of infants and children who are D/HH, including the provision of early access to language, is critical to the lifetime trajectory of outcomes, including language, pragmatics, academic success, executive functioning, and psychosocial well-being.

DEAF CULTURE

It is important to recognize that we as authors do not speak for Deaf individuals or parents of D/HH children but seek to bring awareness of some fundamental norms as a starting point for increasing familiarity and collaboration with these groups. Readers are encouraged to explore the resources cited in this chapter, as well as information provided by Deaf individuals and parents of D/HH children themselves.

Among individuals in America who are D/HH, there is a subset who self-designate as culturally Deaf (intentionally spelled with an uppercase D) who share American Sign Language (ASL) as their primary means of communication and a set of beliefs and traditions that are transmitted across generations. In the United States, the National Association of the Deaf is the organizational body that supports and represents this cultural Deaf community, with a mission "to preserve, protect and promote the civil, human and linguistic rights of deaf and hard of hearing people in the United States of America."

There is a potential conflict between the "hearing" medical community and the culturally Deaf community, with the medical community traditionally operating from a pathology model (identify and fix the problem) and the Deaf community operating from a sociocultural one (there is no problem in need of fixing). Hearing parents and professionals whose societal existence is grounded in listening and spoken language often view being D/HH as a limitation to interpersonal connection, education, and vocation. Deaf individuals, who achieve virtually all the same milestones as hearing individuals do by using a visual language medium, do not view being D/HH as a loss. Among culturally Deaf individuals, the terms "hearing loss" and "hearing impaired" are often viewed as inaccurate and potentially offensive. For those who were born deaf, the experience of hearing is something they never had and therefore have never missed. It is not something that holds them back, but instead is a source of maintaining a positive self-identity and pride in one's culture and community.

Hearing clinicians caring for deaf infants and children or members of the Deaf community must practice with the cultural humility necessary to appreciate the perspectives of the Deaf community (see Chapter 2).

Table 55.1 Common False Assumption About Deaf or Hard of Hearing (D/HH) Infants and Children

FALSE ASSUMPTION	ALTERNATIVE APPROACH
Being D/HH causes language delay.	Often, the parent and deaf infant do not share a common language, creating a language barrier leading to delays. Early identification (by 1-3 mo of age) and intervention by 6 mo of age are critical for language development.
Passing newborn hearing screening tests means one does not need to be concerned about hearing.	Many factors can cause delayed-onset hearing loss. A full audiologic evaluation is indicated for any caregiver concern about hearing or for delays in language development—a "wait and see" approach is never indicated.
All behavioral symptoms or developmental delays are caused by the hearing loss.	Young neurotypical deaf children with adequate access to language through amplification and spoken language, sign language, or both should not be expected to have challenges in development, behavior, or social engagement. Referral for evaluation is essential if these symptoms are present.
Sign language is a last resort for communication for D/HH infants or children.	American Sign Language (ASL) is a full and complex language with a clear syntax and grammar structure. Learning sign language can promote language development when children cannot access spoken language during a period when this input is critical for cortical brain development.

Including access to Deaf individuals as part of healthcare teams involved in the care of D/HH infants and children is an important first step in including this cultural perspective in health service delivery and decision-making.

It is also important to recognize the concept of **intersectionality** (the interconnected nature of social categorizations such as race, ethnicity, class, and gender), which plays a role in the Deaf community. Being Deaf and Black is not just the sum of the experiences of Deaf individuals and Black individuals—the two constructs existing simultaneously in the same person makes for a unique life experience. Intersectionality is recognized within the context of the **Deaf Plus** community because those individuals do not simply experience life as a Deaf person who also happens to have an additional condition. The interplay of these aspects of individuals is a critical part of identity formation, self-esteem, cultural engagement, potential experiences of disadvantage/discrimination, and personhood in general.

EARLY DETECTION AND LANGUAGE DEVELOPMENT

Deaf children who are born to deaf/signing parents are natively exposed to sign language from the first day of life and subsequently can be expected to acquire sign language milestones in a predictable manner similar to typically developing hearing children acquiring spoken language milestones. Deaf children of signing parents achieve their first signs, vocabulary expansion, combining of two discrete sign concepts, progression to more complex phrases and sentences, and other language-related milestones at expected ages if assessed in sign language. However, more than 90% of deaf infants are born to hearing parents who most often do not sign fluently. This creates an immediate and significant loss of a shared intact language. Families will turn to professionals for advice on making decisions regarding language, education, amplification technology, and social engagement. Sometimes these clinicians make false assumptions that delay detection or intervention for children who are D/HH (Table 55.1).

Clinicians should be aware that although language delay may be a presenting symptom in a D/HH child, being deaf in and of itself does not inherently cause delayed language development. Rather, the inability for a parent and an infant to share a common accessible language creates a barrier to the development of language. This is why early identification and support are critical for D/HH infants to support language access, whether to spoken language through amplification and therapy or access to sign language (or both). Even children who have passed their newborn hearing screening who have language delays must have a full audiologic evaluation, as a substantial number of factors can contribute to delayed-onset hearing loss (DOHL) at any time during early, middle, or late childhood. Parental concern about language delay or responsiveness of their child is a sensitive, but not specific, indicator of possible hearing loss. It is important to respond to parental concerns of hearing or language with referrals for hearing assessment, language evaluation, and age-appropriate therapeutic support systems.

Clinicians should also consider the possibility of hearing loss in young children with other behavioral changes. An older child may report a sudden dramatic hearing loss. However, younger children may not have the linguistic capacity or awareness to describe loss of hearing and may present instead with changes in behavior (being upset, aggressive, withdrawn). Some children with a progressive or sudden change in hearing status may appear to have a behavioral condition such as attention-deficit/hyperactivity disorder (ADHD) or may be described as defiant. Children with unidentified hearing changes and children with ADHD can share behaviors—they are perceived as not paying attention, they often are not aware of what is happening in the moment, they may not respond as expected when being addressed, and they may not focus on the things that are being discussed.

Another problematic issue known as **diagnostic overshadowing** can occur when all developmental or behavioral challenges are attributed to one cause (in this case, hearing status) when the symptoms should suggest the possibility of another disorder. For example young neurotypical D/HH children who have adequate access to language (through amplification technology and spoken language, sign language, or a combination of both) should not automatically be expected to have substantial challenges with language development, behavior, and social engagement. If clinicians reflexively attribute delays in social and language development to the fact that the child is D/HH, they may miss the diagnosis of a developmental disorder when they would not have missed the diagnosis in a hearing child.

Sign language has many benefits for D/HH infants and children and should not be regarded as an inferior last resort only to be used if spoken language efforts are not successful. ASL is a full and complex language. Much of the grammatical structure and concept complexity in ASL is conveyed through spatial placement of signs and body movements. Body movements can include body lean and eyebrow shift to indicate a question, furrowing of the brow and pursing of lips to convey negation, and shifting of body position in space to define multiple individuals involved in conversation, to name a few.

The active discouragement of using visual language with any D/HH child is a developmental disservice, particularly so with the profoundly deaf infant whose hearing level is too low to benefit from traditional hearing aids. For these infants, a cochlear implant is likely the only potential route for accessing spoken language input, and the earliest that the Food and Drug Administration (FDA) currently approves cochlear implantation is 9 months of age. There remains a number of children who are not achieving such early ages of cochlear implantation. Lack of access to sign language can mean up to a year or more of complete lack of accessible linguistic input during a period of cortical development when language input is critical; that lack of language input can in turn affect infant bonding with parents. Even after cochlear implantation, it takes a substantial amount of therapy (auditory-verbal/listening and speech-language therapy) to build spoken language skills.

INTERVENTIONS

Supporting children who are D/HH requires a combination of a proactive approach to care, ongoing monitoring for delays in all developmental domains, and timely recognition and intervention of gaps that can occur because of the impact of hearing status on language and overall development.

There is a tendency, especially for those who are not familiar with D/HH children, to assume that a child who does not hear will have reduced developmental outcomes compared to their hearing peers. There is robust evidence supporting the importance of early identification and intervention for long-term outcomes in children who are D/HH. A child's developmental and learning potential should not be defined by their hearing; clinicians should encourage and support families' high expectations for a child's development regardless of hearing status.

The medical home can fill a critical role in supporting a family's journey, though often primary care providers have relatively few children who are D/HH in their practice and may not be well-versed in how to monitor the medical and psychosocial needs of a D/HH child. This prompts the need to seek out information from a variety of sources and link families with reputable information. Because D/HH is a low-incidence condition, it is challenging for one setting (early intervention–based, school-based, clinical-based) to include a variety of children and match appropriate communication approaches. Interventions can be categorized in a variety of ways. A framework for various communication approaches is commonly used for understanding how to support language development in children who are D/HH (Table 55.2), including technology and environmental modifications.

Communication Approaches

Often different approaches to communication are presented as a choice to make during the early years of critical language growth. Many communication approaches have passionate national organizations advocating for a specific approach (Table 55.3). The educational philosophy known as total communication is often misunderstood to mean using both signing and spoken language; however, it refers to incorporating an array of communication modalities (formal signs and fingerspelling, gestures, body language, lip reading, speaking, listening), with the goal of optimizing language development that is tailored to be most effective for the individual child.

We have chosen to refer to the national organizations and the Centers for Disease Control and Prevention (CDC) to guide definitions of communication approaches (see Table 55.2). Each approach has specific components needed for successful implementation and language outcomes. The overall goal to support communication development can be an unfolding journey. Choices and strategies that worked well for a child in early childhood may not be as effective as the child matures, particularly as social engagement and academic demands evolve with age and advancement in school. Thus it is important for families to recognize that communication needs can change over time, prompting a shift from a prior decision to an alternative approach.

Technology

Hearing Aids

Hearing aid technology is very refined. Hearing aids are essentially minicomputers that take sound from the environment and are programmed to adjust how this sound is processed and delivered to the ear. Hearing aids have a number of different features that can augment the quality of sound a child will hear. Hearing aids can analyze the sounds coming into the device and preferentially reduce background noise. They can compress sound waves to preferentially make soft sounds louder and try to avoid distortion of loud sounds (wide dynamic range compression). Hearing aids can have microphones that can receive sound from many directions or focus primarily on sounds coming from in front of a child. A hearing aid can also carry a variety of programs for different listening settings. This allows a child to have a different program for a quiet environment compared to a noisy environment. Technology can also include Bluetooth to link to other devices. There are a number of apps to help monitor battery life and adjust the program for the setting through the app. Follow-up care with audiology is important to ensure continued supports for any amplification used and to monitor for changes in hearing. For children with conductive hearing changes, **bone conduction aids** may be indicated. These devices bypass the outer and middle ear, conducting sound through the skull directly to the cochlea and auditory nerve. When children are 5 years or older, they can be considered for a surgically implanted bone conduction aid called a *bone-anchored hearing aid* (BAHA). These devices also have the capacity to link to a frequency modulation (FM) system.

It is helpful to remember that even with advancements in technology, what children hear with hearing aids is not the same as what people hear with a typically functioning auditory system. It is equally important to consider environmental supports to optimize

Table 55.2 Communication Approaches for Children Who Are Deaf and Hard of Hearing (D/HH)

COMMUNICATION MODALITY	DESCRIPTION	CITATION/ORGANIZATION
American Sign Language (ASL)	ASL is the recognized sign language of the deaf community in the United States. ASL conforms to linguistic principles and is distinct from English.	National Association of the Deaf (https://www.nad.org/about-us/position-statements/position-statement-on-american-sign-language)
Conceptually Accurate Signed English (CASE)	Using conventional ASL signs in an English word order.	https://www.cdc.gov/ncbddd/hearingloss/parentsguide/building/case.html
Manually coded English	Signing Exact English is an example of a manually coded English. It is a sign system that matches signs with the English language and includes manual representation of all components of the English language.	www.signingexactenglish.com
Fingerspelling/Rochester method	The Rochester method was intended to support English literacy and uses fingerspelling for all words.	
Cued Speech	Cued Speech is a visual communication system that uses eight handshapes in four different placements near the face in combination with the mouth movements of speech to make the sounds of spoken language look different from each other.	National Cued Speech Association (https://www.mdaap.org/pdf/CuedSpeech.pdf)
Spoken language and listening	Children learn to listen and talk with the support of hearing technology such as hearing aids, assistive listening devices (such as an FM system), or cochlear implants. Auditory-oral approaches include gestures, listening, speech/lip reading, and spoken speech. Auditory-verbal relies on listening and spoken speech.	Communication Options (https://www.agbell.org/Families/Communication-Options) Centers for Disease Control and Prevention: How People with Hearing Loss Learn Language (https://www.cdc.gov/ncbddd/hearingloss/language.html)

Table 55.3 Resources for Families and Professionals

NATIONAL ORGANIZATIONS: FAMILY SUPPORT	
Hand and Voices (www.handsandvoices.org)	Supports families and children without a platform providing a specific mode of communication.
National Association for the Deaf	Advocates for use of American Sign Language and represents the culturally Deaf community.
Alexander Graham Bell Association for the Deaf and Hard of Hearing (www.agbell.org)	Advocates for people who are D/HH to hear and use spoken language.
Beginnings (www.ncbegin.org)	Promotes language accessibility through cued speech (see Table 55.2).
American Society for Deaf Children (www.deafchildren.org)	
DEAF HISTORY AND CULTURE	
The National Association of the Deaf	https://www.nad.org/about-us/
Deaf Heritage: A Narrative History of Deaf America	This 1981 book by Jack Gannon, a Deaf author and historian, is often referred to as a canon of Deaf culture in the United States. The book covers a number of events throughout history, including the establishment of schools for the deaf and the inception of the National Association of the Deaf and explores topics such as American Sign Language, Deaf artists, Deaf sports, and seminal Deaf publications.
Through Deaf Eyes	A 2007 documentary covering close to 200 years of being Deaf in the United States in a 2-hour run time through a diversity of interviews, movie shorts, and stories that capture the events that have affected Deaf lives throughout American history (https://www.youtube.com/watch?v=PL5d8kyZUQk).
DEAF MENTORS	
The National Center for Hearing Assessment and Management	Houses a directory of D/HH adult involvement programs by state (https://www.infanthearing.org/dhhadultinvolvement/states/index.html)
SKI HI Deaf Mentor Program	Curriculum for infants and young children who are D/HH (http://www.deaf-mentor.skihi.org)

The Joint Committee on Infant Hearing	www.jcih.org

listening environments. Contralateral routing of signal aids (CROS) can be helpful for children with unilateral profound deafness. This amplification system uses a transmitter at the ear that does not hear and routes it to a receiver on the typically hearing ear. Assisted listening devices such as FM systems are used to help address problems hearing in background noise and when speakers are farther away. This system has a small transmitter with a microphone. The speaker wears the transmitter, and this then links directly into headphones or a personal amplification system (hearing aid or cochlear implant). FM systems are traditionally used in the classroom setting, although they may be employed in other settings that tend to have competing background noise such as restaurants or when the focus on a particular individual speaking is important. The teacher may also use a transmitter with microphone that links to a number of speakers around the room (**soundfield system**). In this way, the accommodation is available to all students in the classroom, may benefit children easily distracted by background noise as well as the D/HH student, and does not single out the D/HH child alone.

Cochlear Implants

Cochlear implants are surgically implanted devices that bring direct electrical stimulation to the cochlea. These devices are FDA-approved for children 9 months and older with profound sensorineural hearing loss and in lesser degrees of hearing changes (70 dB or more) when children are not receiving adequate benefit from traditional amplification. A period of hearing aid trial is recommended before implantation. In children with hearing loss caused by meningitis, it is important to monitor for bony changes in the cochlea via imaging. Early signs of ossification would prompt earlier cochlear implantation to ensure the electrodes are in an optimal position to stimulate the auditory nerve. Even for children who are bilaterally profoundly deaf, there can be reasons that a cochlear implant is not appropriate. For example, absence of an auditory nerve would preclude pursuing an implant.

Often pediatric cochlear implant centers use a multidisciplinary approach to determining cochlear implant candidacy and to ensure strong follow-up support. In the past, children with developmental disabilities were deemed not appropriate for cochlear implantation, as results were thought to be limited. Although outcomes can vary in this group of children, a developmental disability alone does not preclude receiving benefit from the device. Ensuring global developmental supports, addressing potential expectations and outcomes, and linking children and families to resources can help children gain benefit from access to sound.

Coordination of care and follow-up is essential in all children with cochlear implants. They initially will see audiologists at frequent intervals to program the implant, and speech therapy is a critical and ongoing component of fostering success with an implant. At the age of 2 years, they should receive the 23-valent pneumococcal vaccine to ameliorate the increased risk of meningitis. The

medical home can play an important role in managing this additional immunization, as well as in monitoring medical issues and developmental progress.

Early implantation has been associated with better hearing, speech perception, and spoken language outcomes, as it ensures early stimulation of the auditory cortex necessary for the development of spoken language. Although FDA approval is for children 9 months and older, there are situations where earlier implantation is indicated, and many in the field of pediatric audiology and pediatric otology are advocating for earlier implantation. Unilateral deafness is another emerging indication for cochlear implantation in children.

Other Supports and Factors Influencing Amplification Decisions

The cost of amplification devices can be quite high. Many insurance plans do not cover hearing aids, though more cover costs associated with BAHAs and cochlear implants. Services and coverages vary by state and insurance plan. Families often need to obtain insurance or additional coverage to cover replacement costs associated with damage or loss of the device. Technology updates can also add further expenses.

There are also many day-to-day factors that affect a child's acceptance of amplification. In early childhood there is rapid growth of the skull and ear canal. With hearing aids, children often need to return to audiology frequently to resize the ear molds to ensure a good fit. Children also can become very adept at removing their hearing aids. Young children in daycare are particularly vulnerable to potentially losing their amplification when rolling, crawling, or playing or when naturally curious peers and playmates attempt to take them. Parents, caregivers, and teachers routinely checking on hearing aids/cochlear implants is a critical support to using amplification technology successfully in young children.

A number of environmental supports can be helpful. For families seeking a spoken language approach, it is helpful to decrease background sounds. Turning off TVs and devices can help children be able to listen and hear what is said. Children often struggle hearing speakers from a distance. This affects incidental learning, as they have fewer opportunities to "overhear" peripheral conversations. Families are often coached in ways to optimize their child's listening environment and ways to highlight spoken language and concepts.

Technologic support can include captioning on the television, video-relay with sign language interpreters, texting, speech-to-text, visual fire alarms, and vibrating alarms. These types of technologies are often not covered through insurance, although some state agencies have programs to help defray costs. Other accommodations for communication access can include sign language interpreters, cued speech interpreters, and open captioning. The Americans with Disabilities Act ensures children, adolescents, and adults have the legal right to communication access. This is particularly important in medical settings. Family members should not be asked to serve as interpreters for the child, as this limits the ability for the parent to listen and be part of the conversation or may limit the child's access to the conversation at hand.

LANGUAGE LEARNING

Language is a critical component of the human condition and allows connection with others. The United Nations has recognized communication as a human right. Communication happens in many ways that can include behavior, nonverbal communication, tone, facial expressions, words, and sentences. These aspects of communication are universal irrespective of mode of communication.

Promoting language development needs to focus on far more than the ear and hearing. As in typical children, the quality and quantity of communication are important (see Chapter 53). Additionally, children who are D/HH are at high risk of missing learning via "the unwritten curriculum": social and cultural learning that occurs incidentally and passively. Hearing children repeatedly overhear conversations that do not directly include them but are related to them, such as when their parents talk to the pediatrician about their care or how the parents interface with office staff when they schedule the next appointment. D/HH children are vulnerable to missing years, if not decades, of incidental learning regarding everyday interactions. Direct teaching of incidental information, or making the implicit explicit, is a tenet of supporting the language development of children and youth who are D/HH. In the medical setting, this can be addressed for the signing D/HH child by having a sign language interpreter present to ensure the child can build an understanding of their own health history and expand health literacy, even if they may be too young to engage in the conversation directly. Although it may feel more comfortable and efficient to get information directly from parents, it is critical for the provider to engage the child directly as much as possible to maximize their involvement in their own plan of care. Addressing incidental learning for children who are D/HH should occur regardless of mode of communication.

As families hold an important role in their child's language development, building and empowering families in the development of skills and strategies is an important component of early intervention. Within the field of early intervention, coaching parents on how to engage and interact with their child to promote optimal development has been noted to be effective for a number of populations of children. Communication is interactional, and coaching puts the family in the position of providing the intervention and thus builds skills to support their child.

When a Child Is Not Progressing

If a child's language development is not progressing, it is necessary to reevaluate factors that could contribute to language development. Factors to consider include problems with devices that have not been fully optimized, aspects of access to language, and coexisting medical, developmental, or behavioral conditions impacting learning.

In evaluating a child's access to language, consider how the child is learning, the language environment, and whether a child is getting a quality language model for learning. If a communication modality is pursued that cannot be supported across the environments the child is in (e.g., school, home, community-based organizations), the D/HH child can lag behind their peers. Overt problematic scenarios include a deaf child without good acoustic access attempting to learn spoken language or a child learning sign language but with limited sign language proficiency in their home, community, and school environments. Regression of language should prompt reevaluation of hearing and consideration of brain-centered as opposed to hearing-centered problems with learning.

A child's response to a communication approach may be affected by broader developmental issues. A child may have a unique learning profile and benefit from alternative approaches to language-based learning. Whereas children who are D/HH often have strong visual problem-solving skills, some children who are D/HH are stronger in the auditory domain. Although it should not be automatically assumed that a D/HH child will have developmental delay, up to 40% also have a developmental disability or condition that can affect progress. Early recognition of a child's broader needs can help ensure children receive effective interventions for all of their needs.

ACADEMIC CONSIDERATIONS

The Individuals with Disabilities Education Act (IDEA) ensures a free, appropriate public education for all students with disabilities, including those who are D/HH. This law recognizes the right to be educated within the least restrictive environment (LRE), or to the maximum extent that is appropriate, education with their peers who do not have disabilities. This must be balanced with the individual student's communication, linguistic, academic, social, emotional, and cultural needs. Because of the varied settings and range of communication support needs, as well as the diversity of individual student strengths, endorsing one specific educational setting is not possible or appropriate.

Reading and literacy skills are associated with language fluency levels and tend to be improved by early age of identification and intervention. Standardized achievement testing from the early

2000s demonstrated that only half of D/HH high school graduates were reading above a fourth-grade level. However, these data are old and do not control for varying factors across students such as coexisting medical or developmental conditions, delays in identification and early language access, and varying teaching methodologies. Academic outcomes are likely to be optimized with early identification and support of language in infants who are D/HH and with the prompt recognition of, and support for, other developmental or behavioral challenges that may interfere with learning.

PSYCHOSOCIAL WELL-BEING

An important consideration for any individual is psychosocial well-being. Because the population of D/HH individuals is heterogenous, it is difficult to make overarching statements regarding mental health and wellness. Hearing loss in the elderly has been associated with depression. This is due—at least in part—to the loss of connection and communication with others. Similar effects can be seen across the life span for deaf individuals who did not develop enough formal language to communicate effectively. Studies have linked a lack of language proficiency with in-patient psychiatric care in adults and psychosocial difficulties in children. A large-scale study in Taiwan spanning over a decade estimated an 11.1% lifetime prevalence of clinically diagnosed unspecified anxiety disorder in the D/HH group, which was twice the incidence in the hearing control group.

A phenomenon described by some D/HH individuals, **deaf anxiety**, is related to interpersonal challenges a D/HH individual can experience when interfacing with a largely hearing society. Although advances in technology with hearing aids and cochlear implants continue to improve access to audiologic input, it is important to consider that these are tools with inherent limitations—they are not an equivalent "replacement" for natural hearing. D/HH adults have described fears such as missing/misunderstanding information, concern with appearing not to be interested in or not paying attention to someone speaking, disproportionately increased difficulty when dealing with noisy environments, and worry about missing significant information in nonaccessible environments such as being unaware that a fire alarm has gone off if there is no visual indicator in addition to the sound alarm.

The experiences of a deaf person in a predominantly hearing world contribute to the critical journey of identity formation for D/HH children as they become young adults. Deaf children, regardless of their success with technology, are still deaf. When a child takes off their hearing aids or cochlear implants to take a bath, swim, or rest, they are deaf. The technology does not change who they are fundamentally. Supporting families in their efforts to understand, accept, and value their child as a deaf individual can provide resilience for identity formation in adolescence. There also needs to be recognition that families are necessarily thrust into a position of making decisions for their young D/HH child with the knowledge they have at the time and may have concerns about how their child as an emerging adult may feel later on about those decisions. Families can benefit tremendously from access to programs that can connect them with other deaf children, deaf adults, and community resources that support a variety of ways to exist as a successful deaf individual.

DEAF PLUS

It is helpful to recognize that some of the risks associated with being D/HH are also risks for other conditions that impact functioning in children who are D/HH (Table 55.4). It is important to look beyond hearing status as the reason for delays so as not to miss other factors contributing to a child's slow rate of progress. Delayed recognition of these factors causes delays in accessing effective intervention strategies. Conversely, the presence of specific coexisting conditions should not be assumed to predict functioning or decisions about communication. A child who is deaf and also has cerebral palsy should not be assumed to be unable to use sign language because of impact on hand/arm movements, as these children may use sign language receptively for language understanding quite well. The need for individually tailored care and education plans is particularly critical in children who are Deaf Plus.

Table 55.4 Rates and Types of Disabilities Among Children Who Are D/HH and Within the General Population

TYPE OF DISABILITY	D/HH (%)	GENERAL POPULATION (%)
No developmental disability	60	83
Cognitive/intellectual disability	8.3	1
Cerebral palsy	8	0.3
Blindness and vision impairment	5.5	0.3
Attention-deficit/hyperactivity disorder	5.4	9
Specific learning disability	8	7
Autism spectrum disorders	7	1.7

Children who are D/HH have vision changes at nearly twice the rates compared to the general population. Vision differences are important to detect, as children who are D/HH often rely on their vision for accessing information. Even among children who receive effective amplification and good acoustic access to information, some reliance on lip reading and visual attention to the speaker can enhance a child's ability to process information. There are no specific standards regarding the timing and frequency of ophthalmologic evaluations and monitoring intervals, but it is important for all children who are D/HH to have regular monitoring of vision and eye health with a pediatric eye care specialist.

For children who have both hearing and vision changes (**DeafBlind**), intervention strategies can be increasingly complex. IDEA specifically defines DeafBlindness as "concomitant hearing and visual impairments, the combination of which causes such severe communication and other developmental and educational needs that they cannot be accommodated in special education programs solely for children with deafness or children with blindness." When the two conditions are present simultaneously, there are additional challenges to be considered regarding language access and acquisition. Each state has a federally funded DeafBlind project that provides resources and technical assistance to support children identified as DeafBlind. For children who are DeafBlind, many are advocating for interveners. Interveners are more than interpreters: they facilitate communication and inclusion and address social and emotional needs within educational settings.

FAMILY JOURNEY

Each family has a unique narrative to their overall family experience, as well as a specific pathway to supporting the growth and development of their D/HH child. Some families experience profound grief around the loss of an expected parenting story. Many families speak of being overwhelmed initially by an immense amount of information and pressured to make crucial decisions in a timely manner. Others move into an advocacy model and have their own unique take on the parenting journey. One

Table 55.5 Approaches in the Medical Home to Support the Family Journey

FAMILY JOURNEY THEMES	CONSIDERATIONS AND STRATEGIES
Family-centered decision-making: Ensure families are central in decision-making	Before the visit: • Physician reflection on their own knowledge, expertise, and biases At the visit: • Listen to family concerns actively and address concerns, referring to others when outside provider expertise is necessary
Families' need for **informed** choice	Before the visit: • Recognize that each family and child are unique and decisions may vary across families • Recognize that decisions may change over the life span of the child • Recognize the passion across communication modalities, which drive potential biases in information and guidance At the visit: • Listen actively to understand the family's values and intended goals and outcomes • Collaboratively seek information from a variety of reputable sources and discuss potential biases across various "experts" in the field (see resource list) • Incorporate the family's values in an action plan together • Refer to experts as appropriate
Family-to-family support: Because having a child who is D/HH can feel isolating and professionals do not carry the same day-to-day experiences, family-to-family connection is an important component of support	Before the visit: • Recognize the importance of family-to-family support • Identify resources to link families with other families (see resources) During the visit: • Discuss the possible isolation families face • Determine interest and readiness for family networking • Share resources that they can rely on when ready to reach out
Access to D/HH adults: To support the family's recognition of what success can be and to provide children with a conceptual framework for D/HH individuals as adults	Before the visit: • Recognize families may be experiencing grief over the loss of their child's expected future and that experiences with other individuals who are D/HH may be limited or nonexistent • Identify resources to link families with Deaf adults and Deaf mentoring programs (see Table 55.3) During the visit: • Discuss family's hopes and fears • Highlight the importance of high expectations for their child • Discuss ways to promote identity, connection, and independence for their child
Child interactions and supports	Before the visit: • Recognize the variability and uniqueness of children who are D/HH in terms of capabilities, skills, and opportunities At the visit: • Engage D/HH children directly rather than rely solely on family members for interpreting communication; for children who use sign language, access to an interpreter is a right under the Americans with Disabilities Act • Recognize children's strengths and resilience • Ensure children have access to their own health information (at their developmental level) and have the opportunity for inclusion in decisions as appropriate • Advocate with children and families to have high expectations for skills, recognizing that often medical and educational settings use a deficit model (the child must be behind) to access supports

simply has to take a look at some of the family stories that are available in the public realm to appreciate the diversity of the family experience in raising a D/HH child.

A number of parent support organizations are available to families, some of which are organized around specific communication philosophies (see Table 55.3).

The pediatrician may be the first medical professional that families turn to if there is concern about language development and/or hearing. Although these physician/family relationships are often just as diverse as the families themselves, some universal concepts start to emerge when listening to parent stories (Table 55.5). Recognizing these themes and identifying ways to partner and support families is a critical role of the medical home.

ACKNOWLEDGMENTS

The authors extend their gratitude to Chris Moreland, MD, and Robert Nutt, MD, for their input from the deaf adult/deaf professional perspective, and to Lauren Tyra, PhD, for her input from the perspective of a parent of a deaf child.

Chapter 56

Developmental Delay and Intellectual Disability

Meghan E. O'Neill and Bruce K. Shapiro

Intellectual disability (ID) refers to a heterogeneous group of disorders that have in common deficits of adaptive and intellectual function and an age of onset before maturity is reached. In Europe, the term *learning disability* is often used to describe ID.

DEFINITION

Contemporary conceptualizations of ID emphasize adaptive functioning and social interaction rather than test scores in isolation. The definition of ID requires significant impairment in general intellectual function (reasoning, memory, learning, problem solving) and adaptive behavior, with severity defined by limitations in adaptive functioning or levels of needed support. This focus encourages the development of individual treatment plans characterizing the supports needed to enhance functioning. Consistent across these definitions is onset of symptoms before adulthood (18-22 years of age). Children with ID have a nonprogressive disorder; loss of developmental milestones or progressive symptoms with a downward developmental trajectory suggest another disorder.

Significant impairment in adaptive behavior reflects the degree to which cognitive dysfunction directly contributes to impairments in daily functioning at home, at school and work, and in the community. **Adaptive behavior** refers to the skills required for people to function in their everyday lives, and individuals with deficits require more support than same-age peers for optimal participation. The American Association on Intellectual and Developmental Disabilities (AAIDD) and *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) classifications of adaptive behavior address three broad sets of skills: conceptual, social, and practical. **Conceptual skills** include language, reading, writing, time, number concepts, and self-direction. **Social skills** include interpersonal skills, personal and social responsibility, self-esteem, gullibility, naiveté, and ability to follow rules, obey laws, and avoid victimization. Representative **practical skills** involve performance of activities of daily living (dressing, feeding, toileting/bathing, mobility), instrumental activities of daily living (e.g., housework, managing money, taking medication, shopping, preparing meals, using phone and mail systems), occupational skills, and maintenance of a safe environment. For a deficit in adaptive behavior to be present, a significant delay in at least one of the three skill areas must be present. The rationale for requiring only one area is the empirically derived finding that people with ID can have varying patterns of ability and may not have deficits in all three areas.

The requirement for adaptive behavior deficits is the most controversial aspect of the diagnostic formulation. The controversy centers on two broad areas: whether impairments in adaptive behavior are necessary for the construct of ID and what to measure. The adaptive behavior criterion may be irrelevant for many children; adaptive behavior is impaired in virtually all children who have IQ scores <50. The major utility of the adaptive behavior criterion is to confirm ID in children with IQ scores in the 60-75 range, especially considering the historical overdiagnosis of ID among individuals of color with typical adaptive functioning and biased IQ testing results. It should be noted that deficits in adaptive behavior are often found in disorders such as autism spectrum disorder (ASD; see Chapter 58) and attention-deficit/hyperactivity disorder (ADHD; see Chapter 50) in the presence of typical intellectual function, often mediated by significant difficulties with executive functioning, self-directedness, or maladaptive behaviors. In contrast, deficits of adaptive functioning in ID are primarily attributable to the individual's overall cognitive limitations.

The issues of measurement are important as well. The independence of the three domains of adaptive behavior has not been validated. The relationship between adaptive behavior and IQ performance is insufficiently explored. Many adults with IQ scores in the 60-75 range do not have significant impairments in practical skills. Adaptive behavior deficits also must be distinguished from *maladaptive behavior* (e.g., aggression, self-injury, inappropriate sexual behavior).

Significant impairment in general intellectual function refers to performance on an individually administered test of intelligence that is approximately 2 standard deviations (SDs) below the mean. Generally, these tests provide a standard score that has a mean of 100 and SD of 15 points, so that IQ scores <70 would meet these criteria. If the standard error of measurement is considered, the upper limits of significantly impaired intellectual function may extend to an IQ of 75. Using a score of 75 to delineate ID might double the number of children with this diagnosis, but the requirement for impairment of adaptive skills limits the false positives. Children with ID often show a variable pattern of strengths and weaknesses. Not all their subtest scores on IQ tests fall into the significantly impaired range.

Onset before age 22 years or adulthood distinguishes dysfunctions that originate during the developmental period from those that begin in adulthood. The diagnosis of ID may be made after 22 years of age, but the cognitive and adaptive dysfunction must have been manifested before age 22 years. Age of onset may be relevant to qualification for certain benefits programs that require a diagnosis of ID.

Intellectual disability as nonprogressive. Individuals with ID will acquire new developmental milestones over time, although at a slower rate than unaffected children. A slowing trajectory is not uncommon as individuals with ID get older. This should be distinguished from *regression* of milestones, which involves true loss of previously acquired skills and demands additional and often more extensive etiologic workup. Sometimes regression is seen in the context of the child's larger medical picture, such as loss of mobility with increasing spasticity and contractures in children with comorbid cerebral palsy (CP) or loss of language skills in the setting of new seizures. Alternatively, regression could suggest a **progressive encephalopathy** caused by an *inborn error of metabolism* or a *neurodegenerative disorder* (see Chapters 104 and 639). Prompt identification is essential, as some of these conditions are treatable or modifiable and some necessitate conversations about future reproductive risk.

Global developmental delay (GDD) is a term often used to describe young children with delays across multiple domains of development that have not yet resulted in a diagnosis of ID. In DSM-5, GDD is a diagnosis given to children <5 years of age who display significant delay (>2 SDs) in acquiring early childhood developmental milestones in two or more domains of development. These domains include receptive and expressive language; gross and fine motor function; cognition, social and personal development; and activities of daily living. Typically, it is assumed that delay in two domains will be associated with delay across all domains evaluated, including cognitive and intellectual abilities. Longitudinal studies following outcomes of children with GDD are sparse but suggest that that upwards of 80% of children with early global delays continue to experience development challenges through the school-age years. However, not all children who meet criteria for a GDD diagnosis at a young age go on to meet criteria for ID later in childhood. Reasons for the lack of concordance between GDD and later diagnosis of ID include lower reliability and predictive validity of developmental testing in children under 5-6 years of age; a positive change in developmental trajectory with maturation or possibly with intervention; reclassification to a different disability category (autism, ADHD, developmental coordination disorder); or imprecise use of the GDD diagnosis initially. Conversely, in patients with more severe early delays, the GDD term is often used beyond the point when the child could be reclassified as having ID, such as when a child has persistently and markedly low developmental quotients on multiple assessments and despite intervention during the first few years of life.

It is important to distinguish the medical diagnosis of GDD from the federal disability classification of "developmental delay" that may be used by education agencies under the Individuals with Disabilities Education Act (IDEA). This classification requires that a child have delays in only one domain of development with subsequent need for special education. Each state determines its own precise definition and terms of eligibility under the broader definition outlined by IDEA, and many states use the label for children up to 9 years of age.

Table 56. 1 Genetic Testing Guidelines for ID/GDD and/or ASD

ORGANIZATION	RECOMMENDATION(S) FOR GENETIC TESTING

Autism and Intellectual Disability Committee of the American Academy of Child and Adolescent Psychiatry (AACAP)	• CMA in all individuals with ID/GDD and/or ASD
	• FMR1 repeat analysis in males and females with ID or a family history of ID
	• Depending on history and physical examination, consider:
	  • PTEN testing if head circumference (HCM) is more than 2.5 SD above the mean for age in a child with ID/GDD and/or ASD
	  • MECP2 testing for Rett syndrome in females with severe ID
	  • Karyotype if a chromosomal syndrome is suspected
	• If other investigations do not provide an etiology and there are unresolved clinical findings, consider ES and mitochondrial DNA testing

American Academy of Pediatrics (AAP)	• If a comprehensive history and exam are indicative of a specific syndrome or disorder, proceed with specific testing in patients with ASD and/or ID/GDD • In all individuals with ASD and ID/GDD without specific findings, consider CMA and FMR1 CGG repeat analysis • In females with ASD and/or ID/GDD without specific findings, consider MECP2 testing • In males with ID/GDD without specific findings, consider an X-linked ID panel (XLID) • If an etiology is not identified, consider a referral to genetics for additional workup, including possible ES
International Standard Cytogenomic Array (ISCA) Consortium	• CMA is the first-tier genetic test in patients with GDD/ID, ASD, and/or multiple congenital anomalies

American College of Medical Genetics (ACMG)	• After a detailed family history and physical examination, proceed with specific testing for patients with ASD if a syndrome is suspected or if features are suggestive of a mitochondrial or metabolic condition
	• If family history and physical exam are not suggestive of a specific diagnosis, metabolic, or mitochondrial condition, proceed with CMA for all patients with ASD and FMR1 repeat analysis for all males with ASD
	• If CMA (in males and females) and FMR1 repeat analysis (in males) are not diagnostic, consider:
	  • MECP2 sequencing in all females with ASD
	  • MECP2 duplication testing in males with ASD if phenotype is suggestive
	  • PTEN testing in patients with ASD if HCM is more than 2.5 SD above the mean for age
	  • FMR1 repeat analysis in females with ASD and additional features suggestive of fragile X (e.g., family history and phenotype)

American College of Medical Genetics (ACMG)	• CMA is the first-tier genetic test in patients with multiple congenital anomalies that are not indicative of a specific genetic syndrome and those with nonsyndromic ID/GDD and ASD
Multidisciplinary Expert Consensus Panel	• ES in all individuals with ID and/or ASD • If ES is nondiagnostic and does not include copy number variant analysis, proceed with CMA • If ES (and CMA if needed) is nondiagnostic, reanalysis of data from testing should be undertaken periodically
American Academy of Neurology (AAN) and Child Neurology Society (CNS)	• High-resolution karyotype and FMR1 repeat analysis for patients with ASD that also have ID, family history of fragile X and/or ID, or dysmorphic features • After obtaining a detailed medical, developmental, and family history for patients with ID/GDD, if a specific etiology is considered, perform appropriate testing such as single gene testing, metabolic testing, or XLID panel • If a specific etiology is not suspected, perform CMA (or, if not possible, karyotype and subtelomeric FISH) for all individuals with ID/GDD, MECP2 testing for females with moderate to severe ID/GDD, and FMR1 repeat analysis in all individuals with mild ID/GDD • If these and other etiologic workups are negative, consider a referral to genetics

From Savatt JM, Myers SM. Genetic testing in neurodevelopmental disorders. *Front Pediatr*. 2021;9:526779, Table 3.

ETIOLOGY

Numerous identified causes of ID may occur prenatally, during delivery, postnatally, or later in childhood. These include infection, trauma, prematurity, hypoxia-ischemia, toxic exposures, metabolic dysfunction, endocrine abnormalities, malnutrition, and genetic abnormalities. Most people with ID will not have a readily identifiable underlying diagnosis based on prenatal or perinatal history or dysmorphology, meriting further medical and genetic evaluation. Practice guidelines recommend that an etiologic workup be pursued in all children with ID or GDD when there is not a readily apparent explanation for the child's presentation (Tables 56.1 and 56.2). It is anticipated that these diagnostic guidelines change because genome sequencing studies have identified severe monogenic etiologies in previously difficult to diagnose developmental disorders despite extensive previous recommended evaluations.

Among children with milder GDD, yield of etiologic workup will likely be lower in comparison to children with more significant delays or disability. With increases in etiologic testing among all children with ID and advancement of technologic capabilities of testing, the number of identified biologic and genetic causes of ID is continuing to increase rapidly. There are slightly over 100 disorders (all of which are metabolic in nature) for which treatment may ameliorate the core symptoms of ID (see https://www.treatable-id.org/), but these conditions account for a relatively small percentage of children with ID (Table 56.3). However, there are several reasons beyond disease modification that should prompt providers to seek etiologic answers in patients with ID. These include insight into possible associated medical or behavioral comorbidities; information on prognosis and life expectancy; estimation of recurrence risk for family planning counseling, potential validation, and closure for the family; increased access to services or specific supports; and better understanding of underlying pathology with the hope for new treatment options. When surveyed, families of children with ID with no identified underlying etiology almost universally report that they would want to know of an etiologic diagnosis if given the choice. Expanded testing will contribute to the growing pathophysiologic understanding of how ID occurs mechanistically and serves as an opportunity for future targeted treatment opportunities and clinical trial development.

Mild and more severe forms of ID have different but overlapping risk factors and etiologies. Nongenetic risk factors that are often associated with mild ID include low socioeconomic status, low maternal education levels, residence in a developing country, malnutrition, and poor access to healthcare. The most common biologic causes of, or risk factors for, mild ID include intrauterine growth restriction; prematurity; perinatal insults; intrauterine exposure to drugs of abuse (including alcohol); postnatal exposure to neurotoxic substances (including lead); some sex chromosomal abnormalities; and some genetic syndromes with multiple, major, or minor congenital anomalies (e.g., 22q11 deletion syndrome, sex chromosomal abnormalities, Noonan syndrome). Familial clustering is common.

Table 56.2 Genetic Tests Commonly Used in Evaluation of Neurodevelopmental Disorders

TEST	RESULTS/VARIANTS DETECTED	DETECTION LIMITATIONS
Chromosomal microarray (CMA)	• Copy number variants (CNV) (generally >250 kb but could be smaller if region is specifically targeted) • Regions of homozygosity*	• Repetitive DNA sequences, including trinucleotide repeat expansions (e.g., *FMR1* repeat expansion) • Balanced chromosomal rearrangements • Sequence-level variants in the exome/genome • Mitochondrial variants • Epigenetics alterations (e.g., methylation abnormalities, uniparental heterodisomy) • Low-level mosaicism
Exome sequencing (ES)	• Sequence-level variants in the coding region (exome) • Copy number variants**	• Repetitive DNA sequences, including trinucleotide repeat expansions (e.g., *FMR1* repeat expansion) • Balanced chromosomal rearrangements • Smaller copy number variants, including deletions/duplications involving one to two exons • Mitochondrial variants • Epigenetics alterations (e.g., methylation abnormalities) • Intronic/noncoding variants • Variants in regions of the exome that are not well-covered by sequencing
FMR1 CGG repeat testing	• CGG repeat number in the *FMR1* gene	• Sequence-level variants in *FMR1* or elsewhere in the exome/genome • Copy number variants • Balanced chromosomal rearrangements • Exon-level deletions/duplications • Mitochondrial variants • Epigenetics alterations (e.g., methylation abnormalities)

*Single-nucleotide polymorphism–based chromosomal microarray (SNP-CMA)
**Several laboratories are now calling CNVs as a routine part of ES, and this trend will continue to expand.
From Savatt JM, Myers SM. Genetic testing in neurodevelopmental disorders. *Front Pediatr*. 2021;9:526779, Table 2.

Table 56.3 Conditions in Which Early Treatment May Significantly Improve the Course of the Disease

CONDITION	TREATMENT
Galactosemia	Lactose-free diet
Fructosemia	Fructose-free diet
Phenylketonuria	Phenylalanine-free diet
Maternal phenylketonuria	Phenylalanine-free diet during pregnancy
Maple syrup urine disease	Diet restricted in branched-chain amino acids + dialysis or exchange transfusion
Hypoglycemia from any cause	Prevent hypoglycemia and/or provide glucose
Lead intoxication	Separate child from source of lead; chelation therapy
Hypothyroidism	Thyroid replacement
Recurrent otitis media	Antibiotic prophylaxis, pressure-equalizing tubes
Malnutrition	Adequate nutrition
Increased intracranial pressure (e.g., hydrocephalus, neoplasm)	Shunt ventricles or cystic structure
Congenital HIV infection	Prenatal/postnatal treatment with AZT (zidovudine)
Congenital toxoplasmosis	Prenatal treatment with spiramycin, pyrimethamine, and sulfonamide
Dopa-responsive dystonia	Responds to levodopa; may be misdiagnosed as cerebral palsy
Biotinidase deficiency	Oral biotin
Biotin-thiamine–responsive basal ganglia disease	Biotin, thiamine
Wilson disease	Copper chelation; liver transplant
Cerebral folate disorder	Folinic acid

CONDITION	TREATMENT
Creatine disorders	Creatine monohydrate
Vitamin B_{12} deficiency	Vitamin B_{12}
Cerebral glucose transporter defect	Ketogenic diet
Metachromatic leukodystrophy	BMT
Niemann-Pick disease	BMT, liver transplantation, implanted amniotic epithelial cells
Adrenoleukodystrophy	BMT
Glycogen storage disease type IV	Liver transplantation
Menkes disease	Parenteral copper histidinate
Lesch-Nyhan syndrome	Allopurinol + BMT
Krabbe disease	BMT
α-Mannosidosis	ERT: velmanase alfa
Aspartylglucosaminuria	BMT
Gaucher disease type III	ERT: Ceredase; SRT: Cerdelga; PCT: Mucosolvan
Hunter syndrome (MPS II)	ERT: Elaprase
Hurler syndrome (MPS I)	ERT: Aldurazyme
Sanfilippo syndrome A (MPS IIIa)	SRT: Genistein
Sanfilippo syndrome B (MPS IIIb)	SRT: Genistein
Sanfilippo syndrome C (MPS IIIc)	SRT: Genistein
Sanfilippo syndrome D (MPS IIId)	SRT: Genistein
Sly syndrome (MPS VII)	ERT: Mepsevii
Neuronal ceroid lipofuscinosis type II	ERT: Brineura

BMT, Bone marrow transplant; ERT, enzyme replacement therapy; MPS, mucopolysaccharidosis; PCT, pharmacologic chaperone therapy; SRT, substrate reduction therapy.
From Muriello M. Neurocognitive and developmental regression. In: Kliegman RM, Toth H, Bordini BJ, Basel D (eds). *Nelson Pediatric Symptom-Based Diagnosis*, 2nd ed. Philadelphia: Elsevier; 2023: Table 28.10, p. 481.

Table 56.4 Identification of Causes in Children with Significant Intellectual Disability

CAUSE	EXAMPLES	% OF TOTAL
Chromosomal disorder	Trisomies 21, 18, 13 Deletions 1p36, 4p, 5p, 11p, 12q, 17p, others Microdeletions Klinefelter, 47,XXX, and Turner syndromes	~20
Genetic syndrome	Fragile X, Prader-Willi, Angelman, and Rett syndromes	~20
Nonsyndromic autosomal mutations	Variations in copy number; de novo mutations in *SYNGAP1*, *GRIK2*, *TUSC3*, oligosaccharyl transferase, and others	~10
Developmental brain abnormality	Hydrocephalus ± meningomyelocele; schizencephaly, lissencephaly	~8
Inborn errors of metabolism or neurodegenerative disorder	Phenylketonuria, ceroid lipofuscinosis, Tay-Sachs disease, other storage diseases	~7
Congenital infections	HIV, toxoplasmosis, rubella, cytomegalovirus, syphilis, herpes simplex, Zika virus	~3
Familial intellectual disability	Environment, syndromic, or genetic	~5
Perinatal causes	Hypoxic-ischemic encephalopathy, meningitis, intraventricular hemorrhage, periventricular leukomalacia, fetal alcohol syndrome	4
Postnatal causes	Trauma (abuse), meningitis, nutritional deficiencies, hypothyroidism	~4
Unknown		20

Adapted from Stromme P, Hayberg G. Aetiology in severe and mild mental retardation: A population-based study of Norwegian children. *Dev Med Child Neurol.* 2000;42:76–86.

In children with more severe ID, a biologic cause (usually with prenatal onset) can be identified in about three fourths of all cases. Causes include chromosomal (e.g., Down, Wolf-Hirschhorn, and deletion 1p36 syndromes) and other genetic and epigenetic disorders (e.g., fragile X, Rett, and Angelman syndromes), abnormalities of brain development (e.g., lissencephaly), and inborn errors of metabolism and mitochondrial disorders (e.g., mucopolysaccharidoses, mitochondrial respiratory chain complex disorders) (Table 56.4). *Nonsyndromic* severe ID may be a result of inherited or de novo gene mutations, as well as microdeletions or microduplications. Currently, >1,300 single genes have been associated with ID. Inherited genetic abnormalities may be mendelian (autosomal dominant de novo, autosomal recessive, X-linked) or nonmendelian (imprinting, methylation, mitochondrial defects; see Chapter 97). De novo mutations may also cause other phenotypic features such as seizures or autism; the presence of these features suggests more pleotropic manifestations of genetic mutations. Consistent with the finding that disorders altering early embryogenesis are the most common and severe, the earlier the problem occurs in development, the more severe its consequences tend to be.

EPIDEMIOLOGY

ID is one of the most common causes of disability in children globally. The prevalence of ID depends on the definition, method of ascertainment, and population studied, both in terms of geography and age. According to the statistics of a normal distribution, 2.5% of the population should have ID (based on IQ alone), and 75% of these individuals should fall into the mild to moderate range. Variability in rates across populations likely results from the heavy influence of external environmental factors and definitional differences on the prevalence of mild ID. The prevalence of severe ID is relatively stable. Globally, the prevalence of ID has been estimated to be approximately 16.4 per 1,000 persons in low-income countries, approximately 15.9/1,000 for middle-income countries, and approximately 9.2/1,000 in high-income countries. A meta-analysis of worldwide studies from 1980 to 2009 yielded an overall prevalence of 10.4/1,000. ID occurs more in boys than in girls, at 2:1 in mild ID and 1.5:1 in severe ID. In part this may be a consequence of the many X-linked disorders associated with ID, the most common being fragile X syndrome (see Chapter 59).

In the United States the prevalence of ID in school-age children ranges from 1.1% to 1.8%. There are several reasons why fewer children are identified as having mild ID than predicted from statistics. Professionals might miss or defer the diagnosis and "give the benefit of the doubt" to the child and await repeated confirmatory testing over time because it is more challenging to diagnose mild ID than the more severe forms. Other reasons that contribute to the discrepancy between predicted and observed prevalence are use of instruments that underidentify young children with mild ID, children diagnosed as having ASD without their ID being recognized or addressed, misdiagnosis as a language disorder or specific learning disability, and a disinclination to make the diagnosis in minoritized students because of concern about biased assessments that historically led to overdiagnosis. In some cases, behavioral disorders may divert the focus from the cognitive dysfunction.

Beyond potential under diagnosis of mild ID, the number of children with mild ID may be decreasing because of public health and education measures to prevent prematurity and provide early intervention and Head Start programs. However, although the number of school children who receive services under a federal disability classification of ID has decreased since 1999, when *developmental delay* is included in analysis of the data, the numbers have not changed appreciably.

The prevalence of *severe ID* has not changed significantly since the 1940s, accounting for 0.3–0.5% of the population. Many of the causes of severe ID involve genetic or congenital brain malformations that can neither be anticipated nor treated at present, though trends toward more expanded prenatal screening (and subsequent termination) may alter this balance, as seen with the decreasing incidence of Down syndrome. Additionally, expanded newborn screening with early treatment has virtually eliminated ID caused by phenylketonuria and congenital hypothyroidism. However, continued high prevalence of fetal exposure to alcohol and illicit drugs, improved survival of very low birthweight premature infants, and increasing overall maternal age during pregnancy (contributing to increased rates of genetic abnormalities) have counterbalanced this effect.

PATHOLOGY AND PATHOGENESIS

The limitations in our knowledge of the neuropathology of ID are demonstrated by the finding that 10–20% of brains of persons with severe ID appear normal on standard neuropathologic study. Many of the brains that appear abnormal show only mild, nonspecific changes that correlate poorly with the degree of ID, including microcephaly, gray matter heterotopias in the subcortical white matter, unusually regular columnar arrangement of the cortex, and neurons that are more tightly packed than usual. Only a minority of the brains show more specific changes in dendritic and synaptic organization, with dysgenesis of dendritic spines or cortical pyramidal neurons or impaired growth of dendritic trees. CNS maturation is defined by genetic, molecular, autocrine, paracrine, and endocrine influences. Receptors, signaling molecules, and genes are critical to brain development.

As the ability to identify genetic aberrations that correspond to particular phenotypes expands through the use of next-generation sequencing, more will be elucidated about the pathogenesis of ID at a genetic and molecular level. This expanding pathophysiologic knowledge base may serve as a framework with which to develop targeted therapies to bypass or correct newly identified defects. For example, use of histone deacetylase (HDAC) inhibitors has been shown to rescue structural and functional neural deficits in mouse models of Kabuki syndrome, a disorder of histone methylation that leads to variable levels of ID and characteristic facial features. Similarly, there is growing interest in the role of mammalian target of rapamycin (mTOR) inhibitor use preventing seizures, neurodevelopmental disabilities, retinal tumors, cutaneous tumors, and other manifestations seen in tuberous sclerosis (see Chapter 636.2).

CLINICAL MANIFESTATIONS

Early diagnosis of ID facilitates earlier intervention, identification of abilities, realistic goal setting, monitoring for potential comorbid conditions, easing of parental anxiety, and greater inclusion of the child in the community. Children with ID may first come to the pediatrician's attention because of dysmorphisms (often in infancy), associated developmental disabilities, or failure to meet age-appropriate developmental milestones (Tables 56.5 and 56.6). Physical exam findings are nonspecific, but constellations of dysmorphisms may be consistent with certain genetic syndromes. With the advent of more sophisticated genetic testing, the limitations of dysmorphology have become more apparent given the phenotypic variability seen with many genetic causes of ID.

Most children with ID lag behind peers in their acquisition of developmental skills. In early infancy, failure to meet age-appropriate expectations can include a lack of visual or auditory responsiveness, unusual muscle tone (hypotonia or hypertonia), or posture and feeding difficulties. Between 6 and 18 months of age, gross motor delay (lack of sitting, crawling, walking) is the most common concern. Language delay and behavior problems are common concerns after 18 months of age (see Table 56.6). For some children with mild ID, the diagnosis remains

Table 56.5 Physical Examination of a Child with Suspected Developmental Disabilities

ITEM	POSSIBLE SIGNIFICANCE
General appearance	May indicate significant delay in development or obvious syndrome
STATURE	
Short stature	Malnutrition, many genetic syndromes are associated with short stature (e.g., Turner, Noonan)
Obesity	Prader-Willi syndrome
Large stature	Sotos syndrome, Sotos-like syndromes
HEAD	
Shape	Flat occiput: Down syndrome, Zellweger syndrome; prominent occiput: trisomy 18 Delayed closure of sutures: hypothyroidism, hydrocephalus Craniosynostosis: Crouzon syndrome, Pfeiffer syndrome Delayed fontanel closure: hypothyroidism, Down syndrome, hydrocephalus, skeletal dysplasia
Macrocephaly	Alexander syndrome, Canavan disease, Sotos syndrome, gangliosidosis, hydrocephalus, mucopolysaccharidosis, subdural effusion
Microcephaly	Virtually any condition that can restrict brain growth (e.g., malnutrition, Angelman syndrome, Cornelia de Lange syndrome, fetal alcohol effects)
FACE	
Specific measurements may provide clues to inherited, metabolic, or other diseases	Midface hypoplasia: fetal alcohol syndrome, Down syndrome Triangular facies: Russell-Silver syndrome, Turner syndrome Coarse facies: mucopolysaccharidoses, Sotos syndrome Prominent nose and chin: fragile X syndrome Flat facies: Apert syndrome, Stickler syndrome Round facies: Prader-Willi syndrome Hypotelorism or hypertelorism; slanted or short palpebral fissure; unusual nose, maxilla, and mandible
Nose	Anteverted nares/synophrys: Cornelia de Lange syndrome Broad nasal bridge: fetal drug effects, fragile X syndrome Low nasal bridge: achondroplasia, Down syndrome Prominent nose: Rubenstein Taybi, Coffin-Lowry syndrome, Smith-Lemli-Opitz syndrome
Mouth	Long philtrum/thin vermilion border: fetal alcohol effects Cleft lip and palate: isolated or part of a syndrome Micrognathia: Pierre Robin sequence, trisomies, Stickler syndrome Macroglossia: hypothyroidism, Beckwith-Wiedemann syndrome
Teeth	Anodontia: ectodermal dysplasia Notched incisors: congenital syphilis Late dental eruption: Hunter syndrome, hypothyroidism Talon cusps: Rubinstein-Taybi syndrome Wide-spaced teeth: Cornelia de Lange syndrome, Angelman syndrome

Table 56.5 Physical Examination of a Child with Suspected Developmental Disabilities—cont'd

ITEM	POSSIBLE SIGNIFICANCE
EYES	
Set	Hypertelorism: fetal hydantoin syndrome, Waardenburg syndrome Hypotelorism: holoprosencephaly sequence, maternal phenylketonuria effect
Prominent	Crouzon, Seckel, Apert syndrome; Beckwith-Wiedemann syndrome and fragile X syndromes
Iris/sclera	Brushfield spots: Down syndrome Lisch nodules: neurofibromatosis Blue sclera: osteogenesis imperfecta, Turner syndrome, hereditary connective tissue disorders
Cataract	Galactosemia, Lowe syndrome, prenatal rubella, hypothyroidism
Cherry-red spot in macula	Gangliosidosis (GM_1), metachromatic leukodystrophy, mucolipidosis, Tay-Sachs disease, Niemann-Pick disease, Farber lipogranulomatosis, sialidosis type III
Chorioretinitis	Congenital infection with cytomegalovirus, toxoplasmosis, Zika virus, or rubella
Corneal cloudiness	Mucopolysaccharidosis types I and II, Lowe syndrome, congenital syphilis
EARS	
Low-set or malformed pinnae	Trisomies such as Down syndrome, Rubinstein-Taybi syndrome, CHARGE syndrome, cerebrooculofacioskeletal syndrome, Treacher Collins syndrome, fetal phenytoin effects
Hearing	Loss of acuity in mucopolysaccharidosis; hyperacusis in many encephalopathies
HEART	
Structural anomaly or hypertrophy	CHARGE syndrome, velocardiofacial syndrome, glycogenosis type II, fetal alcohol effects, mucopolysaccharidosis type I; chromosomal anomalies such as Down syndrome; maternal PKU; chronic cyanosis may impair cognitive development
LIVER	
Hepatomegaly	Fructose intolerance, galactosemia, glycogenosis types I-IV, mucopolysaccharidosis types I and II, Niemann-Pick disease, Tay-Sachs disease, Zellweger syndrome, Gaucher disease, ceroid lipofuscinosis, gangliosidosis
GENITALIA	
Macroorchidism	Fragile X syndrome
Hypogenitalism	Prader-Willi, Klinefelter, and CHARGE syndromes
EXTREMITIES	
Hands, feet; dermatoglyphics, creases	May indicate a specific entity such as Rubinstein-Taybi syndrome or may be associated with chromosomal anomaly Short limbs: achondroplasia, rhizomelic chondrodysplasia Small hands: Prader-Willi syndrome Clinodactyly: trisomies, including Down syndrome Polydactyly: trisomy 13, ciliopathies Broad thumb: Rubinstein-Taybi syndrome Syndactyly: de Lange syndrome Smith Lemli Opitz Transverse palmar crease: Down syndrome Joint laxity: Down syndrome, fragile X syndrome, Ehlers-Danlos syndrome Phocomelia: Cornelia de Lange syndrome
Joint contractures	Signs of muscle imbalance around the joints (e.g., with meningomyelocele, cerebral palsy, arthrogryposis, muscular dystrophy; also occurs with cartilaginous problems such as mucopolysaccharidosis) Williams syndrome
SKIN	
Café-au-lait spots	Neurofibromatosis, Legius syndrome, tuberous sclerosis, chromosomal aneuploidy, ataxia-telangiectasia, multiple endocrine neoplasia type 2b Fanconi anemia, Gaucher disease Syndromes: basal cell nevus; McCune-Albright, Silver-Russell, Bloom, Chediak-Higashi, Hunter, Bannayan-Riley-Ruvalcaba, Maffucci syndromes
Seborrheic or eczematoid rash	PKU, histiocytosis
Hemangiomas and telangiectasia	Sturge-Weber syndrome, Bloom syndrome, ataxia-telangiectasia; Klippel Trenaunay Weber
Hypopigmented macules, streaks, adenoma sebaceum	Tuberous sclerosis, hypomelanosis of Ito
Hair	Hirsutism: De Lange syndrome, mucopolysaccharidosis, fetal phenytoin effects, cerebrooculofacioskeletal syndrome, trisomy 18, Hurler syndrome Low hairline: Klippel-Feil sequence, Turner syndrome Sparse hair: Menkes disease, argininosuccinic acidemia, biotin deficiency Abnormal hair whorls/posterior whorl: chromosomal aneuploidy (e.g., Down syndrome) Hypertrichosis cubiti (elbows): Wiedemann-Steiner, MacDermot-Patton-Williams syndromes Abnormal eyebrow patterning: Cornelia de Lange syndrome

Continued

Table 56.5 Physical Examination of a Child with Suspected Developmental Disabilities—cont'd

ITEM	POSSIBLE SIGNIFICANCE
Nails	Hypoplastic or dysplastic: fetal alcohol, trisomies, Coffin Siris syndrome
NEUROLOGIC	
Asymmetry of strength and tone	Focal lesion, hemiplegic cerebral palsy
Hypotonia	Prader-Willi, Down, and Angelman syndromes; gangliosidosis; early cerebral palsy; muscle disorders (dystrophy or myopathy)
Hypertonia	Neurodegenerative conditions involving white matter, cerebral palsy, trisomy 18
Ataxia	Ataxia-telangiectasia, metachromatic leukodystrophy, Angelman syndrome
Spine	Sacral dimple/hairy patch: spina bifida
OTHER	
Neck	Webbed neck/low posterior hairline: Turner syndrome, Noonan syndrome
Chest	Shield-shaped chest: Turner syndrome Inverted nipples; congenital disorders of glycosylation

CHARGE, Coloboma, heart defects, atresia choanae, retarded growth, genital anomalies, ear anomalies (deafness); CATCH-22, cardiac defects, abnormal face, thymic hypoplasia, cleft palate, hypocalcemia, defects on chromosome 22; PKU, phenylketonuria.
Modified from Simms M. Intellectual and developmental disability. In: Kliegman RM, Lye PS, Bordini BJ, et al, (eds). *Nelson Pediatric Symptom-Based Diagnosis*. Philadelphia: Elsevier; 2018: Table 24.11, p. 376.

Table 56.6 Common Presentations of Intellectual Disability by Age

AGE	AREA OF CONCERN
Newborn	Dysmorphic syndromes, (multiple congenital anomalies), microcephaly Major organ system dysfunction (e.g., feeding, breathing)
Early infancy (2-4 mo)	Failure to interact with the environment Concerns about vision and hearing impairments
Later infancy (6-18 mo)	Gross motor delay
Toddlers (2-3 yr)	Language delays or difficulties
Preschool (3-5 yr)	Language difficulties or delays Behavior difficulties, including play Delays in fine motor skills: cutting, coloring, drawing
School age (>5 yr)	Academic underachievement Behavior difficulties (e.g., attention, anxiety, mood, conduct)

uncertain during the early years and becomes clearer as the demands of the school setting increase.

With increasing expectations for independence at home and socially, limitations among those with mild ID become more salient. Older school-age children and adolescents with mild ID are typically up to date on current trends and are conversant as to "who," "what," and "where." It is not until the "why" and "how" questions are asked that their limitations become apparent. If allowed to interact at a superficial level, their mild ID might not be appreciated, even by professionals such as healthcare providers. Because of the stigma associated with ID, adolescents may refer to themselves as learning disabled, dyslexic, language disordered, or slow learners. Some people with ID emulate their social milieu to be accepted. Adolescents with mild ID are both at high risk of being bullied and of being taken advantage of from a social perspective.

ETIOLOGIC EVALUATION

ID is one of the most frequent reasons for referral to pediatric genetic providers, with separate but similar etiologic evaluation guidelines (see Table 56.1). ID is a diagnosis of great clinical heterogeneity, with only a subset of syndromic etiologies identifiable through classic dysmorphology. If diagnosis is not made after conducting an appropriate history and physical examination, chromosomal microarray and testing for fragile X syndrome are often the recommended first steps in the etiologic evaluation of ID. Other testing to consider in the etiologic evaluation include exome or whole genome sequencing, neuroimaging, metabolic testing, and electroencephalography (Fig. 56.1).

Decisions to pursue an etiologic diagnosis should be based on the medical and family history, physical examination, and the family's wishes. Table 56.7 summarizes clinical practice guidelines and the yields of testing to assist in decisions about evaluating the child with GDD or ID. Yield of testing tends to increase with worsening severity of delays (see also Tables 56.1 and 56.2).

Microarray analysis has replaced a karyotype as first-tier testing, given that it discerns abnormalities that are far below the resolution of a karyotype. Microarray analysis will detect copy number variations but may result in identification of variants of unknown significance or benign variants and therefore should be used in conjunction with a genetic consultation. Karyotyping has a role when concerns for trisomy, inversions, balanced insertions, and reciprocal translocations are present. If microarray analysis is not diagnostic, whole exome sequencing (WES) increases the diagnostic yield in children with nonsyndromic severe ID, especially when associated conditions such as autism, epilepsy, or movement disorders are present. WES will identify nucleotide sequence variants within the coding region of genes which affect protein function, missing structural and noncoding variants, and trinucleotide repeat disorders. *Starting with WES may be more cost-effective and may substantially reduce time to diagnosis with higher ultimate yields compared with the traditional diagnostic pathway.* Whole genome sequencing, which identifies variants within both exons and introns, represents the most comprehensive sequencing option, providing roughly 3,000 times more data than a microarray. Multimodal genome-wide analysis has identified monogenic etiologies in difficult to diagnose patients when previous testing did not reveal a diagnosis.

Molecular genetic testing for fragile X syndrome is currently recommended, although a relatively low diagnostic yield has led some to suggest that this should not be considered a first-line test for all children with ID or GDD. Yields are highest in males with moderate ID, unusual physical features, and/or a family history of ID or for females with more subtle cognitive deficits associated with severe shyness and a relevant family history, including premature ovarian failure or later-onset tremor-ataxia symptoms (see Chapter 59). For children with a strong history of X-linked ID, specific testing of genes or the entire chromosome may be revealing. Testing for Rett syndrome (methyl CpG–binding protein 2 [MECP2]) should be considered in females with moderate to severe disability, though WES may supplant this.

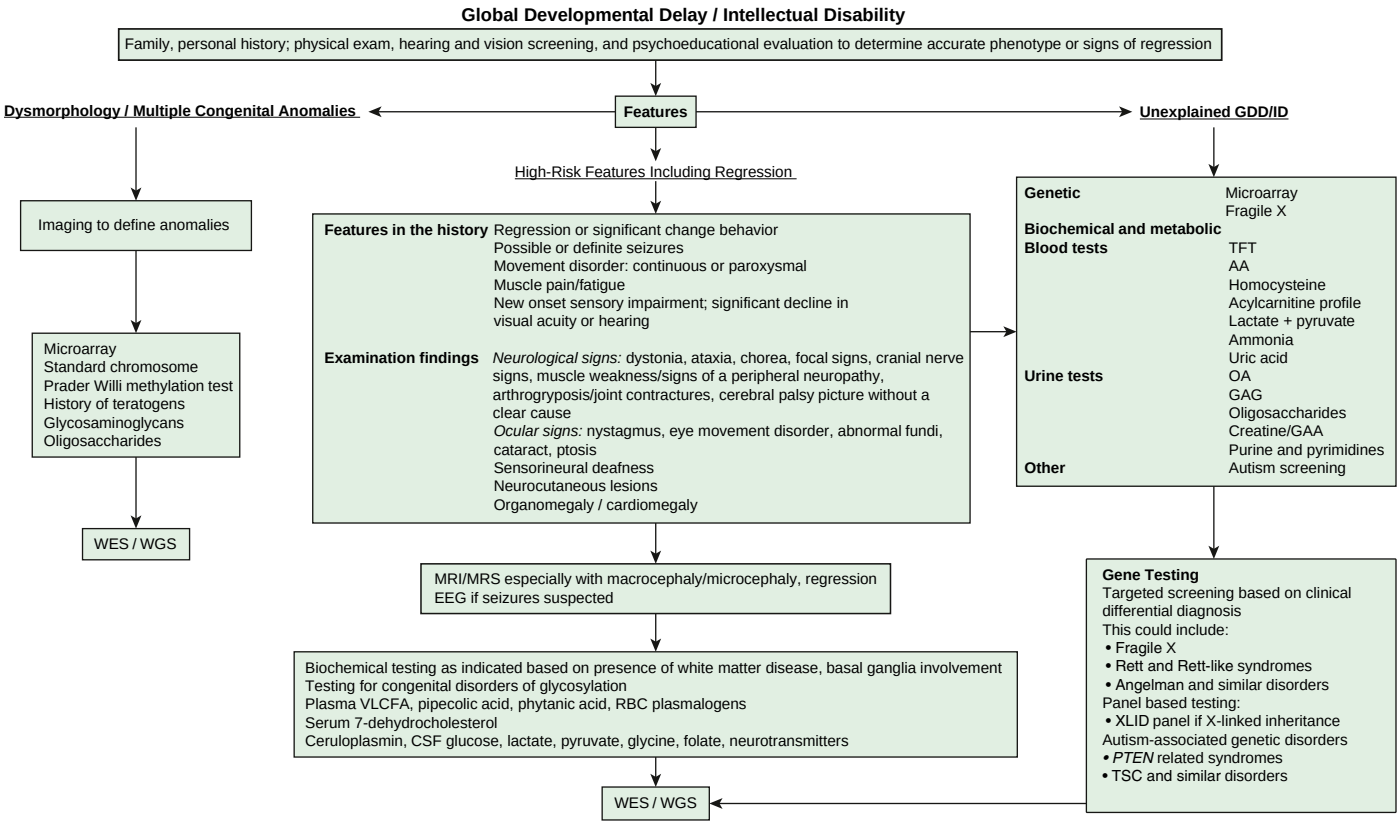

Fig. 56.1 Algorithm for the evaluation of the child with unexplained global developmental delay (GDD) or intellectual disability (ID). AA, Amino acids; ASD, autistic spectrum disorder; CK, creatine kinase; CSF, cerebrospinal fluid; FBC, full blood count; GAA, guanidinoacetic acid; GAG, glycosaminoglycans; LFT, liver function test; OA, organic acids; TFT, thyroid function tests; TSC, tuberous sclerosis complex; U&E, urea and electrolytes; VLCFA, very long-chain fatty acids; WES, whole exome sequencing; WGS, whole genome sequencing; XLID, X-linked intellectual disability genes.

A child with a **progressive neurologic disorder, developmental regression, or acute behavioral changes** needs metabolic investigation, as shown in Figure 56.1. Some advocate for metabolic testing to be done more frequently in children with ID because of the possibility of detecting a condition that could be treatable (Fig. 56.2, Tables 56.3 and 56.8), though with expanded newborn screening many of these conditions can be identified at birth. This is most relevant for children born in countries without widespread newborn screening initiatives, especially when there is a history of consanguinity. In the absence of a specific indication, an **electroencephalogram (EEG)** is typically of low diagnostic utility and should be reserved for evaluation of clinical events that may represent seizures or when significant language regression occurs, which may be concerning for Landau-Kleffner syndrome. **MRI of the brain** may provide useful information in directing the care of a child with microcephaly or macrocephaly, change in head growth trajectory, asymmetric head shape, new or focal neurologic findings, or seizures. MRI can detect a significant number of subtle markers of cerebral dysgenesis in children with ID, but these markers do not usually suggest a specific etiologic diagnosis, and the risk of anesthesia may outweigh the potential benefits in young children without any additional concerning signs or symptoms.

Some children with subtle physical or neurologic findings can also have determinable biologic causes of their ID (see Tables 56.5 and 56.6). How intensively one investigates the cause of a child's ID is based on the following factors:

- What is the degree of delay, and what is the age of the child? If milder or less pervasive delays are present, especially in a younger child, etiologic yield is likely to be lower.
- Is the medical history, family history, or physical exam suggestive of a specific disorder, increasing the likelihood that a diagnosis will be made? Are the parents planning on having additional children, and does the patient have siblings? If so, one may be more likely to intensively seek disorders for which prenatal diagnosis or a specific early treatment option is available.
- Is there a potentially treatable disorder?
- What are the parents' wishes? Some parents have little interest in searching for the cause of the ID, whereas others become so focused on obtaining a diagnosis that they have difficulty following through on interventions until a cause has been found. The entire spectrum of responses must be respected, and supportive guidance should be provided.

DIFFERENTIAL DIAGNOSIS

One of the important roles of pediatricians is the early recognition and diagnosis of cognitive deficits. Developmental surveillance should be multifaceted. Parents' concerns and observations about their child's development should be listened to carefully. Medical, genetic, and environmental risk factors should be recognized. Infants at high risk (prematurity, maternal substance abuse, perinatal insult) should be registered in newborn follow-up programs in which they are evaluated periodically for developmental lags in the first 2 years of life; they should be referred to early intervention programs as appropriate. Developmental milestones should be recorded routinely during healthcare maintenance visits. The American Academy of Pediatricians (AAP) has formulated a schema for developmental surveillance and screening at 9, 18, 24, and 30 months of age, including general developmental and autism screens (see Chapter 28).

Table 56.7 Suggested Evaluation of the Child with Intellectual Disability (ID) or Global Developmental Delay (GDD)

TEST	COMMENT
In-depth history	Includes prenatal, perinatal, and postnatal events (including seizures); developmental attainments; and three-generation pedigree in family history (focusing on neurologic or developmental abnormalities, miscarriages, consanguinity, etc.)
Physical examination	Particular attention to minor or subtle dysmorphisms; growth issues; neurocutaneous findings; eye and skull abnormalities; hepatosplenomegaly; and neurologic examination for focality Behavioral phenotype
Vision and hearing evaluation	Essential to detect and treat; can mask as developmental delay
Gene microarray analysis	A ~15% yield overall Better resolution than with karyotype; may identify up to twice as many abnormalities as karyotyping Often included in exome testing
Karyotype	No longer a first-line test Reserve use when concerned for trisomic/monosomic conditions, inversions and balanced insertions, or reciprocal translocations
Fragile X screen	Combined yield of 2%, preselection on clinical grounds can increase yield to 7.6%
Next-generation gene sequencing	Detects inherited and de novo point mutations, especially in nonsyndromic severe intellectual disability Whole exome sequencing gives an additional yield of about 30–40% Pilot studies of whole genome sequencing (WGS) reveal additional yield of about 15%
Neuroimaging	MRI preferred; positive findings increased by abnormalities of skull contour or microcephaly and macrocephaly or focal neurologic examination (30–40% if indicated, 10–14% if screening) Identification of specific etiologies is rare; most conditions that are found do not alter the treatment plan; need to weigh risk of sedation against possible yield
Thyroid (T_4, TSH)	Near 0% in settings with universal newborn screening program
Serum lead	If there are identifiable risk factors for excessive environmental lead exposure (e.g., low socioeconomic status, home built before 1950)
Metabolic testing	Yield of 0.2–4.6% based on clinical indicators and tests performed Urine organic acids, plasma amino acids, ammonia, lactate, and capillary blood gas Focused testing based on clinical findings is warranted if lack of newborn screen results or suggestive history/exam (e.g., regression, consanguinity, hepatosplenomegaly, course facies) Tandem mass spectrometry newborn screening has allowed for identification of many disorders in the perinatal period and has decreased yield in older children; other disorders have emerged, such as congenital disorders of glycosylation (yield 1.4%) and disorders of creatine synthesis and transport (yield 2.8%)
MECP2 for Rett syndrome	1.5% of females with criteria suggestive of Rett (e.g., acquired microcephaly, loss of skills) 0.5% of males
EEG	May be deferred in absence of history of seizures or significant language regression
Repeated history and physical examination	Can give time for maturation of physical and behavioral phenotype; new technology may be available for evaluation

EEG, Electroencephalogram; CGH, comparative genomic hybridization; MECP2, methyl CpG–binding protein 2; T_4, thyroxine; TSH, thyroid-stimulating hormone.

Before making the diagnosis of ID, other disorders that affect cognitive abilities and adaptive behavior should be considered. These include conditions that mimic ID and others that involve ID as an associated impairment. Sensory deficits (severe hearing and vision loss), communication disorders, refractory seizure disorders, poorly controlled mood disorders, or unmanaged severe attention deficits can mimic ID; certain progressive neurologic disorders can appear as ID before regression is appreciated. Approximately half of children with **cerebral palsy** (see Chapter 638.1) and one third of children with **autism spectrum disorder** (see Chapter 58) also have ID. Differentiation of isolated CP from ID relies on motor skills being more affected than cognitive skills and on the presence of pathologic reflexes and tone changes. Importantly, cognitive testing may be limited because of motor and communication impairments in CP such that an accurate diagnostic assessment often hinges on evaluation by a professional with experience with this population.

In ASD, social communication and social adaptive skills are more affected than nonverbal reasoning skills, whereas in ID, there are usually more equivalent deficits in social, fine motor, adaptive, and cognitive skills. The discrepancy between social communication abilities and overall developmental abilities and the presence, severity, and intensity of restricted and repetitive behaviors differentiates whether an individual has ID alone or a comorbid diagnosis of ASD. Among toddlers with ASD, those with lower verbal and nonverbal cognitive test scores in conjunction with poor adaptive skills have an 85–90% chance of being classified as having ID in adulthood. However, across all levels of cognition in ASD, there is a significant trend toward much lower adaptive functioning than would be expected otherwise.

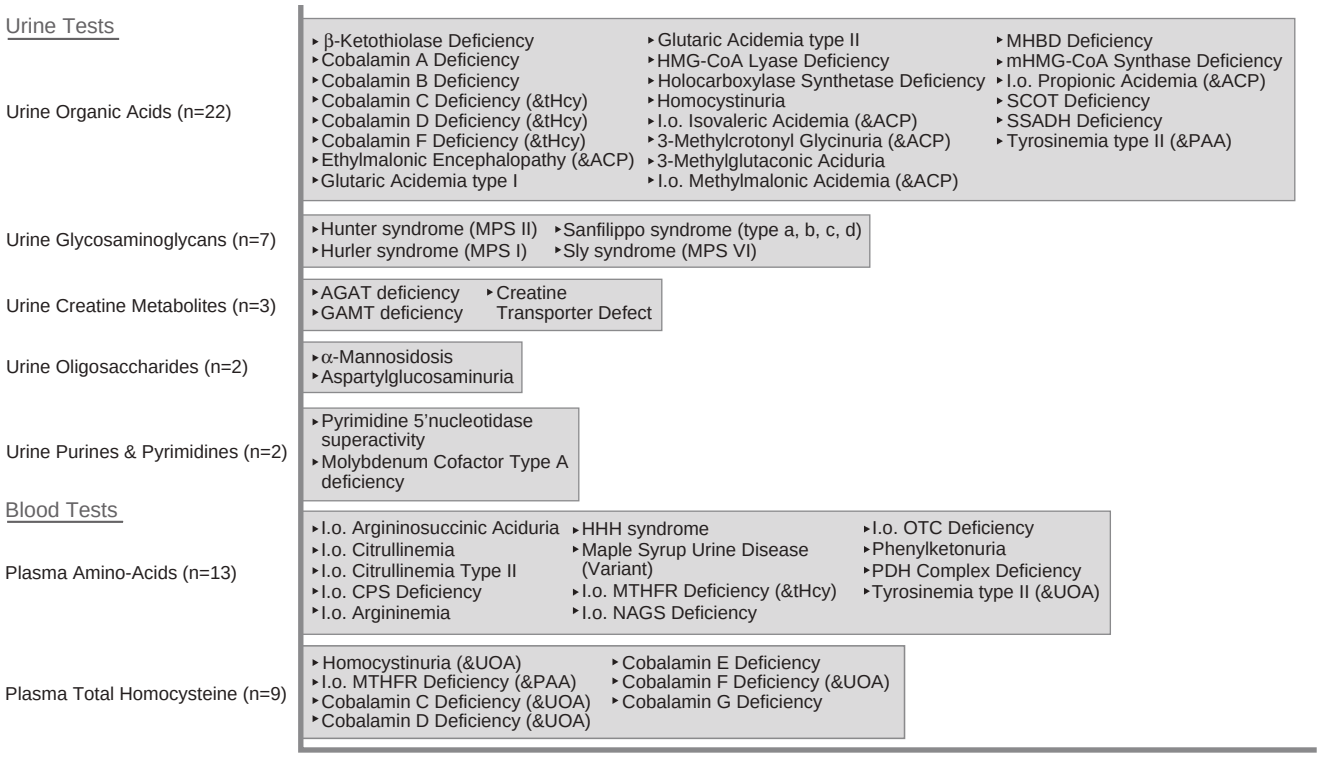

Fig. 56.2 Summary of treatable inherent errors of metabolism (IEM) that can be detected by metabolic tests in affected children, each of which is affordable and accessible and has the potential to identify at least 2 IEM (and up to 22). Each bar represents the yield of the specific screening test and lists the number and types of treatable IEM it can identify. PAA, Plasma amino acids; tHcy, total homocysteine; ACP, plasma acylcarnitine profile; UOA, urine organic acids. *(From van Karnebeek CD, Stockler S. Treatable inborn errors of metabolism causing intellectual disability: A systematic literature review. Mol Genet Metab. 2012;105:368–381, Fig. 1, p. 374.)*

Table 56.8 Treatable Intellectual Disability Endeavor (TIDE) Diagnostic Protocol

***TIER* 1: NONTARGETED METABOLIC SCREENING TO IDENTIFY 54 (60%) TREATABLE IEM**	
Blood	Plasma amino acids, total homocysteine, acylcarnitine profile, copper, ceruloplasmin
Urine	Organic acids, purine and pyrimidines, creatine metabolites, oligosaccharides, glycosaminoglycans, amino acids (when indicated)
***TIER* 2: CURRENT PRACTICE ADHERING TO INTERNATIONAL GUIDELINES* (ONE OR MORE OF THE FOLLOWING)**	
Blood	Cytogenetic testing (array CGH), thyroid studies, complete blood count, lead, metabolic testing, fragile X, targeted gene sequencing/molecular panel
Diagnostics	Brain MRI and 1H spectroscopy (where available)
Referrals	Audiology, ophthalmology
TIER 3: TARGETED WORKUP TO IDENTIFY 35 (40%) TREATABLE IEM REQUIRING SPECIFIC TESTING According to patient's symptomatology and clinician's expertise Use of digital tools (www.treatable-id.org)	
Blood	Plasma cholestanol, 7-dehydroxycholesterol:cholesterol ratio, pipecolic acid and urine α-amino adipic semialdehyde (AASA), very-long-chain fatty acids Plasma vitamin B_{12} and folate, serum lactate to pyruvate ratio, whole blood manganese
CSF	Lactate to pyruvate ratio, amino acids, neurotransmitters, CSF to plasma glucose ratio
Urine	Urine deoxypyridinoline
Other	Enzyme activities (leukocytes): arylsulfatase A, biotinidase, glucocerebrosidase, fatty aldehyde dehydrogenase CoQ measurement: fibroblasts Molecular analysis: *CA5A, NPC1, NPC2, SC4MOL, SLC18A2, SLC19A3, SLC30A10, SLC52A2, SLC52A3, PDHA1, DLAT, PDHX, SPR, TH* genes

*Low threshold for ordering tests.
IEM, Inborn errors of metabolism; CSF, cerebrospinal fluid; CGH, comparative genomic hybridization; CoQ, coenzyme Q (ubiquinone).
Adapted from Van Karnebeek CD, Stockler-Ipsiroglu S. Early identification of treatable inborn errors of metabolism in children with intellectual disability: The Treatable Intellectual Disability Endeavor protocol in British Columbia. *Paediatr Child Health.* 2014;19(9):469–471.

DIAGNOSTIC PSYCHOLOGIC TESTING

The formal diagnosis of ID requires the administration of individual tests of intelligence and adaptive functioning.

The *Bayley Scales of Infant and Toddler Development, Fourth Edition* (BSID-4), the most used infant intelligence test, provides an assessment of cognitive, language, motor, behavior, social-emotional, and general adaptive abilities between 16 days and 42 months of age. The BSID-4 correlates more strongly with other standardized tests of cognition and motor development than did prior versions of the test and permits the differentiation of infants with severe ID from typically developing infants, but it is less helpful in distinguishing between a typical child and one with mild ID.

The most used intelligence tests for children older than 3 years are the Wechsler Scales, although others are also used. The *Wechsler Preschool and Primary Scale of Intelligence, Fourth Edition* (WPPSI-IV) is used for children with mental ages of 2.5-7.6 years. The *Wechsler Intelligence Scale for Children, Fifth Edition* (WISC-V) is used for children who function above a 6-year-old mental age. Both scales contain numerous subtests in the areas of verbal and performance skills. Although children with ID usually score low on all subscales, they occasionally score in the average range in one or more performance areas. Among children who have marked language or verbal limitations, tests like the *Differential Ability Scales-II (DAS-II)* or the *Leiter International Performance Scale,* Third Edition (Leiter-3) may be used to optimally capture nonverbal performance skills.

Several normative scales are used in practice to evaluate adaptive functioning, often through questionnaire or interview formats, with information being attained from caregivers and educators in multiple different environments when possible (home, school, work). For example, the *Vineland Adaptive Behavior Scale* (VABS-3) uses semi-structured interviews with parents and caregivers/teachers to assess adaptive behavior in four domains: communication, daily living skills, socialization, and motor skills. Other tests of adaptive behavior include the *Adaptive Behavior Assessment System* (ABAS-3), the *Woodcock-Johnson Scales of Independent Behavior–Revised,* and the *AAIDD Diagnostic Adaptive Behavior Scale* (DABS). There is usually (but not always) a good correlation between scores on the intelligence and adaptive scales in ID. However, it is important to recognize that adaptive behavior can by influenced by environmentally based opportunities and by family or cultural expectations. Basic practical adaptive skills (feeding, dressing, hygiene) are more responsive to remedial efforts than is the IQ score itself. The trajectory of adaptive skill acquisition may not be consistent over time because of the underlying condition, response to interventions, and environmental expectations.

COMPLICATIONS AND ASSOCIATED CONDITIONS

Children with ID have higher rates of vision, hearing, neurologic, orthopedic, and behavioral or emotional disorders than typically developing children (Table 56.9). These problems are often detected later in children with ID. If untreated, the associated impairments may adversely affect the individual's outcome more than the ID itself.

The more severe the ID, the greater the number and severity of associated impairments. Knowing the cause of the ID can help predict which associated impairments are most likely to occur. For example, fragile X syndrome (see Chapter 59) and fetal alcohol syndrome (see Chapter 146) are associated with a high rate of behavioral disorders and may be amenable to certain treatments. Children with fetal alcohol syndrome may have a less robust response to stimulant use, whereas preliminary data suggest that children with fragile X syndrome may see behavioral improvements with the use of metformin. Other genetic conditions may have well-established medical comorbidities that should be screened for throughout the life span. For example, Down syndrome (see Chapter 57) has many medical complications (hypothyroidism, hearing and vision impairments, obstructive sleep apnea, congenital heart disease, atlantoaxial subluxation). Such associated impairments can require ongoing physical therapy, occupational therapy, speech-language therapy, behavioral therapy, adaptive and mobility equipment, glasses, hearing aids, and medication or other medical management. Failure to identify and treat these impairments can hinder successful habilitation and result in difficulties in the school, home, and neighborhood environment.

Table 56.9 Conditions Associated with ID

MEDICAL/PHYSICAL CONDITIONS	DEVELOPMENTAL/ PSYCHIATRIC CONDITIONS
Cerebral palsy/severe motor impairment	Attention-deficit/hyperactivity disorder
Seizures	Emotional disorders (anxiety, mood disorders, posttraumatic stress disorder)
Endocrine abnormalities (e.g., hypothyroidism, short stature)	Obsessive-compulsive disorder
GI issues (constipation, reflux)	Behavioral disorders (self-injurious behavior, aggression, adjustment disorder, disruptive behavior)
Dysphagia	Autism spectrum disorder
Other organ system anomalies (e.g., congenital heart disease, malformations)	Eating and feeding disorders
Hearing loss	Psychotic disorders
Vision impairment (refractive error, cataracts, strabismus)	Movement disorders (tics, stereotypies,)
Dental caries	Developmental coordination disorder
Lead poisoning from associated pica	Learning disabilities (difficulties not explained by cognition alone)
Sleep disorders (OSA, behavioral sleep dysfunction)	Substance abuse
Obesity	Victimization (bullying, sexual abuse, physical abuse)

GI, Gastrointestinal; OSA, obstructive sleep apnea.

Special attention should be given to screening for accidental injury, neglect, and abuse. Children with ID have a greater risk of preventable death from accidental injury. They are more likely to be victims of frequent, continual abuse at the hands of multiple abusers and are more frequently abused by unrelated or unfamiliar perpetrators compared to typically developing peers. Up to 15–30% of children with ID are victims of sexual abuse, with female teens with ID being at highest risk. Abuse may precipitate the onset of maladaptive behaviors and changes in mood. As such, a high index of suspicion must be maintained, with the knowledge that even individuals with severe ID may be able to reliably disclose victimization and abuse.

PREVENTION

Examples of primary programs to prevent ID include the following:

- Increasing the public's awareness of the adverse effects of alcohol and other drugs of abuse on the fetus (the most common preventable cause of ID in the Western world is fetal alcohol exposure).
- Encouraging safe sexual practices, preventing teen pregnancy, and promoting early prenatal care with a focus on preventive programs to limit transmission of diseases that may cause congenital infection (syphilis, toxoplasmosis, cytomegalovirus, HIV).
- Preventing traumatic injury by encouraging the use of safety technologies (car seats, window locks, helmets, gun locks).
- Preventing poisonings by teaching parents about securing medications and potential poisons.

- Implementing immunization programs to reduce the risk of ID caused by encephalitis, meningitis, and congenital infection.

Presymptomatic detection of certain disorders can result in treatment that prevents adverse consequences. State newborn screening by tandem mass spectrometry (now detecting >60 rare genetic disorders in most states), newborn hearing screening, and preschool lead poisoning prevention programs are examples. Additionally, screening for comorbid conditions can help to limit the extent of disability and maximize the level of functioning in certain populations. Annual thyroid, vision, and hearing screening in a child with Down syndrome is an example of presymptomatic testing in a disorder associated with ID.

TREATMENT

Although the core symptoms of ID can be prevented in some conditions, they are generally not treatable once ID is diagnosed. Many associated impairments are amenable to intervention and therefore benefit from early identification. Most children with an ID do not have a behavioral or emotional disorder as an associated impairment, but challenging behaviors (aggression, self-injury, oppositional defiant behavior) and internalizing disorders (mood and anxiety disorders) occur with greater frequency in this population than among children with typical intelligence. These behavioral and emotional disorders are the primary cause for out-of-home placements, increased family stress, reduced employment prospects, and decreased opportunities for social inclusion. Some behavioral and emotional disorders are difficult to diagnose in children with more severe ID because of the child's limited abilities to understand, communicate, interpret, or generalize. Other disorders are masked by the ID. The detection of ADHD (see Chapter 50) in the presence of moderate to severe ID may be difficult, as may be discerning a thought disorder (psychosis) in someone with autism and ID.

Behavioral disorders in ID often result from a mismatch between the child's abilities and the demands of the situation, organic problems, and family difficulties. These behaviors may represent attempts by the child to communicate, gain attention, gain access to desired tangibles, escape certain demands, exert control, or avoid frustration. Determining the antecedents, functions, and consequences of behavior can help in developing an effective behavior intervention plan. The most formal iteration of this is a functional behavioral assessment carried out by a well-trained behavior analyst. In assessing the challenging behavior, one must also consider whether it is inappropriate for the child's *mental or developmental age,* rather than the *chronological age.* However, if the behavior is dangerous to the individual or the external world, intervention is required regardless of whether it is "appropriate" for their developmental age. When intervention is needed, an environmental change, such as a more appropriate classroom setting, may improve certain behavior problems. Behavior management techniques and parent training are valuable; psychopharmacologic agents may be appropriate in certain situations, such as aggression or self-injurious behaviors with high levels of intensity and frequency.

No medication has been found that improves the core symptoms of ID. However, several agents are being tested in specific disorders with known biologic mechanisms (e.g., mTOR inhibitors in tuberous sclerosis and PTEN disorder), with the hope for future pharmacologic options that could alter the natural course of cognitive impairment seen in patients with these disorders. Medication is most useful in the treatment of associated behavioral and psychiatric disorders that do not respond to initial behavioral approaches and environmental manipulation. Additionally, underlying medical disorders and abuse/neglect should be considered as part of the differential before medication initiation in patients with self-injury, aggression, irritability, or significant disruptive behaviors.

Medications used among individuals with ID generally target specific associated symptom complexes, including inattention, impulsivity, and hyperactivity (stimulant medications and alpha-agonists); self-injurious behavior and aggression (antipsychotics); anxiety, obsessive-compulsive disorder, and depression (selective serotonin reuptake inhibitors); and sleep-related dysfunction (melatonin, alpha-agonists, gabapentin, trazodone). Even if a medication proves successful, its use should be reevaluated at least yearly to assess the need for continued treatment of the target behaviors and improvements in functional goals. Generally, medications should be started at a low dose and increased slowly, with frequent assessments of whether benefits outweigh any adverse effects. Adverse effects and idiosyncratic responses to medications may be more common in this population.

PRIMARY CARE, SUPPORTIVE CARE, AND MANAGEMENT

Each child with ID needs a medical home with a primary care clinician who is readily accessible to the family to answer questions, help coordinate care, and discuss concerns. Healthcare clinicians can have effects on patients and their families that are still felt decades later. The role of primary care includes involvement in prevention efforts, early diagnosis, identification and management of associated deficits, longitudinal developmental surveillance and screening, referral for appropriate diagnostic and therapeutic services, interdisciplinary management, provision of anticipatory guidance (see Chapter 13), and advocacy for the child and family. The management strategies for children with an ID should be multimodal, with efforts directed at all aspects of the child's life: health, education, social and recreational activities, behavior problems, and associated impairments. Support for parents and siblings should also be provided (Table 56.10). A strengths-based approach focusing on optimizing participation in all aspects of life tends to be more beneficial than an exclusive focus on cognitive or academic skill attainment. Goals of overall care should include maximizing the individual's independent functioning, identifying effective communication strategies, preserving and enhancing physical fitness and well-being, supporting positive relationship building, and ensuring opportunities for the individual to participate fully in the community and find purpose and enjoyment in life activities. Goals should be individualized, flexible, appropriate, and attainable.

The AAP has published a series of guidelines and/or toolkits for health supervision of children with specific disorders associated with ID (Down syndrome, fragile X syndrome, Williams syndrome, fetal alcohol spectrum disorder). Another source for disorder-specific information can be found at https://www.medicalhomeportal.org/diagnoses-and-conditions.

Goals should be considered and programs adjusted as needed during the primary care visit. Decisions should also be made about what additional information is required for future planning or to explain why the child is not meeting expectations. Other evaluations, such as formal neuropsychologic or educational testing, can be helpful for diagnostic clarification, attaining more appropriate school-based supports, understanding strengths and challenges, or assisting with the process of transition at various time points.

Interdisciplinary Management

The primary care clinician has the responsibility for consulting with other disciplines to make the diagnosis of ID and coordinate treatment services. Consultant services may include speech-language pathology, physical therapy, occupational therapy, psychology, audiology, nutrition, nursing, and social work, as well as medical specialties such as neurodevelopmental disabilities, neurology, genetics, physical medicine and rehabilitation, psychiatry, developmental-behavioral pediatrics, and surgical specialties. Contact with early intervention and school personnel is equally important to help prepare and assess the adequacy of the child's individual family service plan or individual education plan. The family should be an integral part of the planning and direction of this process. Care should be family centered and culturally sensitive; for older children, their participation in planning and decision-making should be promoted to whatever extent possible. Goal setting should be appropriate, individualized, and achievable

Continued

Table 56.11 Severity of Intellectual Disability and Adult-Age Functioning

LEVEL	SUPPORT LEVEL	FUNCTIONAL AGE EQUIVALENT AS ADULT	ADULT ADAPTATION
Mild	Intermittent	9-11 yr	Reads at fourth- to fifth-grade level; simple multiplication and division; can write a simple list or letter; completes job application; basic independent job skills (arrive on time, stay at task, interact with coworkers); uses public transportation, might qualify for driver's license; keeps house, cooks using recipes; challenges with planning and money management; at risk of being manipulated by others; may need support for making decisions in healthcare, shopping, finances, and raising a family.
Moderate	Limited	6-8 yr	Sight-word reading; copies information (e.g., address from card to job application); matches written number to number of items; recognizes time on clock; communicates; some independence in self-care; housekeeping with supervision or cue cards; meal preparation, can follow picture recipe cards; job skills learned with much repetition; employment in a supported environment; use of public transportation with some supervision; successful friendships attained, but social judgment and life decisions require support.
Severe	Extensive	3-5 yr	Little understanding of written language or number, time, and money concepts; needs extensive supports for problem solving; trainable in some basic activities of daily living, but needs some level of continuous support and supervision for most activities; might communicate wants and needs with use of basic words, phrases, gestures, or with the use of augmentative and alternative communication techniques; trainable in some basic activities of daily living.
Profound	Pervasive	<3 yr	Dependent for self-care, continence, communication needs with supports required for all activities of everyday living; co-occurring physical and sensory limitations are common; may use objects in a goal-directed fashion for recreation or self-care; limited understanding of symbolic communication, but may understand some gestures and emotional cues; uses nonverbal expressions; might need complete custodial or nursing care.

Data from World Health Organization. International Statistical Classification of Diseases and Related Health Problems, 10th revision. Geneva: WHO; 2011 and American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed. Washington, DC: American Psychiatric Association.

Periodic Reevaluation

The child's abilities and the family's needs change over time. As the child grows, more information must be provided to the child and family, goals must be reassessed, and programming needs should be adjusted. A periodic review should include information about the child's health status and the child's functioning at home, at school, and in other community settings. Other information, such as psychologic or educational testing, may be helpful. Reevaluation should be undertaken at routine intervals (every 6-12 months during early childhood), at any time the child is not meeting expectations, or when the child is moving from one service delivery system to another. This is especially true during the transition to adulthood, beginning at age 16, as mandated by the IDEA Amendments of 2004, and lasting through age 21, when care should be transitioned to adult-based systems and providers (see Chapter 152).

Federal and Education Services

Education is the single most important discipline involved in the treatment of children with an ID. In the United States, the IDEA, Part B, mandates a free and appropriate public education (FAPE) in the least restrictive environment (LRE) for all school-age children (3-21 years of age). Additionally, Part C mandates early intervention services from birth through 36 months of age to be delivered in a natural environment (usually home) for all qualifying infants and toddlers. The developmental and educational program for children with GDD or ID must be relevant to the child's unique needs and address the child's individual strengths and challenges. The child's developmental level, requirements for support, and goals for independence provide a basis for early intervention services to establish an **individualized family service plan (IFSP),** which focuses on the family's needs to help them optimize the development of their child. For children over 36 months of age, the school system develops an **individualized education program (IEP)**, which focuses on the child's educational needs. Inclusive education seeks to support the right of every child, regardless of ability, to participate in a broad range of activities and contexts as full members of families, communities, and societies with an effort to maximize access, participation, and supports. Research on inclusion reveals benefits for individuals with disabilities and for typically developing children. As such, to the maximum extent appropriate, children with disabilities should be educated with children who do not have disabilities. In general, removal from the regular educational environment should occur only when the nature or severity of the child's disability is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily, not simply because significant curriculum modifications are needed. Children who are educated in more inclusive settings, regardless of overall developmental level, tend to have higher rates of community participation as adults. Behavioral challenges are the most limiting factor in terms of full inclusion, both in school and within the community, emphasizing the importance of implementing early and consistent behavior management strategies.

Beyond education services, families of children with ID often are eligible for federal or state-provided social services. All states offer developmental disabilities programs that provide home and

community-based services to eligible children and adults, potentially including in-home supports, care coordination services, residential living arrangements, vocational and employment support programs, and additional therapeutic options. A variety of Medicaid waiver programs are also offered for children with disabilities within each state. Children with ID who live in low-income-status households can qualify to receive supplemental security income (SSI), but many of these families do not receive the benefits to which they are eligible.

Leisure and Recreational Activities

The child's social and recreational needs should be addressed. Although young children with ID are generally included in play activities with children who have typical development, adolescents with ID often do not have opportunities for enriching social interactions. Community participation among adults with ID is much lower than that of the typical population even though these individuals tend to have the same preferences and wishes for leisure activities as their nondisabled peers. Individuals with ID experience high rates of marginalization, especially from involvement in formal recreational programs, often because of insufficient resources to accommodate participation, difficulties with expenses and transportation, and so forth. To reduce isolation, ideas for inclusion in leisure activities should be explored with families, including church group involvement, Boy and Girl Scout chapters, 4H clubs, local park district programs, and musical opportunities like choir and instrumental lessons. Participation in sports should be encouraged (even if the child is not competitive) because it offers many benefits, including weight management, development of physical coordination, maintenance of cardiovascular fitness, and improvement of self-image. Inclusion in class trips, dances, dating, and other social events should be encouraged. International programs such as Special Olympics and Best Buddies International seek to enhance inclusion and visibility of individuals with disabilities and can be a valuable resource.

Family Counseling

Many families adapt well to having a child with ID, but some have emotional or social difficulties. The risks of parental depression and child abuse and neglect are higher in this group of children than in the general population. The factors associated with good family coping and parenting skills include stability of the marriage, good parental self-esteem, limited number of siblings, higher socioeconomic status, lower degree of disability or associated impairments (especially behavioral), parents' appropriate expectations and acceptance of the diagnosis, supportive extended family members, and availability of community programs and respite care services. In families in whom the emotional burden of having a child with ID is great, family counseling, parent support groups, sibling support groups and camps, respite care, and home health services should be an integral part of the treatment plan.

Transition to Adulthood

The transition to adulthood can present a stressful and chaotic time for the adolescent with ID and their family (see Chapter 152). A successful transition correlates with better quality of life but requires significant advanced planning. The transition process for those with ID extends beyond medical care and needs to include education and employment, health and well-being, finances and independence, and social and community life. Specific issues include:

- Decision-making (supported decision-making, guardianship, power of attorney)
- Accessing and securing social benefits for which the person is eligible (e.g., SSI, Medicaid)
- The choice of living arrangements and necessary supports (independent living, shared living arrangements, or living with parents; community-integrated living arrangements; group homes)
- Estate planning for the parents (ABLE accounts, special needs trust)
- Postsecondary training (vocational choices, postsecondary education – pacer.org)
- Community participation and involvement in leisure activities (e.g., community service and volunteering activities, religious groups, Special Olympics, Best Buddies, local clubs)

Successful transition is difficult to achieve because of policies, systems, and services that are not comprehensive or coordinated. In moving from child to adult care, families tend to find that services are less readily available, more fragmented, and more difficult to navigate across multiple agencies and jurisdictions.

Transition planning is a required element of the IEP process by age 16 years, and options for continued education or entry into the workforce after high school should be thoroughly considered, with the greater goal of ultimate community-based employment. Postsecondary education possibilities might involve community college or vocational training. In 2008, the U.S. Higher Education Opportunity Act (HEOA) granted students with ID access to federal financial aid to attend colleges with **Comprehensive Transition Programs** (CTPs), which are designed for postsecondary students with ID to continue academic, career and technical, and independent living instruction to prepare for employment. As of 2019, more than 265 nondegree postsecondary programs for students with ID exist nationwide in the United States.

Although employment is a critical element of life adaptation for persons with ID, only 15% are estimated to have jobs, with significant gaps in pay and compensation compared to workers without disability. Employment selection should be "customized" to the individual's interests and abilities. Options may include participation in competitive employment, supported employment, high school–to–work transition programs, job-coaching programs, and consumer-directed voucher programs.

Self-Advocacy

The self-advocacy movement represents an important effort by persons with ID and other disabilities to advocate for maximal autonomy and self-determination in all aspects of life. This movement is a part of the greater disabilities rights movement and represents a resistance to historical systemic injustices experienced by individuals with ID, including neglect, abuse, nonautonomy, marginalization, incarceration, sterilization, and isolation. Self-advocacy stresses that individuals with ID should be able to speak for themselves, should be involved maximally in decision-making, should be treated as equal and fully included in society, and should be given as much control over their own self-direction as possible. This movement emphasizes the tenet of "nothing about us without us" and has led to nationwide changes in terms of policy and medical and legal nomenclature. Above all, the self-advocacy movement has sought to redefine the approach to disability, moving toward a social model of acceptance, equality, accommodation, and inclusion, putting the onus on society to change its attitudes and practices rather than calling on the individual with ID to change.

OUTCOMES

In children with severe ID or ID requiring significant supports, the prognosis is often evident by early childhood. Mild ID might not always be a lifelong disorder. Children might meet criteria for GDD at an early age, but later the disability can evolve into a more specific developmental disorder (language disorder, autism, ADHD, specific learning disability, or borderline intelligence). Others with a diagnosis of mild ID during their school years may develop sufficient adaptive behavior skills that they no longer fit the diagnosis as adolescents or young adults, or the effects of maturation and plasticity may result in children moving from one diagnostic category to another (from

moderate to mild ID). Conversely, some children who have a diagnosis of a specific learning disability or communication disorder might not maintain their rate of cognitive growth and may fall into the range of ID over time.

The apparent higher prevalence of ID in low- and middle-income countries is of concern, given the limitations in available resources. **Community-based rehabilitation (CBR)** is an effort promoted by the World Health Organization (WHO) over the past 4 decades as a means of making use of existing community resources for persons with disabilities in low-income countries, with the goal of increasing inclusion and participation within the community. CBR is now being implemented in >90 countries, although the efficacy of such programs has not been established.

The long-term outcome of persons with ID depends on the underlying cause; degree of cognitive and adaptive deficits; presence of associated medical, developmental, and behavioral impairments; capabilities of the families and schools; and availability of community supports, services, and training provided to the child and family (see Table 56.10). As adults, many persons with mild ID can gain economic and social independence with functional literacy, but they may need periodic support or supervision (especially when under social, economic, or health-related stress). Most live successfully in the community, either independently or in supervised settings. Many will marry, some will have children, and meaningful and long-lasting relationships can be expected.

For persons with moderate ID, the goals of education are to enhance adaptive abilities and "survival" academic and vocational skills, so they are better able to live and function in the adult world (Table 56.11). The concept of supported employment has been very beneficial to these individuals; the person is trained by a coach to do a specific job in the setting where the person is to work, bypassing the need for a "sheltered workshop" experience and resulting in successful work adaptation in the community and meaningful inclusion. These persons generally live at home with family or in a supervised setting in the community, such as a **community integrated living arrangement (CILA)** where different levels of supervision and support are provided depending on the needs of the individuals. There has been a strong movement away from institutionalized living, defined as residence in a facility of four or more people who did not choose to live together.

As adults, people with severe to profound ID usually require extensive to pervasive supports (see Table 56.11). These individuals often have associated impairments, such as CP, behavioral disorders, epilepsy, or sensory impairments, that further limit their adaptive functioning. They can perform simple tasks in supervised settings. Most people with this level of ID can live in the community with appropriate supports, though some may require a higher level of "institutional care" that is best provided though smaller community-run group home settings.

The life expectancy of people with mild ID is similar to the general population, with a mean age at death in the early 70s. However, persons with severe and profound ID have a decreased life expectancy at all ages, presumably from associated serious neurologic or medical disorders, with a mean age at death in the mid-50s. Given that persons with ID are living longer and have high rates of comorbid health conditions in adulthood (e.g., obesity, hypertension, diabetes), ID is now one of the costliest ICD-10 diagnoses, with an average lifetime cost of 1-2 million dollars per person. Thus the priorities for pediatric primary care are to improve healthcare delivery systems during childhood; facilitate the transition of care to adult providers; and ensure high-quality, integrated, community-based services for all persons with ID.

Chapter 57

Down Syndrome and Other Abnormalities of Chromosome Number

Mary Pipan

PRINCIPLES OF CARING FOR CHILDREN WITH COMPLEX GENETIC DISORDERS

Down syndrome (trisomy 21) is the most common genetic cause of intellectual disability, with an incidence of 1 in 700 live births in the United States. Many of the principles of care for individuals with Down syndrome generalize to other complex genetic disorders. Genetic disorders generally affect all cells in the body, and hence tend to be multisystemic disorders. Trisomy 21's multisystem effects require monitoring of all organ systems for potential related issues.

Chromosome 21 is the smallest human autosome, which likely accounts for the relatively high fetal survival rate in trisomy 21. The clinical manifestations of *other* trisomies and aneuploidies are shown in Tables 57.1 and 57.2 and Figs. 57.1, 57.2, and 57.3. Fetuses with other

full autosomal trisomies are not always viable, but partial trisomy and quatrosomy (trisomy or quatrisomy of only part of the chromosome) or mosaic trisomy (only part of the cell lines contain the aneuploidy) can be viable.

The Down syndrome phenotype can occur as a result of full trisomy 21 (95%), partial trisomy 21 (part of the 21st chromosome in triplicate), mosaic trisomy 21, or translocation. Maternal nondisjunction in meiosis is the most common cause of trisomy 21. Paternal origin accounts for less than 10%.

Chromosome abnormalities affect not only the product and function of that particular group of genes but can have upstream and downstream effects on other gene products in linked pathways. The over 314 triplicate genes in Down syndrome are known to affect the products and metabolic activity of genes from every other chromosome. Possible phenotype (condition) gene relationships in trisomy 21 are noted in Figure 57.4.

The link between children's physical health, development, and behavior becomes obvious when caring for children with complex genetic disorders. Children with developmental disabilities often cannot adequately communicate the symptoms of illness. Challenging behaviors can also interfere with adequate assessment and intervention. Too often, sources of distress, developmental challenges, and behavioral issues are attributed to the genetic disorder and dismissed by family, medical, and educational caregivers. Providing care for genetically complex children requires health and other providers to consider a range of potential differential diagnoses when presented with a change in behavior, a plateau or regression in development, or a new physical complaint.

Trisomy 21 affects brain development across the life span, leading to differences in brain anatomy, neurotransmission, and connectivity that affect processing, glial cell function, infrastructure support, energy metabolism, and in adults, the formation of amyloid plaques leading to high risk for early Alzheimer disease. Alterations in brain development and functioning affect learning, behavior, and emotions, leading to an increased incidence of neurobehavioral and psychiatric disorders such as autism spectrum disorders (ASDs), attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, and depression.

It is important for the clinician to understand that children with genetic disorders are genetically more closely related to their biologic family than they are to other children with similar disorders. Children with Down syndrome will have similar patterns of familial heritability for heritable traits and medical conditions as their biologic siblings. Individuals with genetic disorders need to be seen as children/persons first who happen to have a genetic disorder. Using person-first language (child with Down syndrome, *not* Downs child) helps everyone focus on this principle.

Down syndrome: An insight of the disease. J Biomed Sci. 2015;22:41, Fig. 1.)*

CLINICAL CHARACTERISTICS

Children with Down syndrome are at increased risk for a variety of congenital anomalies and comorbid medical conditions. Typically, they have a characteristic facial appearance and other physical characteristics that allow clinical recognition of trisomy 21 in the newborn period (Figs. 57.5 and 57.6 and Table 57.3).

The increased risk for a variety of medical conditions continues throughout the life span (Table 57.4). The American Academy of Pediatrics (AAP) has developed Down Syndrome Health Supervision Guidelines for clinicians caring for children with trisomy 21 (Table 57.5). Individuals with Down syndrome often have significant communication deficits, which can result in difficulty reporting pain and discomfort; clinicians need to pay attention to the caregiver's observation of changes in behavior when evaluating the level of pain or illness. Paying close attention to subtle cues on exam

and asking direct questions about specific areas of pain or discomfort can be helpful (e.g., "Does your throat hurt?" while pointing to or touching their throat).

Ophthalmology

The red reflex should be evaluated in the newborn period with a thorough ophthalmologic exam in the first 6 months of life and then annually until age 5, then every 2-3 years thereafter. Children with DS are at higher risk for cataracts, glaucoma, nystagmus, strabismus, astigmatism, refractive error, accommodative error, blepharitis, and keratoconus. Visual acuity and visual processing are foundational for development.

Ear, Nose, and Throat

The pinna and external ear canals are often small with a predisposition to cerumen impaction. Middle ear effusion occurs in the majority of children, starting in infancy, and may require referral to an ear/nose/throat (ENT) specialist for better visualization because of stenotic ear canals. Chronic nasal congestion, choanal atresia, adeno/tonsillar hypertrophy, laryngo/tracheomalacia, subglottic stenosis, and laryngeal cleft all can affect feeding and breathing, including contributing to sleep apnea. Most children with DS require regular ENT follow-up.

Many children with DS have some degree of hearing loss (HL). Most commonly this is conductive HL associated with middle ear effusion. Smaller numbers have mixed or sensorineural HL. Hearing is foundational for speech development. Hearing should be screened in the newborn period and with audiologic assessment between 6 and 9 months and every 6 months thereafter until an accurate ear-specific audiologic evaluation is obtained, then annually. Hearing assessment through auditory brainstem responses (requiring sedation) may be needed if audiologic evaluation is inconclusive. Lack of parental concern about hearing should not preclude obtaining audiologic assessment. Aggressive treatment of otitis media and middle ear effusion reduces the frequency of hearing loss.

Dental

Children with DS often have delayed tooth eruption, malformed teeth, microdontia, permanent tooth agenesis, tooth impaction, malocclusion, and supernumerary teeth. Periodontal disease is

Table 57.5 Summary of Down Syndrome-Specific Care

Action	Pre-natal	Birth up to 1 mo	1 mo up to 1 yr	1 yr up to 5 yr	5 yr up to 12 yr	12 yr up to 21 yr
1. Confirm DS diagnosis with either CVS or amniocentesis prenatally or karyotype postnatally	■	⋯	⋯	⋯	⋯	⋯
2. Review recurrence risk and offer the family referral to a clinical geneticist or genetic counselor.	⋯	⋯	⋯	⋯	⋯	⋯
3. Offer parent-to-parent and support group information to the family.	⋯	⋯	⋯	⋯	⋯	⋯
4. Use CDC DS-specific growth charts to monitor weight, length, weight-for-length, head circumference, or BMI. Use standard charts for BMI after age 10 years.		All healthcare visits				
5. Order an echo, to be read by a pediatric cardiologist.		■	⋯	⋯	⋯	⋯
6. Feeding assessment or video study if any: marked hypotonia, underweight (<5th %ile weight-for-length or BMI), slow feeding or choking with feeds, recurrent or persistent abnormal respiratory symptoms, desaturations with feeds		Any visit				
7. Obtain objective hearing assessment (may be in NBS protocols) and follow EHDI protocols.		■	Up to 6 mo			
8. If TM can't be visualized, refer to otolaryngologist for exam with microscope until reliable TM and tympanometry exams are possible		Every 3-6 mo				
9. Car safety seat evaluation before hospital discharge.		■				
10. CBC with differential		By day 3				
11. If TAM, make caregivers aware of risk/signs of leukemia (e.g., easy bruising/bleeding, recurrent fevers, bone pain)		■				
12. TSH		At birth (if not in NBS)	Every 5-7 mo	Annually, and every 6 mo if antithyroid antibodies ever detected		
13. RSV prophylaxis based on AAP guidelines.		Annually		Through 2 yr		
14. Discuss cervical spine-positioning for procedures and atlantoaxial stability precautions.		All HMV		Biennially		
15. Assess for CAM use, discourage any unsafe CAM practices.		All HMV				
16. Refer children to early intervention for speech, fine motor or gross motor therapy.		Any visit	Up to 3 yr			
17. If middle ear disease occurs, obtain developmentally-appropriate hearing evaluation.			When ear clear	After treatment		
18. Rescreen hearing with developmentally-appropriate methodology (BAER, behavioral, ear-specific).			Start at 6mo, every 6 mo until established normal bilaterally by ear-specific testing, then annually			
19. Refer to ophthalmologist with experience and expertise in children with disabilities.			By 6 mo	⋯	⋯	⋯
20. CBC with differential if easy bruising or bleeding, recurrent fevers, or bone pain			Any visit			
21. Assess for sleep-disordered breathing; if present, refer to physician with expertise in pediatric sleep disorders.			At least once by 6 mo, then all subsequent HMV thereafter			
22. Ensure child is receiving developmental therapies, and family understands and is following therapy plan at home.		All HMV				
23. CBC with differential and either (1) a combination of ferritin and CRP, or (2) a combination of serum iron and Total Iron Binding Capacity				Annually		
24. If a child has sleep problems and a ferritin less than 50 mcg/L, the pediatrician may prescribe iron supplement.				Any visit		
25. Vision screening			All HMV, use developmentally-appropriate criteria	Photoscreen (all HMV); if unable, refer to ophthalmologist annually	Photoscreen (all HMV); if unable, refer to ophthalmologist biennially	Visual acuity or photoscreening at all HMV, or ophthalmology-determined schedule
26. If a child has myelopathic symptoms, obtain neutral C-spine plain films (see text for details).				Any visit		
27. Obtain polysomnogram.				Between 3-5 yr		
28. Prepare family for transition from early intervention to preschool.				At 30 mo		
29. Discuss sexual exploitation risks.				At least once	At least once	At least once
30. Make developmentally-appropriate plans for menarche, contraception (advocate/offer LARC), and STI prevention.					As developmentally-appropriate, then all subsequent HMV	
31. Discuss risk of DS if patient were to become pregnant.					At least once	At least once
32. Assess for any developmental regression.			All HMV			
33. Discuss and facilitate transitions: education, work, finance, guardianship, medical care, independent living					All HMV starting at 10 yr	

■	Do once at this age
⋯	Do if not done previously
	Repeat at indicated intervals
(border)	See report for end point

seen in the majority of individuals with DS. Starting oral health preventive programs young, close supervision and support of dental hygiene and chemical adjuvants improve outcomes. Children with DS should first see a pediatric dentist at age 1 year and follow up at least every 6 months. For children who do not tolerate dental examinations or procedures, sedated examinations may be necessary, preferably in a hospital with anesthesiologists familiar with caring for patients with DS.

Endocrine

Children with DS are at risk for congenital and acquired hypothyroidism (HT) and hyperthyroidism (Graves disease [GD]). Thyroid testing should be done at birth as part of newborn screening. Acquired HT and GD are autoimmune disorders with elevated thyroid antibodies. Thyroid-stimulating hormone (TSH) testing can detect both HT and hyperthyroidism and should be checked by 6 months, at 1 year, and then annually thereafter. Most cases of thyroid disorders are asymptomatic and would be missed without screening. Compensated HT refers to mild elevations in TSH with normal T_4, requiring continued monitoring. Low TSH can indicate Graves disease. Children with DS who have GD can develop HT, and those with HT can develop GD. Thyroid disorder should be considered as part of the differential diagnoses with mood or behavior changes, slowing of growth, exophthalmos, high blood pressure, or tachycardia.

Type 1 diabetes mellitus (DM) is more common in children with DS. Screening for type 2 DM, especially in obese individuals, should follow similar guidelines to the typically developing (TD) population.

Cardiac

Congenital heart disease (CHD) affects about half of all children with DS, including atrioventricular (AV) canal defects, atrial septal defect (ASD), ventricular septal defect (VSD), tetralogy of Fallot (TOF), patent ductus arteriosus (PDA), and patent foramen ovale (PFO). All children with DS should have an infant echocardiogram even with a normal physical examination. Cardiology follow-up will be based on echocardiogram findings. Signs of heart failure such as failure to thrive, tachypnea, easy fatigue, or sweating with feeds require expedited referral back to cardiology. Pulmonary hypertension can also occur in children with DS related to congenital heart defects or to respiratory illness. Later in adolescence and adulthood, clinicians should be aware of the increased risk for valvular heart disease and endocarditis.

Pulmonary

Respiratory infections are the most common cause for hospital admission of children with DS without CHD and are a common cause of mortality in children with CHD. Respiratory compromise may present with subtle signs of respiratory distress such as tachypnea, intercostal retraction, shortness of breath, and easy fatigue with exertion. The lack of overt distress may lead clinicians to underestimate the level of respiratory compromise. Both anatomy and immunodeficiency associated with DS can lead to increased risk for upper and lower respiratory infections. Macro and micro pulmonary structural anomalies have been reported. Gastroesophageal reflux disease, swallowing dysfunction, and upper airway differences (including transesophageal [TE] fistula) increase the risk of aspiration.

Sleep

The estimated prevalence of obstructive sleep apnea (OSA) ranges from 31% to 79%, and onset occurs from infancy through adulthood. A sleep study before the age of 4 years is recommended. Clinicians should consider ordering a sleep study at any age, with chronic signs of respiratory compromise when awake or asleep or daytime symptoms of nonrestorative sleep. There is some evidence that OSA causes difficulties in cognitive, behavioral, and adaptive functioning in children with DS. Obesity increases the risks for OSA in many children with DS.

Neurology

Children with DS ages 6-18 months are at increased risk for infantile spasms (IS). The outcome is often better with treatment than the non–DS population with ID but is variable, ranging from no obvious sequelae to ongoing seizure disorders, ASD, and more severe intellectual disability. In addition to the classic signs of IS, change in mental status in an infant or toddler or a plateau or regression in development should lead to prompt neurologic evaluation, including an electroencephalogram (EEG). Children with trisomy 21 are at increased risk for other seizure disorders. There is an increased risk for strokes possibly related to CHD, vascular malformations (including moyamoya syndrome), and other risk factors.

Gastrointestinal

Most children with DS have structural or functional gastrointestinal (GI) comorbidities, many of which can affect individuals across the life span. There is evidence of abnormalities in enteric nerves affecting microanatomy and nerve function. Congenital anomalies include esophageal atresia, TE fistula and duodenal atresia, stenosis, and webs, Hirschsprung disease, and anorectal malformations. Constipation and gastroesophageal reflux disease (GERD) are frequent causes of irritability, GI discomfort, feeding issues, toileting refusal, and incontinence. There appears to be a strong association between GERD, pneumonia, and OSA. Children with DS are also at higher risk of celiac disease, which can cause GI, nutritional, and behavioral issues. The AAP guidelines do not recommend routine celiac screening, but rather to maintain a high index of suspicion with GI complaints, growth faltering, or behavioral concerns. Many others, however, have performed routine screening because many patients with DS who have celiac disease are asymptomatic; there may be a lag of 2-3 years before symptoms appear.

Nutrition/Obesity

In infancy and early childhood, dysphagia, GI conditions, cardiac, and respiratory complications may cause failure to thrive. Weight faltering can continue for older children because of the same issues but may be more intermittent. Because of the high rates of dysphagia in infants with DS, video swallow studies should be considered when there is any sign of weight faltering, aspiration, feeding difficulties, or recurrent respiratory infections. Thickened formulas, low-flow bottles/nipples, or slower paced feeding may be required. Nasogastric (NG) or gastric tube (GT) supplementation to assure adequate nutrition may be needed. Many babies with DS can successfully breastfeed, and clinicians need to be encouraging but watchful for growth faltering.

Obesity becomes more prominent in early childhood and extending into adulthood. In school-age children with DS, those at 50% or greater on DS-specific BMI charts are in the obese range. Thus to gauge the level of overweight for children with DS, the Centers for Disease Control and Prevention (CDC) curves for BMI should be used. When children with DS gain more autonomy in feeding, overeating can become a problem. Many do not appear to satiate and will continue to eat as long as food is presented or will seek food. Caregivers therefore cannot rely on the child's satiety to determine caloric sufficiency. Decreased basal metabolic rates (reduced caloric needs) and lower physical activity can also contribute to obesity. Anticipatory guidance regarding healthy nutritional practices, meal and snack limits, and active lifestyle choices should be part of well-child visits from a young age.

Genitourinary

Renal and urinary tract abnormalities, including ureteropelvic junction obstruction, vesicoureteral reflux, renal hypoplasia, obstructive uropathy and posterior urethral valves, hypospadias,

Table 57.6 Neurodevelopmental, Neurobehavioral, and Psychiatric Characteristics of Trisomy 21

MOTOR SKILLS	
Gross motor skills	0-24 mo: Mild delays initially which widen with age At 2 years 25% walking
Oromotor	Dysphagia 0-6 mo: 50% Self-feeding delays: 70%
Fine motor skill	Early skills delays: ~75% Bimanual skill delays: 100%
SPEECH AND LANGUAGE	
Intelligibility	Frequently unintelligible (parent report): 5-21 yr: 54–57% Motor speech impairment: Delay: 27% Articulation: 60% Apraxia: 33% Dysfluency: Stuttering: 10–45% Cluttering (abnormally rapid or irregular pace or both): 80%
Language	Receptive: Similar to mental age–matched controls Expressive: More delayed relative to mental age–matched controls Syntax: More impaired than expressive vocabulary Pragmatics: Same variety of language functions as mental age–matched peers; may be less likely to ask for clarification
SOCIAL AND EMOTIONAL DEVELOPMENT	
	High sociability Joint attention compared with mental age–matched peers Strong imitation skills Pro-social empathetic responses to others in distress Underexpression of emotional distress Less frequent and shorter social referencing Reduced ability to read facial expressions More restricted repetitive behaviors and interests Average social motivation but lower social cognition
COGNITION	
	Intellectual disability: Mild: ~25% Moderate: ~50% Severe: ~25% Decline in IQ throughout childhood (slowing in developmental progress relative to same-age peers) Strengths: Implicit memory, visual spatial sequencing, visual spatial construction, and nonverbal memory Weaknesses: Working memory capacity, explicit memory, verbal processing, auditory short-term memory, complex visual spatial skills, executive functioning
Oppositional behaviors	70%
Aggression	4–15%
Self-injurious behavior	18%
Autism spectrum disorders	15–20%
ADHD	14–40%
Anxiety disorders	10–22%
Obsessive-compulsive disorders	0.5–4.5%
Depression	5–11%
Catatonia/Down syndrome disintegrative disorder	Multiple case series and case reports

IQ, Intelligence quotient; ADHD, attention-deficit/hyperactivity disorder.

asymptomatic renal pelvic dilatation, kidney ectopia, proteinuria and hematuria, immunoglobulin A (IgA) nephropathy, and focal segmental glomerulosclerosis, occur more frequently than in the general population. There are no current guidelines for regular surveillance, but clinicians need to maintain a high index of suspicion.

Sexuality and Reproductive Health

Males and females with DS undergo puberty at similar ages to peers. In males, after puberty, testicular volume decreases and gonadal dysfunction worsens with age. Males are infertile, with few exceptions. Females with DS are fertile, having a 33% chance of having a child with DS. Menstrual problems, including irregular periods, and premenstrual irritability are common reasons for use of oral contraceptives. Most females manage menstrual periods well, but there may be difficulties with hygiene. Menopause tends to occur early.

Individuals with DS are at increased risk for sexual abuse, and caregivers should discuss appropriate and inappropriate contact and relationships from an early age. Sexuality education should be included in their educational curriculum. Clinicians should discuss sexuality, birth control, and reproductive issues at health maintenance visits.

Hematology-Oncology

AAP guidelines recommend a complete blood cell count (CBC) with differential for all newborns with DS. Neonates with DS commonly have hematologic abnormalities, including peripheral blasts, neutrophilia, thrombocytopenia, or polycythemia. Five to ten percent of neonates with DS have transient myeloproliferative disorder (TMD) (also called *transient abnormal myelopoiesis* [TAM]), which is associated with pathologic variants in *GATA1*. Typically, this resolves spontaneously within the first 1-3 months of life, but 10–20% will develop acute megakaryocytic leukemia (AMKL) in the first 4 years of life. AMKL is sensitive to treatment in most cases and has a good prognosis.

Children with DS are ~20 times more likely to get acute lymphoblastic leukemia (ALL) (1 in 900-1,000) than the typical population, which is associated with pathologic variants in *JAK2*. Treatment trials show lower response rates, higher recurrence rate, and higher treatment-related mortality.

Annual hemoglobin screening for anemia is recommended throughout childhood with additional testing for ferritin and C-reactive protein (CRP) when iron deficiency is suspected. The incidence of anemia in DS may be similar or increased compared with the general population. Other common CBC findings include macrocytosis, low white blood cell (WBC) count, and polycythemia, the clinical significance of which is unknown.

Immunology/Allergy

Individuals with DS are more susceptible to infections because of mild to moderate T- and B-cell lymphopenia, with a decrease in naive lymphocytes, impaired mitogen-induced T-cell proliferation, reduced specific antibody responses to immunizations, and defects of neutrophil chemotaxis. Nonimmunologic anatomic factors also contribute to the increased risk of respiratory infections. Children with DS with significant numbers of serious infections or difficulty clearing infections need further immunologic evaluation.

Autoimmune disorders are also more common, including thyroid disorders, celiac disease, alopecia areata, vitiligo, type 1 DM, juvenile idiopathic arthritis, and systemic lupus erythematosus.

Musculoskeletal

Individuals with DS have short stature across the life span and stop growing sooner than typical peers, the mechanism of which is unclear. Growth hormone is rarely deficient. Ligamentous laxity is common, especially in the ankles and feet. Inflammatory arthritis is underrecognized, and scoliosis is more common. Joint instability is most apparent in the neck (atlantoaxial instability [AAI]), hips, and knees. Joint pain and impaired mobility can contribute to motor skills deficits, impede independence, and add to behavioral difficulties.

Radiographic screening for AAI is not recommended because flexion/extension neck x-rays are not predictive for future neurologic risk. Signs and symptoms of AAI occur because of compression of the spinal cord from slippage of the C1 or C2 vertebrae, which can occur after an injury or anesthesia but can also be seen spontaneously. Neck pain, stiffness, and/or myelopathic signs and symptoms (e.g., change in gait, bowel, or bladder pattern or weakness) should prompt referral to orthopedics or neurosurgery. Universal neck precautions are recommended for all children with DS, assuming that all are at risk for injury from AAI, including limited participation in any activities that would be associated with forcible neck movement such as contact sports, diving, and universal cervical precautions with intubation procedures/surgery. Children with DS should be secured in rear-facing car seats until 40 pounds and may need harness-style car restraints over 40 pounds.

Hip instability resulting in recurrent (often painless and voluntary) hip dislocation and patellar instability can impair ambulation and may require surgical interventions.

Dermatology

Although causing minor morbidity, dermatologic problems can be highly distressing to patients and families due to appearance (e.g., alopecia), discomfort (e.g., eczema, hidradenitis), or intractability (e.g., onychomycosis). Common conditions include folliculitis, hidradenitis suppurativa, eczematous and seborrheic dermatitis, autoimmune alopecia and vitiligo, fungal infections including tinea pedis and onychomycosis, angular cheilitis, and hyperkeratosis.

DEVELOPMENTAL AND BEHAVIORAL CHARACTERISTICS

Development and behavior concerns are almost universal. Some concerns are easily explained and remediated and are responsive to appropriate therapeutic or behavioral interventions, but others may indicate an underlying neurobehavioral disorder such as autism, ADHD, depression, or anxiety (Table 57.6). Thinking through the categories that follow will help clinicians understand this complexity and direct families to appropriate resources.

Motor Skills

Children with DS often have marked delays in motor skills in early development related to hypotonia, ligamentous laxity, and lack of coordination.

Acquisition of early gross motor skills is foundational for postural control, feeding, visual motor development, socialization, and communication. Without stimulation and support, infants with DS may persist in lax postural control, further adding to motor delays. Through toddler and childhood many gradually improve but have persistent deficits in motor control and coordination and more difficulty with speed and complex postural changes, as well as persistent hypotonia. **Physical therapy** in the first years of life concentrates on core strengthening and ensuring acquisition of adaptive motor planning that supports effective ambulation. Gait abnormalities and persistent low core strength often require ongoing physical therapy. Developing physical literacy in recreational fitness activities, such as swimming, and community sports can also support health and well-being in school-age and adult years.

Oromotor skills are often delayed, with dysphagia in half of infants, requiring feeding therapy, thickening of formula, low-flow nipples, pacing between swallows, and sometimes supplemental enteral feeding. **Feeding therapy** helps young children learn to handle food boluses, chew, and drink from a cup.

Fine motor skills are also delayed, although they seem to be acquired in the same sequence as typically developing peers, but with a wider age range of acquisition. Most unaffected children are able to write their name between 60 and 72 months, but in children with DS, this usually occurs between 120 and 216 months. **Occupational therapy** often helps remediate or compensate for motor difficulties interfering with independence in activities of daily living.

Speech and Language Skills

Individuals with DS often have difficulty speaking clearly enough to be readily comprehensible to listeners across the life span resulting in communication breakdowns, which can be frustrating to both parties. Typical children are 90–100% intelligible by age 4 years. In individuals with DS over 50% of parents reported frequent difficulties in intelligibility over the age of 5 years into adulthood, and almost all qualify for a diagnosis of a motor speech disorder. Differences in voice quality, articulation, phonology, fluency, prosody, and motor coordination (apraxia) all contribute to making speech hard to understand (see Chapter 53). The complexity of speech impairments in children with DS requires **speech therapy** evaluation with targeted interventions for each individual.

Children with DS relative to children matched for nonverbal skills show similar abilities in receptive vocabulary but impairments in expressive vocabulary, syntax, grammar, and verbal short-term

memory indicative of a specific language impairment (SLI). The frequency of such impairments requires comprehensive language assessment for all children with DS. The language impairment may be associated with decreased ability to express thoughts and feelings verbally and use of fewer words in answer to questions or to carry on a conversation.

Misunderstandings may occur if the individual refers to past events in the present tense or thinks that something described as a future event will happen immediately. Verbal short-term memory deficits affect comprehension of more complex language (e.g., multistep instructions, complex sentences, conversation, and narrative) and reading comprehension. Visual, contextual, and multisensory supports incorporated into both receptive and expressive language can be helpful.

Speech and language intervention has been shown to be effective, especially when of higher intensity; focused on individual needs and targeted skills; and when taking into account the individual's age, interests, and motivators. Use of **applied behavior analysis** to teach communication skills improves outcomes. Incorporating interventions across contexts (classroom, home, and community settings) and into pragmatic language situations outside of structured learning settings (e.g., peer interaction, conversation) supports generalization of skills learned in therapy. For some individuals with DS, speech and language intervention will be required through school and possibly into adulthood.

Social and Emotional Development

Social and emotional development occurs as a complex transactional process between the child and their social partners. Children with developmental delays will likely also have delays in their social interactions, social communication, and play. Children with DS often have a strong orientation toward sociability. From early infancy, mutual gaze in babies with DS emerges more slowly but once established tends to last longer, with sometimes strong preferences for looking at people as opposed to toys and other objects. Development of joint attention is commensurate with developmental age-matched peers and may be a relative strength. Strong imitation skills are noted in children with DS. Children with DS show stronger pro-social empathetic responses to others' distress, but their own expression of distress tends to be dampened (often described as high pain tolerance or, in older children, a perceived reluctance to acknowledge feelings of distress).

There are relative weaknesses in social development, which can help explain some of the social difficulties caregivers encounter. Children with DS have been shown to socially reference less frequently, with shorter glances toward others, and some have more difficulty interpreting the facial expressions of others. Older children with DS have more restricted repetitive behaviors and interests, including rigidity and insistence on sameness. Despite typical social motivation, they may have difficulties with social cognition and difficulty gaining and maintaining friendships. Having friends has been associated with improved quality of life in children with DS. Most adolescents are happy with their level of friendships, but friends may include helpers and adult companions. Leisure time is often spent at home with family or by themselves, and socializing with same-age peer-friends occurs predominantly in the context of common educational or community activities. Building healthy sustained friendships with both TD peers and those with developmental disabilities often requires active ongoing caregiver and community support to prevent social isolation and loneliness as children transition to adulthood.

Cognition

Individuals with DS have varied degrees of intellectual and learning disabilities. Intelligence quotient (IQ) scores of adults with DS are mostly in the 40s-60s, and tests of adaptive functioning typically have standard scores in the low 50s. In children with DS, IQ scores tend to decline with age because progress is slower than same-age peers, and deficits are more marked in higher-level thinking. Thus the gap between children with DS and same-age peers widens with age. An actual plateau in functioning before mid-adolescence or a decline at any age is not typical and should prompt thorough etiologic evaluation.

IQ scores are of limited value for intervention planning, as they provide limited information about relative strengths and weaknesses. Children with DS often have relative strengths in areas of imitation, implicit memory, visual spatial sequencing, visual spatial construction, and nonverbal memory. Relative weaknesses tend to occur in working memory capacity, explicit memory, verbal processing, auditory short-term memory, more complex visual spatial skills (mental rotation, closure, wayfinding), and executive functioning (see Chapter 49). Recognizing a child's individual learning profile and building on strengths while supporting weaknesses will help caregivers, teachers, and therapists work together to teach children effectively to their potential.

Children's reading skills are generally commensurate with their nonverbal mental age. Many children with DS can learn to read, some phonologically, some orthographically. Reading comprehension largely relies on language comprehension skills and is often more difficult.

Mathematics is much more difficult because of weak working memory, language deficits, and fine motor skills. Math interventions generally include direct instruction, modeling, guided and repeated practice, and use of concrete materials.

Neurobehavioral Challenges and Disorders

Autism Spectrum Disorder

Due to the sociability associated with children with DS, ASDs have been underrecognized in the past but are estimated to occur in 15–20% of children with DS. Studies also have shown that autism symptoms are not attributable to the degree of developmental disability and that individuals with DS and ASD are distinct from those with DS alone. *Children with DS who show high levels of repetitive behavior, maladaptive behaviors (e.g., aggression, self-injury, destructive behaviors), social isolation, or difficulty with reciprocal social interaction should be referred for further evaluation, even when overtly sociable.* Children with ASD require specialized behavioral and educational interventions with an emphasis on functional communication, social and play skills development, and sensory-based supports (see Chapter 58).

ADHD

The reported incidence of ADHD in children with DS varies greatly, from 14% to 44%. Inattention, impulsivity, and hyperactivity, the core symptoms of ADHD, are nonspecific, and it can be difficult to differentiate all the factors contributing to these symptoms in children with DS (see Chapter 50). From a clinical perspective, the diagnosis of ADHD relies on reports of ADHD symptoms from two different settings (usually parent and teacher) and dysfunction caused by the ADHD symptoms in areas such as learning, socialization, and safety. Medication use in ADHD has been shown to be effective in children with DS, but the response rates are lower than in typical peers with ADHD. Further, there are higher rates of significant side effects, with some children showing decline in behavior and cognitive performance on medication.

Aggression and Self-Injurious Behaviors

Aggressive behavior is more common in children with many genetic disorders, including DS. The estimated incidence in DS is 4–15%, which is higher than the general population but less than many other genetic syndromes. Aggression disproportionately affects quality of life for the individual and family members and may result in the use of medications and more restrictive educational placements. These behaviors occur more often in males and in individuals with ASD, ADHD, or poor communication skills. Self-injurious behavior (SIB) occurs in

~18%. Individuals with DS who engage in SIB are likely to have lower cognitive and communication ability (may be nonverbal), more repetitive behaviors, higher levels of activity and impulsivity, and fewer social interactions. Assessment of aggression or SIB should include a functional behavioral analysis (FBA) along with overall skills assessment with emphasis on communication. New onset or escalation of aggression or SIB should also include careful assessment for potential sources of pain or discomfort that may exacerbate these behaviors. Behavioral interventions designed based on the results of the FBA should be the initial intervention. Medications may be needed to address symptoms of ADHD, irritability, mood, or anxiety.

Oppositional Behaviors

Disobedience and stubbornness are common. In some cases, this behavior may relate, at least in part, to differences in cognitive processing. Children with DS have difficulty shifting attention or disengaging from activities. They often desire sameness and resist changes to routine or to the way they think things should be done. Difficulties with language comprehension or frustration with a task or trying to express oneself may result in behaviors that are seen as oppositional. When combined with difficulty problem solving, low frustration tolerance, and emotional dysregulation, disruptive or sometimes verbally or physically aggressive behaviors may result. Before diagnosing a child as having oppositional defiant disorder (see Chapter 42), clinicians should try to understand potential comprehension or skill deficits that may be contributing to the behavior. If the child has difficulty with transitions, interventions to help them shift activities more easily such as transition routines, warnings, or countdowns may be most helpful. Visual schedules can also be helpful to prepare the child for what is next, as can providing some additional time for the transition. Simplifying language can help avert communication frustration.

Anxiety

There is an increased prevalence of anxiety disorder in children with DS compared with typical peers. Generally, anxiety disorders are diagnosed based on verbal descriptions of fear or worry and the impact of the fear or worrying on functioning or individual distress. Whereas some individuals with DS have the language skills to describe these experiences, others do not. Clinicians often need to rely on the history from caregivers and contextual cues. Behavioral reactions to anxiety can result in flight-or-fight responses. Thus anxiety could manifest with aggressive or escape/avoidance behaviors. Cognitive-behavioral therapy or exposure therapies can be helpful, and medication management is sometimes needed when anxiety is overwhelming or affects sleep or daytime functioning. Evidence for effectiveness of intervention in DS specifically is sparse.

Obsessive-Compulsive or Perseverative Behaviors

Children and adults with DS often need specific things to be a certain way or may have repetitive patterns of behavior that can seem obsessive or compulsive. They may spend many minutes arranging pillows on their bed, need all doors in the house to be shut, make long lists, or perseveratively ask about upcoming events. These behaviors can be associated with anxiety, and the possibility of increased anxiety should be investigated if there are sudden increases in intensity or frequency of these behaviors.

Depression

The prevalence of depression in DS ranges from 4% to 11%, with most studies being done in adults. This may be an underestimation, as depression in individuals with intellectual disability can be difficult to diagnose because of limited abilities to self-report internal mood states. Behavioral symptoms can include anxiety, increases in obsessive-compulsive behaviors, depressed affect, crying for no reason, lack of emotion, social isolation, anhedonia, irritability with increases in outbursts or aggression, sleep disturbance, psychomotor retardation, low self-esteem, catatonia, and psychosis. Clinicians need to consider potential contributing factors, including medical factors, recent life stressors, trauma, and family history. Anecdotally, interventions that involve reengagement in previously enjoyed activities and treatment with selective serotonin reuptake inhibitors (SSRIs) can be effective.

Catatonia (Also Known as Down Syndrome Disintegrative Disorder or Down Syndrome Regression Disorder)

Older children and young adults can experience a sudden regression in communication, socialization, and daily living skills associated with psychomotor retardation, negative mood or mood lability, refusal to participate in activities, social withdrawal, and insomnia with signs and symptoms of catatonia on the Bush Frances Catatonia Scale (see Chapter 47.3). Patients should undergo a medical evaluation for mental status change. Contributing etiologic factors include stressful events, depression, anxiety, or high physiologic stress. Treatment consists of addressing the underlying suspected cause and may include a trial of Ativan and then electroconvulsive therapy (ECT) if Ativan is unsuccessful.

Chapter 58

Autism Spectrum Disorder

Carolyn F. Bridgemohan and Carol C. Weitzman

DEFINITION

Autism spectrum disorder (ASD) is a neurobiologic disorder with onset in early childhood. The key features are impairment in social communication and social interaction and restricted and repetitive behaviors. The presentation of ASD can vary significantly from one individual to another, as well as over the course of development for a particular child. There is currently no diagnostic biomarker for ASD. Accurate diagnosis therefore requires careful review of the history and direct observation of the child's behavior.

DIAGNOSTIC CRITERIA AND SYMPTOMS

The diagnostic criteria in the *Diagnostic and Statistical Manual, Fifth Edition* (DSM-5) focus on symptoms in two primary domains: (1) social communication and social interaction and (2) restricted interests and repetitive behaviors (Table 58.1). To meet criteria for ASD, the symptoms need to have been present since the early developmental period, significantly affect functioning, and not be better explained by the diagnosis of intellectual disability (ID) or global developmental delay (GDD; Chapter 56). Table 58.2 provides associated features not included in the DSM-5 criteria.

Symptoms can present in infancy, with reduced response to name and unusual use of objects being strong predictors for risk of ASD. However, symptoms before age 12 months are not as reliably predictive of later diagnosis. Individuals with milder severity may not present

Table 58.1 DSM-5 Diagnostic Criteria for Autism Spectrum Disorder

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history:
   1. Deficits in social-emotional reciprocity.
   2. Deficits in nonverbal communicative behaviors used for social interaction.
   3. Deficits in developing, maintaining, and understanding relationships.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history:
   1. Stereotyped or repetitive motor movements, use of objects, or speech.
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior.
   3. Highly restricted, fixated interests that are abnormal in intensity or focus.
   4. Hyperreactivity or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment.

C. Symptoms must be present in the early developmental period (may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay.

From the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*. (Copyright 2013). American Psychiatric Association, pp. 50–51.

Table 58.2 Associated Features of Autism Not in DSM-5 Criteria

Atypical language development and abilities
- Age <6 yr: frequently disordered and delayed in comprehension; two thirds have difficulty with expressive phonology and grammar
- Age ≥6 yr: disordered pragmatics, semantics, and morphology, with relatively intact articulation and syntax (i.e., early difficulties are resolved)

Motor abnormalities: motor delay; hypotonia; catatonia; deficits in coordination, movement preparation and planning, praxis, gait, and balance

For version with full references, see American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*. Washington DC: American Psychiatric Association; 2013. Adapted from Lai MC, Lombardo MV, Baron-Cohen S. Autism. *Lancet*. 2014;383:896–910.

until preschool or school age, when the social demands for peer interaction and group participation are higher.

Social Communication and Social Interaction

Individuals with ASD have difficulty understanding and engaging in social relationships. The problems are pervasive and affect three major areas: social-emotional reciprocity, nonverbal communication, and understanding of social relationships. The presentation can vary with severity and developmental functioning. A diagnosis of ASD requires the presence of symptoms from all three categories (Table 58.3).

Social-Emotional Reciprocity

Reduced social interactions in ASD may range from active avoidance or reduced social response to having an interest in, but lacking ability to initiate or sustain, an interaction with peers or adults. A young child with ASD may not respond when their name is called, may exhibit limited showing and sharing behaviors, and may prefer solitary play. In addition, the child may avoid attempts by others to play and may not participate in activities that require taking turns, such as peek-a-boo and ball play. An older child with ASD may have an interest in peers but may not know how to initiate or join in play. The child may have trouble understanding the rules of conversation and may either talk at length about an area of interest or abruptly exit the interaction. Younger children often have limited capacity for imaginative or pretend play. Older children may engage in play and conversation but lack flexibility and may be highly directive to peers. Some children with ASD interact well with adults but struggle to interact with same-age peers.

Nonverbal Communicative Behavior

Difficulties with nonverbal communication may manifest as reduced or overly intense use of eye contact and gestures such as pointing. Children may also show reduced awareness or response to the eye gaze or pointing of others. They may use eye contact only when communicating a highly preferred request or may have difficulty coordinating the use of nonverbal with verbal communication. Children with ASD may have limited range of facial social-communicative expression or expressed emotion.

Developing, Maintaining, and Understanding Relationships

Children with ASD have limited insight regarding social relationships. They may have difficulty understanding the difference between a true friend and a casual acquaintance, and even when the definitions are well understood, there may still be difficulty in developing and maintaining more intimate relationships They have trouble picking up on the nuances of social interactions and understanding social expectations for polite behavior. They may have reduced understanding of personal boundaries and may stand too close to others. In addition, they can have trouble understanding and inferring others' emotions and are less likely to share emotion or enjoyment with others. Adolescents and young adults have difficulty engaging in group interactions and navigating romantic relationships.

Restrictive and Repetitive Behavior

A diagnosis of ASD requires the presence of two of the four symptoms of restrictive and repetitive patterns of behavior discussed next.

Stereotyped Motor Movements or Speech

Stereotyped (or stereotypic) movements and repetitive behaviors may include hand flapping, finger movements, body rocking and lunging, jumping, running and spinning, and repetitive speech such as echoing words immediately after they are said. Repetitive patterns of play may be present, such as lining up objects, repetitively turning light switches on and off or opening and closing doors, spinning objects, or arranging toys in a specific manner. These repetitive patterns may not be seen in very young toddlers but may develop as they get older. Stereotyped movements can change over time and in older children are seen more often in individuals with lower cognitive functioning.

Insistence on Sameness

Children with ASD have difficulty tolerating transitions or change. They may insist on certain routines or schedules and can become very distressed with unexpected events or new situations. They may repeat scripts from shows or movies or watch the same portion of a video repeatedly. Intolerance for change can cause significant impairment and irritability and have an effect on child and family function.

Restricted Interests

This symptom may manifest as interests that seem of greater intensity when compared to same-age peers. Younger children may play with a limited range of toys or may insist on retaining a small object in each hand. Older children may have a strong preference for a particular story or movie. The area of interest may be shared by peers (e.g., Disney movies, Legos, Thomas the Train) but *unusual* in its intensity. Other affected children may have interests that are both intense and

Table 58.3 Signs and Symptoms of Possible Autism in Preschool Children (or Equivalent Mental Age)

Spoken Language
- Language delay (in babbling or using words; e.g., using <10 words by age 2 yr).
- Regression in, or loss of, use of speech.
- Spoken language (if present) may include unusual features, such as vocalizations that are not speechlike; odd or flat intonation; frequent repetition of set words and phrases (echolalia); reference to self by name or "you" or "she" or "he" beyond age 3 yr.
- Reduced and/or infrequent use of language for communication (e.g., use of single words, although able to speak in sentences).

Responding to Others
- Absent or delayed response to name being called, despite normal hearing.
- Reduced or absent responsive social smiling.
- Reduced or absent responsiveness to other people's facial expressions or feelings.
- Unusually negative response to the requests of others ("demand avoidance" behavior).
- Rejection of cuddles initiated by parent or caregiver, although the child may initiate cuddles.

Interacting with Others
- Reduced or absent awareness of personal space, or unusually intolerant of people entering their personal space.
- Reduced or absent social interest in others, including children of own age—may reject others; if interested in others, child may approach others inappropriately, seeming to be aggressive or disruptive.
- Reduced or absent imitation of others' actions.
- Reduced or absent initiation of social play with others; plays alone.
- Reduced or absent enjoyment of situations that most children like (e.g., birthday parties).
- Reduced or absent sharing of enjoyment.

Eye Contact, Pointing, and Other Gestures
- Reduced or absent use of gestures and facial expressions to communicate (although may place an adult's hand on objects).
- Reduced and poorly integrated gestures, facial expressions, body orientation, eye contact (looking at people's eyes when speaking), and speech used in social communication.
- Reduced or absent social use of eye contact (assuming adequate vision).
- Reduced or absent "joint attention" (when one person alerts another to something by means of gazing, finger pointing, or other verbal or nonverbal indication for the purpose of sharing interest). This would be evident in the child from lack of:
  - Gaze switching
  - Following a point (looking where the other person points to—may look at hand)
  - Using pointing at or showing objects to share interest

Ideas and Imagination
- Reduced or absent imagination and variety of pretend play.

Unusual or Restricted Interests and/or Rigid and Repetitive Behaviors
- Repetitive "stereotypic" movements such as hand flapping, body rocking while standing, spinning, and finger flicking.
- Repetitive or stereotyped play (e.g., opening and closing doors).
- Overfocused or unusual interests.
- Excessive insistence on following own agenda.
- Extremes of emotional reactivity to change or new situations; insistence on things being "the same."
- Overreaction or underreaction to sensory stimuli, such as textures, sounds, or smells.
- Excessive reaction to the taste, smell, texture, or appearance of food, or having extreme food fads.

Adapted from Baird G, Douglas HR, Murphy MS. Recognizing and diagnosing autism in children and young people: Summary of NICE guidance. *BMJ*. 2011;343:d6360, Box 1, p. 901.

unusual, such as an interest in brands of vehicles, license plate numbers, or fans and heating systems. These interests interfere with social interactions; a child may only want to talk about their area of interest or may insist that peers act out a particular story in a rigid and inflexible manner.

Hyporeactivity or Hyperreactivity to Sensory Input

Children with ASD may be overly sensitive to sensory input, such as noise, smells, or texture. Children may scream or react strongly when they hear a siren or vacuum and may gag and choke with certain foods or odors. They may refuse to wear certain clothing or may become very distressed with bathing or with cutting nails and hair. Conversely, some affected children seem to crave sensory input. They may engage in repetitive jumping or hugging and may smell or lick objects or people. Young children may inappropriately touch the face or hair of others.

Diagnosing ASD with DSM-5 criteria can be challenging in very young children because of reduced expression of repetitive behaviors, particularly stereotyped behavior and intense interests. Studies monitoring development in high-risk young children who have an older sibling with ASD indicate these additional symptoms may emerge over time. This creates a dilemma for specialty clinicians evaluating very young children for ASD, because they may not be able to endorse sufficient symptoms to make an early diagnosis and access specialized intervention services.

Severity Levels Defined in DSM-5

Severity levels in ASD are based on the level of support the individual requires in each of the major domains impacted—social communication and restricted interests and repetitive behavior. Levels range from "needing support" (level 1), to "needing substantial support" (level 2), to "needing very substantial support" (level 3) (Table 58.4).

Specifiers Defined in DSM-5

A formal diagnosis of ASD also includes documenting associated conditions, including whether the individual has cognitive and/or language impairment; any related medical, genetic, or environmental factors; and any other neurodevelopmental or behavioral health conditions, including catatonia (Table 58.5). This process helps to better characterize the presentation in an individual child and ensures that the diagnosis has been made by considering the symptoms in the context of the child's current cognitive and language abilities.

EPIDEMIOLOGY

The prevalence of ASD is estimated at 1 in 36 persons by the U.S. Centers for Disease Control and Prevention (CDC). This information comes from prevalence data of 8-year-olds derived from 11 sites participating in the Autism and Developmental Disabilities Network (ADDM) and shows a greater than 300% increase in prevalence since systematic surveillance began in the year 2000. The increased prevalence relates, at least in part, to improved diagnosis and case finding, as well as inclusion of less severe presentations within the autism *spectrum*. There is a 4:1 male predominance, although new emerging information suggests that the prevalence in females may be higher than previously believed. Females with ASD often use "camouflaging," which is intentionally or unconsciously hiding social communication difficulties by mimicking the facial expressions of others, having more effective compensatory behaviors, and displaying less clearly unusual preoccupying interests. All of these things, including clinician bias, may decrease girls with ASD being diagnosed. The prevalence is increased in siblings (up to 18% recurrence rate) and particularly in identical twins. There are no racial or ethnic differences in prevalence. Individuals from racial minorities and lower socioeconomic status are at risk for later

Table 58.4 DSM-5 Severity Levels for Autism Spectrum Disorder

SEVERITY LEVEL	SOCIAL COMMUNICATION	RESTRICTED, REPETITIVE BEHAVIORS
Level 3 "Requiring very substantial support"	Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. *For example,* a person with few words of intelligible speech who rarely initiates interaction and, when he or she does, makes unusual approaches to meet needs only and responds to only very direct social approaches.	Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great distress/difficulty changing focus or action.
Level 2 "Requiring substantial support"	Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place; limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. *For example,* a person who speaks simple sentences, whose interaction is limited to narrow special interests, and who has markedly odd nonverbal communication.	Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and interfere with functioning in a variety of contexts. Distress and/or difficulty changing focus or action.
Level 1 "Requiring support"	Without supports in place, deficits in social communication cause noticeable impairments. Difficulty initiating social interactions, and clear examples of atypical or unsuccessful responses to social overtures of others. May appear to have decreased interest in social interactions. *For example,* a person who is able to speak in full sentences and engages in communication but whose to-and-fro conversation with others fails and whose attempts to make friends are odd and typically unsuccessful.	Inflexibility of behavior causes significant interference with functioning in one or more contexts. Difficulty switching between activities. Problems of organization and planning hamper independence.

From the Diagnostic and Statistical Manual of Mental Disorders, 5th ed (Copyright 2013). American Psychiatric Association, p. 52.

diagnosis, although the most recent prevalence data suggest that this gap is closing.

ETIOLOGY

The etiology of ASD is thought to result from disrupted neural connectivity and is primarily impacted by genetic variations affecting early brain development. Animal models and studies of individuals with ASD indicate changes in brain volume and neural cell density in the limbic system, cerebellum, and frontotemporal regions. One study documented changes in early brain development, characterized as "hyperexpansion of cortical surface area," at age 6-12 months on brain MRI, which correlated with later development of impaired social skills. Functional studies show abnormalities of processing information, particularly related to foundational social skills such as facial recognition. The disruptions in early brain development likely are responsive to treatment. Early developmental therapies in young children with ASD have demonstrated the capacity for normalization of electrophysiologic response to visual stimuli, including faces.

Numerous genes involved in brain development and synaptic function have been associated with ASD. Pathogenic variants that include large genetic deletions or duplications and small sequencing changes have been implicated; these can be inherited or occur de novo. Heterozygous mutations in genes, such as present in deletion or duplication of 15q11.2 or 16p11.2, may have variable expression within a family. Rare recessive mutations have been implicated in some populations with high levels of consanguinity. Patients with a number of genetic syndromes (e.g., fragile X, Down, Smith-Lemli-Opitz, Rett, Angelman, Timothy, Joubert), as well as disorders of metabolism and mitochondrial function have higher rates of ASD than the general population (Tables 58.5, 58.6, and 58.7).

There is also possible evidence for environmental contributions to ASD. Older maternal or paternal age may increase the risk of ASD. In addition, factors influencing the intrauterine environment, such as maternal obesity or overweight, short interval from prior pregnancy, premature birth, and certain prenatal infections (e.g., rubella, cytomegalovirus), are associated with ASD. Population-level associations have been investigated for environmental toxins such as organophosphates, pesticides, air pollution, and volatile organic compounds. An epigenetic model is considered one explanation for the etiology; individuals with genetic vulnerability may be more sensitive to environmental factors influencing early brain development.

Despite frequent concerns from families that vaccines or the preservatives in vaccines lead to ASD, *there is no evidence to support this claim.* Multiple research studies and meta-analyses have failed to show an association of vaccines with ASD.

No biomarkers are available yet, but there is emerging evidence from neuroimaging findings, electrophysiologic testing, and eye tracking that hold the promise for presymptomatic detection along with accurate clinical diagnosis and prognostic assessment.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ASD is complex because many conditions in the differential can also occur with ASD. The most important conditions to consider in young children are language disorder (see Chapter 53), ID or GDD (Chapter 56), and hearing loss (Chapter 55). Children with **language disorder** may have impairments in social communication and play; their social and play skills, however, are typically on par with their language level. In addition, they do not have associated restricted and repetitive behavior or atypical use of language, such as scripting. The diagnosis of **social communication disorder** is also distinguished from ASD by the lack of restrictive and repetitive behaviors. Children with **ID** or **GDD** may have delays in social and communication skills as well as stereotyped behavior. However, social and communication skills are typically commensurate with their cognitive and adaptive functioning. Children with **hearing loss** may present with some "red flags" for ASD, such as poor response to name. However, they typically develop nonverbal communication and play skills as expected and do not have stereotyped or restricted behavior patterns.

In older children, disorders of attention, learning, and mood regulation must be considered in the differential diagnosis of ASD. Children with **attention-deficit/hyperactivity disorder (ADHD)** may present with reduced eye contact and response to name caused by poor attention rather than lack of social awareness. Children with ADHD, however, do not have associated impairments in shared enjoyment and social reciprocity or repetitive behaviors. Children with **social anxiety** or other anxiety disorders may present with some symptoms suggestive of ASD. Shy children may have reduced eye contact and social initiation. Anxious children can be resistant to change and prefer familiar routines. Children with anxiety, however, typically will have preserved social interest and insight and will not exhibit high levels of stereotyped behaviors. **Reactive attachment disorder** can be difficult to distinguish from ASD, particularly in younger children with a history of prolonged

Table 58.5 Common Co-occurring Conditions in Autism Spectrum Disorder (ASD)

COMORBIDITY	INDIVIDUALS WITH AUTISM AFFECTED	COMMENTS
DEVELOPMENTAL DISORDERS		
Intellectual disability	~45%	Prevalence estimate is affected by the diagnostic boundary and definition of intelligence (e.g., whether verbal ability is used as a criterion). In individuals, discrepant performance between subtests is common.
Language disorders	Variable	An autism-specific language profile (separate from language disorders) exists, but with substantial interindividual variability.
Tic disorders	14–38%	~6.5% have Tourette syndrome.
Motor abnormality	≤79%	See Table 58.2.
GENERAL MEDICAL DISORDERS		
Epilepsy	35-46%	Increased frequency in individuals with intellectual disability or genetic syndromes. Two peaks of onset: early childhood and adolescence. Increases risk of poor outcome.
Gastrointestinal problems	9–70%	Common symptoms include chronic constipation, abdominal pain, chronic diarrhea, cyclic vomiting, and gastroesophageal reflux. Associated disorders include gastritis, esophagitis, gastroesophageal reflux disease, inflammatory bowel disease, celiac disease, Crohn disease, and colitis.
Immune dysregulation	≤38%	Associated with allergic and autoimmune disorders.
Genetic disorders	10–20%	Collectively called *syndromic autism.* Examples include fragile X syndrome (21–50% of individuals affected have autism), Rett syndrome (most have autistic features but with profiles different from idiopathic autism), tuberous sclerosis complex (24–60%), Down syndrome (5–39%), phenylketonuria (5–20%), CHARGE syndrome* (15–50%), Angelman syndrome (50–81%), Timothy syndrome (60–70%), and Joubert syndrome (~40%).
Sleep disorders	50–80%	Insomnia is the most common.
BEHAVIORAL HEALTH DISORDERS		
Any behavioral health disorder	70–90%	
ADHD	40–70%	
Anxiety	~40%	Common across all age-groups. Most common are social anxiety disorder (13–29% of individuals with autism) and generalized anxiety disorder (13–22%). High-functioning individuals are more susceptible (or symptoms are more detectable).
Catatonia	Unknown	Autism shutdown disorder similar to Down syndrome disintegrative disorder (see Chapters 47.3 and 57).
Depression	12–70%	Common in adults, less common in children. High-functioning adults who are less socially impaired are more susceptible (or symptoms are more detectable).
Obsessive-compulsive disorder (OCD)	7–24%	Shares the repetitive behavior domain with autism that could cut across nosologic categories. Important to distinguish between repetitive behaviors that do not involve intrusive, anxiety-causing thoughts or obsessions (part of autism) and those that do (and are part of OCD).
Psychotic disorders	12–17%	Mainly in adults. Most commonly recurrent hallucinosis. High frequency of autism-like features (even a diagnosis of ASD) preceding adult-onset (52%) and childhood-onset schizophrenia (30–50%).
Substance use disorders	≤16%	Potentially because individual is using substances as self-medication to relieve anxiety.
Oppositional defiant disorder	16–28%	Oppositional behaviors could be a manifestation of anxiety, resistance to change, stubborn belief in the correctness of own point of view, difficulty seeing another's point of view, poor awareness of the effect of own behavior on others, or no interest in social compliance.
Eating disorders	10-21%	Avoidant/restrictive food intake may lead to nutrient deficiencies and poor growth.
PERSONALITY DISORDERS†		
Paranoid personality disorder	0–19%	Could be secondary to difficulty understanding others' intentions and negative interpersonal experiences.
Schizoid personality disorder	21–26%	Partly overlapping diagnostic criteria.
Schizotypal personality disorder	2–13%	Some overlapping criteria, especially those shared with schizoid personality disorder.
Borderline personality disorder	0–9%	Could have similarity in behaviors (e.g., difficulties in interpersonal relationships, misattributing hostile intentions, problems with affect regulation), which requires careful differential diagnosis. Could be a misdiagnosis of autism, particularly in females.
Obsessive-compulsive personality disorder	19–32%	Partly overlapping diagnostic criteria.
Avoidant personality disorder	13–25%	Could be secondary to repeated failure in social experiences.

Table 58.5 Common Co-occurring Conditions in Autism Spectrum Disorder (ASD)—cont'd

COMORBIDITY	INDIVIDUALS WITH AUTISM AFFECTED	COMMENTS
BEHAVIORAL DISORDERS		
Aggressive behaviors	≤68%	Often directed toward caregivers rather than noncaregivers. Could be a result of empathy difficulties, anxiety, sensory overload, disruption of routines, and difficulties with communication.
Self-injurious behaviors	≤50%	Associated with impulsivity and hyperactivity, negative affect, and lower levels of ability and speech. Could signal frustration in individuals with reduced communication, as well as anxiety, sensory overload, or disruption of routines. Could also become a repetitive habit. Could cause tissue damage and need for restraint.
Pica	~36%	More likely in individuals with intellectual disability. Could be a result of a lack of social conformity to cultural categories of what is deemed edible, or sensory exploration, or both.
Suicidal ideation or attempt	11–14%	Risks increase with concurrent depression and behavioral problems and after being teased or bullied.

*Coloboma of the eye; heart defects; atresia of the choanae; retardation of growth and development, or both; genital and urinary abnormalities, or both; and ear abnormalities and deafness.

neglect or trauma. However, social behaviors in these children generally improve with positive caretaking.

The differentiation of ASD from **obsessive-compulsive disorder (OCD)**, tics, and stereotyped behaviors can sometimes be challenging. In general, stereotyped behaviors may be calming or preferred, whereas tics and compulsive routines generally are distressing to the individual. Children with OCD have intense interests, as well as repetitive behaviors and rituals, but do not have impairment in social communication or interaction. Children with **stereotypic movement disorder** will not have impaired social skills or other types of restricted and repetitive behaviors. Children with **Landau Kleffner syndrome (LKS)** present with a loss of skills in language comprehension (auditory verbal agnosia) and verbal expression (aphasia) associated with onset of epileptic seizures during sleep (see Chapter 53). In contrast to ASD, children with LKS usually present with typical early development followed by loss of language function at age 3-6 years.

CO-OCCURRING CONDITIONS

Between 35% and 50% of individuals with ASD have ID, ranging in severity from mild to severe (see Table 58.5). An additional 23% of children have intellectual functioning in the borderline range (IQ = 71-85), and approximately 40% of individuals with ASD are nonverbal. ID is associated with higher rates of both identified genetic conditions and epilepsy. Children with ASD often have associated language impairments, including delays in expressive, receptive, and pragmatic (social) language skills. Language function can range

widely from nonverbal status to age appropriate. Gastrointestinal (GI) problems such as cyclic vomiting, constipation, esophagitis, and gastroesophageal reflux disease (GERD) are reported in up to 70% of children with ASD. Epilepsy occurs in up to 35–46% of children with ASD and presents in two peaks: in early childhood and in adolescence. Children with ID, female gender, and lower gestational age are at higher risk for having seizures.

Overall, between 70% and 90% of children with ASD are identified as having a co-occurring behavioral health condition, with ADHD being the most common, occurring in between 40% and 70% of children with ASD. There are higher rates of anxiety (~40%) and mood disorders in ASD, particularly during adolescence. Children with ASD are also at increased risk for being bullied and may present with secondary irritability, anxiety, or depression. Adolescents may develop gender-nonconforming roles, gender variance, and transgender identities; this may also lead to being bullied. Children with ASD are at high risk for suicidal ideation and attempts. **Catatonia** can also occur, most commonly developing during the teenage years, and may present with changes in activity level, unusual movements, and behavioral regression or loss of skills (Chapter 47.3).

Sleep problems, including delayed sleep onset, frequent night waking, and abnormal sleep architecture, are reported in 50–80% of children with ASD. There is some evidence for baseline abnormalities in melatonin secretion. The use of screen-based activities such as television, computers, or tablets before bedtime can inhibit melatonin secretion.

Children with ASD commonly have high rates of feeding and toileting problems resulting from resistance to change, sensory sensitivity, and repetitive behavior patterns. Many children with ASD have **restrictive feeding patterns** and food selectivity. DSM-5 introduced the diagnosis of avoidant and restrictive food intake disorder (ARFID) that, although not specific to children with ASD, describes a pattern of a severely disturbed eating experience resulting in nutritional deficiency or inadequate weight gain and may affect as many as 21% of children with ASD. Restrictive eating patterns may lead to nutritional deficiencies, such as scurvy, rickets, anemia, or protein malnutrition. Children with ASD also have higher rates of overweight, possibly because of diets higher in carbohydrates, reduced physical activity, use of food rewards to regulate behavior, and side effects from medications used for managing mood and behavior. As many as 25% of preschool-age children with ASD have pica (eating of nonfood items), and this tends to persist in children with co-occurring ID.

Self-injury and aggression are common in ASD patients, but most common in individuals with lower cognitive function and limited language. Sleep deprivation, nutritional deficits, pain, epilepsy, and medication side effects may contribute to these behaviors.

Wandering frequently co-occurs with ASD, with nearly 50% of children between 4 and 10 years of age reported as trying to elope. In children who were missing long enough to call the police, approximately 66% were at risk for traffic-related injury and nearly 30% had near-drowning events, which is the leading cause of death in children who wander.

SCREENING

The American Academy of Pediatrics recommends screening for ASD for *all* children at age 18 months and 24 months (see Chapter 28). Screening should also occur when there is increased risk for ASD, such as a child with an older sibling who has ASD, or whenever there is concern for possible ASD. Screening can be done by a parent checklist or direct assessment. The most frequently used screening tool is the *Modified Checklist for Autism, Revised/Follow-Up Interview* (MCHAT-R/FU), a 20-item parent report measure, with additional standardized parent interview completed for intermediate scores. The MCHAT-R/FU can be used from age 16-30 months. Children who score ≥8 or between 3 and 7 after the parent interview are at high risk for a diagnosis of ASD or some developmental delay. The Parent's Observation of Social Interaction (POSI) is another commonly used autism specific screener. It includes seven items.

ASSESSMENT

Diagnostic assessment optimally should include medical evaluation and assessment of the child's cognitive, language, and adaptive function. Developmental-behavioral pediatricians, neurodevelopmental disability specialists, neurologists, psychiatrists, and psychologists are qualified to make a formal diagnosis of ASD. Other specialists, including speech-language pathologists and occupational therapists, should also be included depending on the child's age and the presenting concerns.

Assessment of ASD includes direct observation of the child to evaluate social-communicative skills and behavior. Informal observation can be supplemented with structured diagnostic tools such as the *Autism Diagnostic Observation Schedule, Second Edition* (ADOS-2) or the Toddler module (ADOS-T). These structured play-based assessments provide social prompts and opportunities to evaluate the frequency and quality of a child's social responsiveness to, initiation, and maintenance of social interactions, the capacity for joint attention and shared enjoyment; the child's behavioral flexibility; and the presence of repetitive patterns of behavior and preoccupying interests. These measures also provide some understanding of a child's insight about social relationships and emotional awareness. The ADOS-2 and ADOS-T are not required for accurate diagnosis and do not stand alone, but rather can be used to augment a careful history and observation. The *Childhood Autism Rating Scale, Second Edition* (CARS-2) is a 15-item direct clinical observation instrument that can assist clinicians in the diagnosis of ASD. The *Autism Diagnostic Interview-Revised* (ADI-R) is a lengthy clinical interview tool that is used primarily in research settings because it takes several hours to administer. Other tools include standardized rating scales, such as the Social Responsiveness Scale or the Social Communication Questionnaire, that parents and teachers can complete to report on the child's social skills and behaviors. There is an emergence of the use of telehealth to assess children with ASD, and preliminary studies have suggested that 80% of children could be determined to have or not have ASD with reasonable certainty.

Medical evaluation should include a thorough history and detailed physical examination of the child, including direct behavioral observations of communication and play. In addition, the examination should include measurement of head circumference, careful evaluation for dysmorphic features, and screening for tuberous sclerosis with Wood lamp exam. Children with ASD should have genetic testing, an audiology examination to rule out hearing loss, and in children with pica, a lead test (Table 58.8).

There are currently several specialty-specific clinical guidelines for genetic evaluation of children diagnosed with ASD. Genetic testing is shown to impact clinical decision-making, but no studies have evaluated the impact of genetic testing on the outcome for the child. The American College of Medical Genetics recommends a tiered approach to genetic testing.

Initial Etiologic Assessment

All children with ASD should have a **chromosomal microarray (CMA)**. CMA will be positive in 10–15% of individuals with ASD. The rate is increased to almost 30% in individuals who have complex presentations, such as associated microcephaly, dysmorphic features, congenital anomalies, or seizures. CMA technology will identify copy number variants but not DNA sequencing errors, balanced translocations, or abnormalities in trinucleotide repeat length. *Fragile X DNA testing is recommended for all males with ASD.* Fragile X testing should also be considered in females with physical features suggestive of fragile X syndrome or with a family history of fragile X, X-linked pattern of ID, tremor/ataxia, or premature ovarian failure (see Chapter 59).

Second Tier Etiologic Assessment

Females with ASD should have testing for pathologic variants in the *MeCP2* gene. Males who have hypotonia, drooling, and frequent respiratory infections should have *MeCP2* deletion/duplication testing. All individuals with ASD and a head circumference greater than 2.5

Table 58.8 Medical and Genetic Evaluation of Children with Autism Spectrum Disorder

PHYSICAL EXAMINATION
Dysmorphic physical features
Muscle tone and reflexes
Head circumference
Wood lamp examination for tuberous sclerosis
DIAGNOSTIC TESTING
Chromosomal microarray (CMA) in all individuals
Fragile X DNA test in males
Audiology and vision evaluation
Lead test in children with pica
ADDITIONAL TARGETED GENETIC TESTING
Fragile X DNA test in females with symptoms suggestive of fragile X, family history of X-linked intellectual disability, tremor, ataxia, or premature ovarian failure
MeCP2 sequencing in females
PTEN testing if head circumference >2.5 standard deviations (SD) above the mean
MeCP2 deletion/duplication testing in males with significant developmental regression, drooling, respiratory infections, and hypotonia
Karyotype if unable to obtain CMA or if balanced translocation suspected
ADDITIONAL TARGETED DIAGNOSTIC TESTING
Electroencephalogram (EEG) in children with seizures, staring spells, or developmental regression
Brain MRI in children with dysmorphology, microcephaly, focal neurologic findings, seizures, severe hypotonia, or developmental regression
Metabolic testing in children with developmental regression, hypotonia, seizures, food intolerance, cyclic vomiting, lethargy, hearing loss, ataxia, or course facial features
Exome or genome sequencing if atypical features are present (behavioral or dysmorphic) (see Table 56.1)

Data from Schaefer GB, Mendelsohn NJ. Clinical genetics evaluation in identifying the etiology of autism spectrum disorders: 2013 guideline revisions. *Genet Med.* 2013;15(5):399–407 and Lord C, Charman T, Havdahl A, et al. The Lancet Commission on the future of care and clinical research in autism. *Lancet.* 2022;399:271–326.

standard deviations (SD) above the mean should have testing for pathologic variants in the *PTEN* gene because there is a risk for hamartoma tumor disorders (Cowden, Proteus-like, Bannayan-Riley-Ruvakaba syndromes) in these individuals. Cytogenetic testing (karyotype) has a lower yield than CMA. Karyotype is recommended if microarray is not available and in children with suspected balanced translocation, such as history of multiple prior miscarriages.

Further medical diagnostic testing is indicated by the child's history and presentation. Brain imaging (MRI) is indicated in cases of microcephaly, significant developmental regression, seizures, or focal findings on neurologic examination. Because of the high rate (up to 25%) of macrocephaly in ASD, imaging is not indicated for macrocephaly alone. MRI is not recommended for minor language regression (loss of a few words) during the second year of life that is often described in toddlers with ASD. Children with concern for seizures, spells, or developmental regression should have an electroencephalogram (EEG). Metabolic screening is indicated for children with signs of a metabolic or mitochondrial disorder, such as developmental regression, weakness, fatigue, lethargy, cyclic vomiting, or seizures (see Table 58.7 and Chapters 56 and 104).

Next-Generation Sequencing

Whole exome sequencing (WES) can identify single-nucleotide variants, including pathogenic loss of function mutations and missense mutations; studies have identified a molecular diagnosis in nearly 30% of individuals tested because of the presence of a neurodevelopmental disorder. If the initial genetic testing is negative, clinicians should consider ordering this test in conjunction with genetic counseling to aid in understanding results.

TREATMENT AND MANAGEMENT

Approaches to Intervention

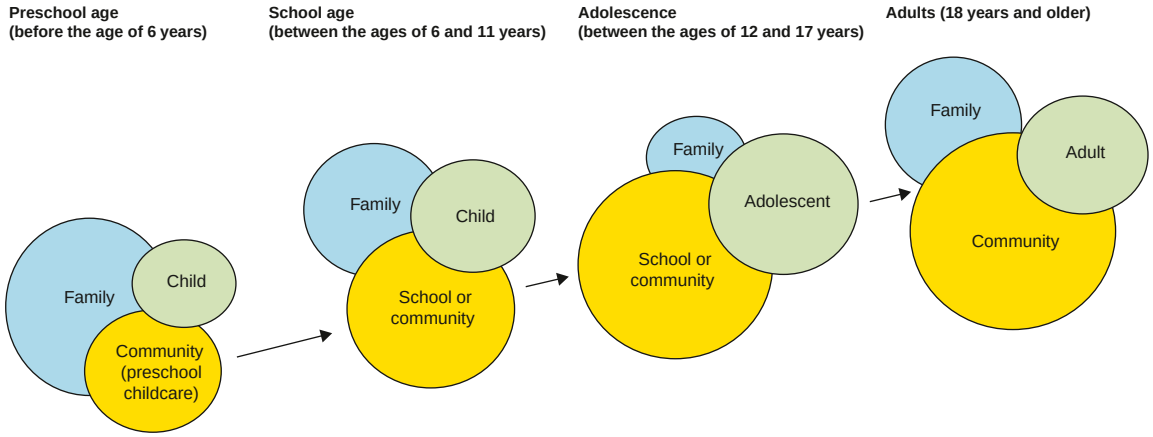
The primary treatment for ASD is done outside the medical setting and includes developmental and educational programming (Fig. 58.1). Numerous resources have been developed that can help families in the complex process of treatment planning (Table 58.9). Intensive behavioral therapies have the strongest evidence to date. Earlier age at initiation of treatment and higher intensity of treatment are associated with better outcomes, although recent studies comparing two different treatments at different levels of intensity (15 vs 25 hr/wk) did not show significant differences between groups in any of the outcomes assessed. Programming must be individualized, and no approach is successful for all children. In addition, research treatments are often conducted with a high level of intensity and fidelity that is difficult to scale up or reproduce in community settings. Higher cognitive, play, and joint attention skills and lower symptom severity at baseline are predictors for better outcomes in core symptoms, intellectual function, and language function.

There are many evidence-based approaches to treating children with ASD, with three main approaches identified. The intervention with the strongest evidence base is **applied behavioral analysis (ABA)**, which is based on the principles of direct incremental teaching of skills within a traditional behavioral framework using reinforcement of desired behavior, careful data collection, and analysis and adjustment of the treatment program based on review of data. The second is **developmental relationship-based intervention (DRBI)**, which includes parent-mediated interventions that focus on building warm, meaningful interaction to improve communication, learning, and problem solving. The best-known approach in this category is **Floortime.** The third approach is the **naturalistic developmental behavioral intervention**, which builds upon ABA to incorporate more choices for children and is implemented in natural situations. Comprehensive models integrating behavioral and developmental approaches that build on key foundational skills, such as joint attention, shared enjoyment, and reciprocal communication, show strong evidence of efficacy for young children, particularly toddlers, with ASD. Examples include the *Early Start Denver Model* (ESDM), *Joint Attention Symbolic Play Engagement and Regulation* (JASPER), and *Social Communication/Emotional Regulation/Transactional Support* (SCERTS).

Educational approaches such as the *Treatment and Education of Autistic and Communication Handicapped Children* (TEACCH) incorporate structured teaching, visual supports, and adjustment of the environment to the individual needs of students with ASD, such as difficulty with communication, understanding time, and need for routine. These approaches have demonstrated efficacy for improved cognitive and adaptive skills. For older children with more severe symptoms, approaches that use behavioral principles in addition to adjusting the environment may be most effective.

Speech and language therapy can help build vocabulary, comprehension, and pragmatic skills. Children with ASD benefit from visual supports for comprehension, understanding expectations, and communicating their needs. **Augmentative communication** approaches using photographs or picture icons can improve comprehension and ability to communicate (see Chapter 54). There are a range of options with varying levels of complexity, flexibility, and technology. Using augmentative communication does not inhibit acquisition of verbal language. On the contrary, supporting a child's language development with augmentative supports can facilitate the development of spoken language, even in older children.

Additional strategies to build social skills are used for school-age children and adolescents and may be administered in the school or community setting by a variety of specialists, including speech therapists, psychologists, and counselors. **Social skills programs** that include training peer mentors have higher rates of efficacy.



Family
- Family psychoeducation
- Family coaching around core features
- Parent-mediated treatments (eg, JASPER, Early Social Interaction, and PACT)
- Behavior management (as advocates)

Child
- Specific short-term therapies (eg, JASPER)
- General approaches (eg, PRT, Project ImPACT, and DTT)
- Comprehensive curricula (eg, ESDM and Lovaas approach
- Specific disciplines (eg, occupational therapy and speech)

Community
- Support in childcare and preschool (no evidence)

Occupational and physical therapy may be indicated for individuals with motor delay and difficulty acquiring adaptive skills such as dressing and toileting.

For some high school students with ASD, training in life skills and vocational skills is critical for maximizing independence in adulthood. Training may focus on basic self-care (e.g., dressing, hygiene), functional academics (e.g., money management, banking skills), learning to fill out a job application, and understanding how to behave with strangers and in work settings. Social skills and job coaching may be needed even for adolescents with strong cognitive and academic function, because they may struggle with social perception and may be vulnerable to exploitation by others.

There continue to be disparities in regard to accessing care, with racially and ethnically minoritized groups and children from low-income families showing less access to acute care and specialized, community and educational services, when compared with higher-income and White families.

Co-occurring Conditions

Additional medical or behavioral health treatment is often required for the management of co-occurring conditions in ASD. Seizures occur in up to 35% of children with ASD and should be managed with appropriate antiepileptic therapy (see Chapter 633). GI problems (e.g., cyclic vomiting, constipation, esophagitis, GERD) may present with nonspecific irritability, sleep disturbance, self-injury, aggression, and signs of pain or discomfort, such as crying, and can be managed with the same approaches used in typically

Table 58.10 Common Pharmacologic Treatments in Autism Spectrum Disorder (ASD)

TARGET SYMPTOM	MEDICATION CLASS*	EFFECTS	SIDE EFFECTS	MONITORING
Hyperactivity and/or Inattention	Stimulants	Decreased hyperactivity, impulsivity, improved attention	Activation, irritability, emotional lability, lethargy/social withdrawal, stomach ache, reduced appetite, insomnia, increased stereotypy	Height, weight, BP, HR
	α_2-Agonists	Decreased hyperactivity, impulsivity, improved attention	Drowsiness, irritability, enuresis, decreased appetite, dry mouth, hypotension	Height, weight, BP, HR
	Selective norepinephrine reuptake inhibitor	Decreased hyperactivity, impulsivity, improved attention	Irritability, decreased appetite, fatigue, stomach ache, nausea, vomiting, racing heart rate	Height, weight, BP, HR
Anxiety	Selective serotonin reuptake inhibitors	Decreased anxiety	Activation, hyperactivity, inattention, sedation, change in appetite, insomnia, stomachache, diarrhea Citalopram: prolonged QTc interval	Weight, BP, HR
Irritability	Atypical antipsychotics (risperidone, aripiprazole)	Decreased irritability, aggression, self-injurious behavior, repetitive behavior, hyperactivity	Somnolence, weight gain, extrapyramidal movements, drooling, tremor, dizziness, vomiting, gynecomastia	Weight, BP, HR Monitor CBC, cholesterol, ALT, AST, prolactin, glucose or hemoglobin A_{1c}
Insomnia	Melatonin	Shortened sleep onset	Nightmares, enuresis	—

*Specific medication names are provided in parentheses when there is a Food and Drug Administration (FDA)–approved indication for the use of the medication to treat the symptom in children with ASD. Further information about these medications is available in Chapter 33.
BP, Blood pressure; HR, heart rate; CBC, complete blood count; ALT, alanine transaminase; AST, aspartate transaminase.

developing children. Children with pica should have lead and iron levels monitored.

Management of co-occurring attention and mood disorders is similar to that for typically developing children. Strategies to increase structure and organization in the environment and use of visual supports (e.g., schedules) can improve attention and reduce anxiety. Some children with ASD benefit from modified cognitive-behavioral therapy to address anxiety and OCD. (see Chapter 31).

Strategies to promote **sleep hygiene** and use of behavioral approaches, such as structured bedtime routines, can address delayed sleep onset. Other medical problems, such as epilepsy or GERD, can also contribute to poor sleep and should be treated directly. In cases refractory to behavioral approaches, medications may be used.

Structured behavioral approaches for delayed toilet training in concert with treatment to prevent constipation are often needed for children with ASD. For children with highly restrictive diets, nutrition counseling and behaviorally based feeding therapy may be needed to address poor caloric intake or lack of nutritional quality. Because of limited diets, children with ASD may be at risk for low levels of calcium, vitamins C and D, and iron. Children who are overweight may still have poor nutrition as a result of restrictive diets.

Irritability is a nonspecific symptom and can be a reflection of pain, anxiety, distress, or lack of sleep. Children with ASD are prone to irritability because of their difficulty tolerating change and their limited communication skills. Management of irritability includes evaluating carefully for medical problems that may be causing pain and for any factors in the child's home or school environment that may be causing distress. Possible causes of distress range from common experiences such as changes in the routine to undisclosed abuse or bullying. Treatment should be targeted first at any underlying cause. Medications are often used to treat irritability in ASD, but should only be used after appropriate behavioral and communication supports have been implemented.

Pharmacology

There are currently no medications that treat the core symptoms of ASD. Medications can be used to target specific co-occurring conditions or symptoms (Table 58.10; see also Table 58.5). Families should be cautioned, however, that the effect size may be lower and the rate of medication side effects higher in children with ASD.

Preliminary data suggested that intranasal therapy with neuropeptide oxytocin may improve social functioning in children with ASD, particularly those with low pretreatment oxytocin levels, but a recent randomized trial did not demonstrate any effect of oxytocin on social or cognitive functioning.

There is evidence to support the use of stimulant medications, atomoxetine, and α-agonists for ADHD in ASD. Selective serotonin reuptake inhibitors (SSRIs) can be used for anxiety and OCD and in adolescents may also be useful for depression. Benzodiazepines may be useful for situational anxiety, for example, triggered by dental and medical procedures or air travel. Medications used to treat ADHD and anxiety may result in activation or irritability in ASD and require careful monitoring.

Melatonin can be used to improve sleep onset but will not address night waking. Clonidine or trazodone may be used for sleep onset and maintenance. No medications are specifically labeled for treatment of insomnia in ASD.

The α-adrenergic agonists may be helpful in children who present with significant behavioral dysregulation. There are two atypical antipsychotic medications that have U.S. Food and Drug Administration (FDA) recommendation for irritability and aggression in children with ASD. Both risperidone and aripiprazole have several studies documenting efficacy for reducing irritability, aggression, and self-injury. Secondary improvements in attention and repetitive behavior were also noted. Side effects include weight gain and metabolic syndrome, as well as tardive dyskinesia and extrapyramidal movements. Careful laboratory monitoring is recommended. Mood-stabilizing antiepileptic medications have also been used to treat irritability.

Complementary and Alternative Medicine

Families of children with ASD often use complementary and alternative medicine (CAM) approaches. These treatments can include supplements, dietary changes, and body or physical treatments. There is limited evidence to inform families, who often learn about these treatments from friends and family members, alternative medicine providers, or the internet. For most therapies, evidence is insufficient to show benefit. There is strong evidence that secretin and facilitated communication are not effective. Some therapies, such as hyperbaric oxygen, chelation, and high-dose vitamins, are potentially harmful. For children with restrictive diets, taking a daily multivitamin and 400 IU vitamin D may be indicated, although there is no evidence to support megadoses of vitamins. Similarly, for children with evidence of gluten sensitivity, a trial of a gluten-free diet may be indicated. However, current evidence does not support this as a treatment for all children with ASD. There is an interest in the use of cannabidiol (CBD) to treat core autism symptoms or co-occurring problems such as anxiety, ADHD, or sleep problems, but there is currently no evidence to support this therapy.

When discussing CAM with a family, it is best to use open and collaborative communication, encouraging them to share their current practices and any questions. Specifically ask if they use any herbal treatments, supplements, or other therapies, such as acupuncture, massage, or chiropractic treatment, and what they have observed since trying the treatment. Provide accurate information regarding potential benefit and risk for any treatment. Educate about "red flags" such as treatments that are marketed as a cure for multiple conditions, that report no risk of side effects, or that are marketed by the clinician recommending the treatment. Encourage families to identify a target symptom, "try one thing at a time," and monitor response carefully.

Transition

Navigating a successful transition to adult care is a key role for the pediatric provider. This process should ideally start as early as age 12-13 years. Parents are faced with a complex and disconnected system of diverse agencies that they need to navigate. Use of structured-visit templates and care coordinators can help ensure that families and their youth with ASD are able to make appropriate decisions about secondary and postsecondary educational programming, vocational training, guardianship, finances, housing, and medical care. High school educational programming should include individualized and meaningful vocational training, as well as instruction regarding sexuality, relationships, safety—particularly internet safety and abuse prevention—finances, travel training, and general self-advocacy. More than half of young adults with ASD remain unemployed and unenrolled in higher education 2 years after high school graduation. Individuals with ASD who are of average cognitive intellectual functioning will need help accessing supports for college or postsecondary skills training and may benefit from referral to their state vocational rehabilitative services and personal life coaches or counselors. Families who have adult children with more significant cognitive disability need information about the range of adult disability services; how to apply for supplemental security income (SSI); and the process for considering guardianship, medical and financial conservatorship, or supported decision making for their adult child. These decisions are complex and must be individualized for the adult with ASD and the family.

OUTCOME

ASD is a lifelong condition. Although a minority of individuals no longer meet criteria for the diagnosis, most will make progress but continue to have some impairment in social, behavioral, learning, language, or emotional functioning as adults. Adult outcome studies are sobering, indicating that many adults with ASD are socially isolated, lack gainful employment or independent living, and have higher rates of depression and anxiety. It is not clear if these data can be extrapolated to younger children currently receiving intensive educational therapies. There is a growing network of adult self-advocates who promote the unique strengths in individuals with ASD. Outcome, as measured by developmental progress and functional independence, is better for individuals who have higher cognitive and language skills and lower ASD severity at initial diagnosis.

Chapter 59

Fragile X Syndromes

Amanda E. Bennett and Marcy Schuster

Fragile X syndrome (FXS) is a genetic disorder associated with intellectual, learning, and behavioral symptoms and some specific physical characteristics. In FXS an expansion of >200 CGG repeats on the distal long arm of chromosome Xq27.3 silences the *FMR1* gene, which leads to a deficiency in fragile X mental retardation protein (FMRP) and affects synaptic function throughout much of the brain. It is the most common heritable cause of intellectual disability and has a prevalence rate of approximately 1 in 4,000 males and 1 in 7,000 females. Like many X-linked disorders, males with fragile X tend to present with more features and more significant impairments than females.

On average, unaffected individuals have 30 CGG repeats in the untranslated region of the *FMR1* gene. Those with 55-200 repeats are described as having the premutation. Females with the premutation are at increased risk of expansion of the number of CGG repeats causing FXS in their children (Table 59.1). When males with the premutation alleles pass them to daughters, they typically remain as premutation alleles. Those with premutation alleles may also have clinical manifestations (Tables 59.2 and 59.3).

Fragile XE syndrome (FRAXE) resembles FXS and manifests within a variable spectrum of intellectual and learning disabilities. The involved gene *(AFF2)* results in an expansion of CCG trinucleotide repeats and is inherited as an X-linked disorder. Symptoms also include aggressive behaviors, agitation, autistic behaviors, clumsiness, and delayed speech and language development. *This form of FXS will not usually be detected with standard fragile X testing.*

EVALUATION AND DIAGNOSIS

The phenotype of FXS early in life can be nonspecific with symptoms such as developmental delay, including motor and language delays, and autistic-like behaviors, such as repetitive motor mannerisms, sensory sensitivities, and deficits in eye contact. Manifestations in early to middle childhood often include problems with learning, attention-deficit/hyperactivity disorder (ADHD), anxiety, and aggressive behaviors. The physical features become more pronounced during or after puberty and include macroorchidism, hyperextensible finger joints, and characteristic facial features, including a long face, large ears, and a prominent square jaw (Fig. 59.1). Females affected with FXS show varying degrees of intellectual disability and/or learning disabilities, and they may present with symptoms of ADHD and anxiety as well.

Children with FXS are at increased risk for ophthalmologic, feeding, and orthopedic problems, as well as recurrent otitis media in early childhood. Females are at increased risk for precocious puberty.

Adolescents should be monitored for seizures and heart murmurs, and adults with FXS are at increased risk for mitral valve prolapse. Adults are also at risk for intention tremor and ataxia and premature menopause, which can also occur in those with the premutation. Table 59.3 includes phenotypic features, clinical signs, and their typical age of onset.

Family History and Premutation Carriers

Collecting a detailed family history can help identify potential risk factors for FXS. Individuals with premutation triplet repeat expansions have been found to have a variety of clinical manifestations. **Fragile X–associated tremor/ataxia syndrome (FXTAS) is a progressive neurodegenerative disorder** that most commonly affects males over age 50 years. Females are less commonly affected and tend to have mild disease. Symptoms include an intention tremor followed by ataxia that may manifest as needing support when walking or with a wide-based gait. Females with premutation triple repeat expansions are at risk for developing **fragile X–associated premature ovarian insufficiency (FXPOI)**. Women with this condition undergo menopause approximately 5 years earlier than women without the condition, but symptoms are variable, with the most severely affected experiencing irregular or absent menstrual periods before age 40 and often infertility. A variety of neuropsychiatric symptoms, including anxiety, ADHD, social deficits, or autism spectrum disorder (ASD), have also been associated with the premutation. Asking about family members for a history of developmental, behavioral, or learning problems or adult family members with early menopause, fertility challenges, or adult-onset neurologic problems may help to identify risk for a positive fragile X test in a child with developmental or behavioral concerns. Asymptomatic siblings or other family members may benefit from testing to determine premutation status, which can also be associated with the symptoms noted earlier. See Table 59.3 for additional information about clinical symptoms in **premutation carriers**.

Table 59.1 Risk of Expansion of a Premutation to a Full Mutation in Male Offspring Based on Maternal Number of CGG Triplet Repeats

MATERNAL CGG TRIPLET REPEAT NUMBER	RISK FOR EXPANSION OF PREMUTATION TO FULL MUTATION
59-69	37%
70-79	65%
80-89	70%
90-99	95%
100 or more	100%

Copyright Elsevier. All rights reserved; with data from Hersh JH et al. Health supervision for children with fragile X syndrome. *Pediatrics*. 2011;127(5):994–1006, Table 1; and Saul RA et al. FMR1-related disorders. In: Pagon RA et al, eds. *GeneReviews [internet]*. University of Washington; 1993–2018.

Diagnostic Testing

A diagnosis of FXS is possible through PCR and Southern blot analysis of a patient's blood. Positive DNA testing shows an expansion of >200 trinucleotide CGG repeats inside an area of the *FMR1* gene on the X chromosome. Diagnostic testing that reports methylation status of the gene region is preferred because methylation status is inversely correlated with cognitive functioning. Because the physical features of FXS are not always apparent in early childhood, diagnostic testing is recommended for any child who presents with global developmental delay, intellectual disability, or ASD (see Chapters 56 and 58). Any positive test for fragile X should include genetic counseling to inform of inheritance risk, phenotypic variability, and medical conditions associated with FXS and premutation status. Specific gene (*AFF2*) testing for FRAXE should be considered if CGG repeat testing is negative.

Table 59.2 Phenotypic and Genetic Effect of Number of CGG Repeats

VARIATION TYPE	CGG ALLELE SIZE	TYPICAL PHENOTYPE	GENETIC CONSEQUENCES
Full mutation	More than 200 repeats	Males are affected with fragile X syndrome About 50% of females are affected with fragile X syndrome	Repeat expansion and methylation typically result in partial or complete silencing of *FMR1* Females usually benefit from having two X chromosomes, because usually one of them is unaffected (i.e., no expanded CGG repeats) and X-inactivation does not silence all copies of it
Premutation	About 55-200 repeats	Patients typically have normal intellect, and some may have mild manifestations associated with fragile X syndrome Carriers may be at increased risk for fragile X–associated tremor ataxia syndrome and *FMR1*-related primary ovarian insufficiency	FMRP expression is usually not significantly impaired; however, larger mutations may have lowered expression Alleles are at risk for CGG expansion during maternal gametogenesis, and offspring are at risk for fragile X syndrome
Intermediate (gray zone)	About 45-54 repeats	Patient does not have fragile X syndrome caused by CGG repeats	A minority of intermediate/gray zone alleles may have minor instability; however, expansion of CGG repeats is unlikely, and if it occurs, it will not reach full mutation number within a single generation
Normal	About 5-44 repeats	Patient does not have fragile X syndrome caused by CGG repeats	No meiotic or mitotic instability is present; alleles are transmitted without any change in repeat number

FMR1 gene, FMRP translational regulator 1; FMRP, fragile X mental retardation protein.

Table 59.3 Clinical Features of Fragile X Syndrome and Premutation Carriers

COGNITIVE, BEHAVIORAL, AND PHYSICAL CHARACTERISTICS	AGE REPORTED
FULL MUTATION FRAGILE X SYNDROME (>200 CGG REPEATS)	
Hypotonia	Infancy
Reflux	Infancy
Poor suck	Infancy
Developmental delay/intellectual disability (96% males, 64% females)	Early childhood
Autism (46% males, 16% females)	Early childhood
Attention problems (84% males, 67% females)	Early childhood
Hyperactivity (66% males, 30% females)	Early childhood
Anxiety (70% males, 56% females)	Early childhood
Aggression (38% males, 14% females)	Early childhood
Self-injurious behaviors (41% males, 10% females)	Early childhood
Depression (12% males, 22% females)	Early childhood
Recurrent otitis media (>60%)	Early childhood
Seizures (18% males, 7% females)	Early childhood
Strabismus (20%)	Early childhood
Sleep disturbances	Early childhood
Flat feet	Early childhood
Low muscle tone	Early childhood
Hyperextensible joints	Early childhood
Large prominent ears	Early/middle childhood
Elongated face	Early/middle childhood
Large testes	Adolescence
Obesity (30%)	Adolescence
Mitral valve prolapse	Adulthood
Cognitive decline/parkinsonism (17%)	Adulthood
Perseveration	Adulthood
PREMUTATION CARRIERS (55-200 CGG REPEATS)	
Attention problems	Early childhood
Autism spectrum disorder	Early childhood
Seizures	Early childhood
Anxiety	Adolescence
Depression	Adulthood
Hypertension	Adulthood
Sleep disturbances	Adulthood
Migraine	Adulthood
Fibromyalgia	Adulthood
Hypothyroidism	Adulthood
Fragile X–associated primary ovarian insufficiency (FXPOI) (~20%)	Adulthood
Fragile X–associated tremor ataxia syndrome (FXTAS) (40% males, 16% females)	Later adulthood

MANAGEMENT OF FRAGILE X SYNDROME

Management of FXS in children often requires a multidisciplinary approach focused on monitoring for and managing developmental and/or behavioral symptoms. In addition to health supervision visits with a primary care clinician, many children with FXS benefit from ongoing care with a medical professional with experience or knowledge of FXS. Families will also benefit from accessing educational and behavioral health resources in the community.

Educational

Many individuals with FXS will require educational support to meet their needs starting from a young age. **Early intervention** services, including speech therapy, occupational therapy, physical therapy, and special instruction, are often vital components of addressing developmental delays. As a child ages and ongoing assessment occurs, special education support through an **individualized education plan (IEP)** may be warranted (See Chapter 49). There are interventions shown to be specific to the learning needs of individuals with FXS. Biologic males typically demonstrate strengths in receptive language, verbal labeling, simultaneous processing, imitation, and daily living activities. Biologic females typically demonstrate areas of strength in vocabulary, comprehension, reading, writing, spelling, and short-term visual memory. These advantages should be explored when educational interventions are being developed. Areas often in need of interventions for individuals with FXS include improving complex problem solving, maintaining attention, improving impulse control, understanding spatial relationships, and math concepts.

Environmental modifications and adaptive technologies can be an asset for an individual with FXS. This can include a modified keyboard and/or mouse and touch-screen computer options integrated into classroom lessons. A quiet environment with minimal distractions can help improve focus on tasks. Small group and one-on-one instruction for teaching new tasks can minimize anxiety and improve generalization of skills to the larger classroom. Teaching students to request breaks when feeling overwhelmed can minimize overall frustration. Visual schedules, manipulatives, clutter-free areas, and social stories are all interventions to improve compliance and learning.

Behavioral

Individuals with FXS can present with a variety of cognitive and behavioral challenges. ASD is diagnosed in between 50% and 60% of individuals with FXS. ASD is characterized by deficits in communication and social skills along with restricted interests and/or repetitive behaviors that interfere with one's daily life (see Chapter 58). Individuals with FXS can struggle with making eye contact, engaging in conversations, and expressing wants and needs. Often individuals with FXS want social contact but may avoid it due to anxiety. Hyperarousal is a common behavioral symptom, particularly in social situations where eye contact is expected, suggesting the presence of significant sensory aversions. Behavioral interventions that include skill development and anxiety management can be helpful in addressing social skills deficits. Other sensory-aversive behaviors can be related to auditory, visual, or tactile stimuli. Tantrums, and occasionally aggression, can emerge when children with FXS are overstimulated.

Sensory-seeking behaviors can also be present in individuals with FXS. These may include repetitive movements, narrowed interests, rigid routines, and atypical sensory exploration. Behaviors such as rocking, pacing, and jumping could occur to obtain sensory input. Individuals with FXS can become extremely anxious if a routine is changed or if a preferred activity is interrupted. Teaching coping strategies along with the recognition of triggers for anxiety can be helpful as a behavior management strategy.

Individuals with FXS can present with deficits in attention and focus, impulsivity, and/or hyperactivity, particularly during childhood. This can lead to a diagnosis of ADHD (see Chapter 50). These deficits can affect learning in school and require specialized

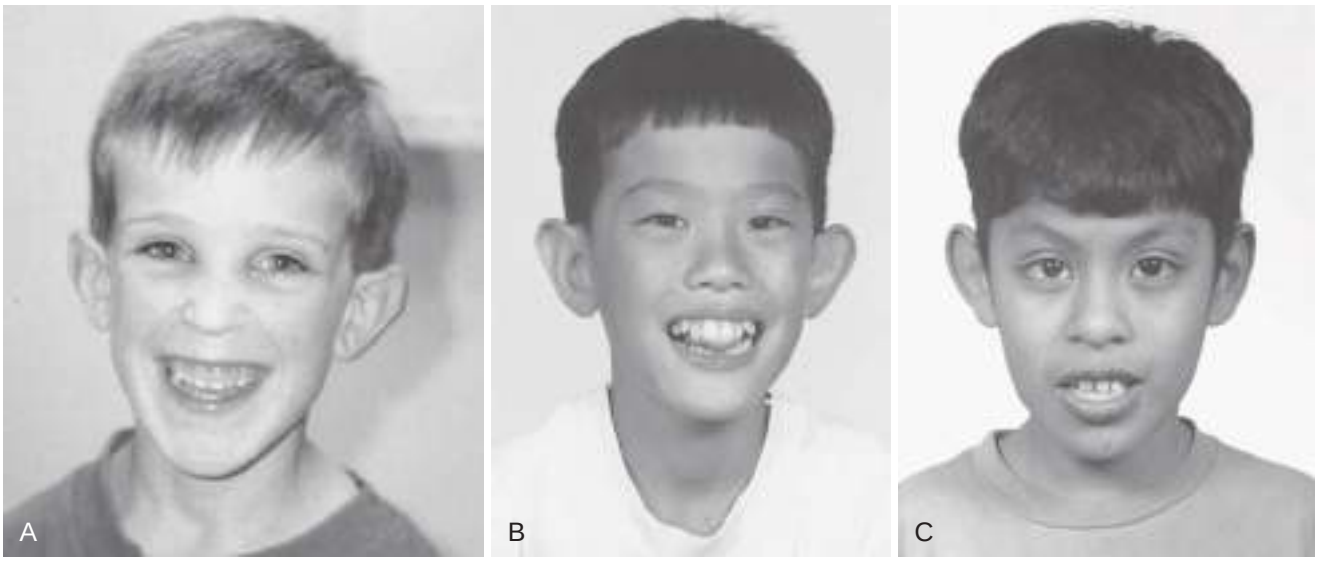

Fig. 59.1 Boys with fragile X syndrome. Note the long faces, prominent jaws, and large ears and the similar characteristics of children from different ethnic groups: European (**A**), Asian (**B**), and Latin American (**C**). *(From Jorde, LB, Carey JC, Bamshad MJ. Medical Genetics, 6th ed. Philadelphia: Elsevier; 2020: Fig. 5.20.)*

instruction or classroom accommodations to help improve focus and participation.

Individuals with FXS can present with aggressive behavior directed toward themselves and toward others. These behaviors are seen in approximately 50% of males with FXS and tend to increase with age. Individuals who exhibit ongoing aggression also typically present with more significant intellectual impairment, communication delays, and anxiety. Aggression can put a strain on caregivers or lead to injury and therefore often emerges as a primary focus of treatment.

Behavior management techniques vary depending on a child's needs. If an ASD diagnosis is present, applied behavioral analysis (ABA) programs are often integrated into treatment. ABA promotes multiple areas of development, including language, emotion, and cognition. ABA focuses on tracking specific behaviors through observation and data collection, learning their antecedents (the event or environment before the behavior occurred), and managing their consequences (the response others have after the behavior occurs) through a structured approach. Most interventions for unwanted behaviors (e.g., aggression or self-injury) aim to change the antecedents to reduce the likelihood of the behavior occurring or to change the consequence in order to make the behavior less rewarding for the individual. Interventions that aim to increase a desired behavior (e.g., complying with an instruction or toilet training) will incorporate environmental changes to remind and encourage the behavior and identify rewarding consequences that can be delivered after the behavior has occurred. ABA interventions delivered during daily living activities, community participation, and family interactions allow for optimal skill development. Special education programs often include similar behavior management techniques throughout the early childhood for individuals with FXS.

Medical

In addition to educational and behavioral management, many children with FXS may present with certain medical conditions and may require additional monitoring or care by a specialist (see Table 59.3). Monitoring in infancy and early childhood should emphasize assessment for orthopedic, growth, and/or feeding concerns. Because young children with FXS are more susceptible to otitis media and may lack communication skills to convey discomfort, a full physical examination, including ear examination, is recommended if a child presents with acute behavior changes. Young children should also be routinely screened for ophthalmologic problems, such as strabismus or astigmatism, and monitored for symptoms related to connective tissue problems, such as hypermobile joints or inguinal hernias. Seizures are more prevalent in children with FXS; symptoms concerning for any type of seizure should be investigated with electroencephalogram (EEG) when the child is both awake and asleep. Although risk for mitral valve prolapse is not typically increased until adulthood, examination for murmurs, clicks, or changes in blood pressure should be performed regularly. Sleep disturbances commonly reported among children with FXS include delayed sleep onset, frequent night waking, and occasionally obstructive sleep apnea. Screening for sleep concerns should be done at every visit, and parents should be counseled on behavioral strategies to address sleep onset and waking challenges (see Chapter 31). Concerns for apnea or snoring may require further evaluation by a sleep specialist or with polysomnography. Medications to help address sleep concerns may include melatonin or clonidine, neither of which is currently approved by the Food and Drug Administration (FDA) for use in children with FXS.

There are currently no approved treatments for the core symptoms of FXS, but many individuals will benefit from medication to address some of the commonly co-occurring behavioral symptoms associated with absence of FMRP. If behavioral strategies are not sufficient to address hyperactivity or impulsivity, a young child (<5 years) may benefit from a trial of an α_2-adrenergic agonist, such as clonidine or guanfacine. School-aged children with FXS often show improvements in hyperactivity, impulsivity, and/or attention problems when treated with a stimulant, but side effects such as irritability or aggression may occur. Selective serotonin reuptake inhibitors (SSRIs) can be safe and effective in reducing anxiety, obsessive-compulsive symptoms, and sometimes aggression in young children with FXS; one trial of sertraline in young children with FXS demonstrated improvements in visual reception and fine motor coordination in 2- to 6-year-olds. Additional analyses demonstrated improvements in expressive language skills for children with FXS and ASD. Treatment with an atypical antipsychotic, such as risperidone or aripiprazole, may be needed in cases of severe anxiety, aggression, or mood instability that have not responded to other medications.

Neurobiologic studies of FXS have identified overactivation of brain glutamate pathways and underactivation of gamma-aminobutyric acid (GABA) pathways leading to studies of

medications targeting these pathways in the hopes that they would improve cognitive outcomes. Although some studies in animal models were encouraging, human trials have yet to demonstrate consistent benefits. Some clinical trials are ongoing.

In addition to continued monitoring for cardiac, seizure, sleep, and behavioral symptoms, health supervision in late childhood and adolescence should also include discussion of adult transition issues, including vocational training, accessing state-specific adult disability services, and transition to adult medical care.

Nutrition

PART V

Chapter 60

Nutritional Requirements

Martine Saint-Cyr, Stephanie W. Waldrop, and Nancy F. Krebs

Nutrition for infants, children, and adolescents should maintain current weight and support normal growth and development. Growth during infancy is rapid, critical for neurocognitive development, and has the highest energy and nutrient requirements relative to body size compared with any other period of growth. It is followed by growth during childhood, when 60% of total growth occurs, and finally by puberty. Nutrition and growth during the first 3 years of life predict adult stature and some health outcomes. Although the antecedents are numerous and occur earlier, the major risk period for linear **growth faltering or stunting** (length- or height-for-age z score ≤-2) is between 6 and 24 months of age. Therefore it is critical to identify nutrient deficiencies promptly and to address them aggressively early in life, because missing them can impart lasting adverse effects on later growth and development.

Dietary intake should meet **energy requirements,** as well as provide the essential macronutrients and micronutrients needed for sustaining the function of multiple vital processes. Nutrient deficiencies can limit growth, impair immune function, affect neurodevelopment, and increase morbidity and mortality. Worldwide, malnutrition and undernutrition are the leading causes of acquired immunodeficiency and a major factor underlying morbidity and mortality in children <5 years of age.

The transition in food supply and the type of nutrition chosen in many developing countries from a traditional to Western diet has resulted in increased life expectancy and adult stature. It is associated with decreases in the incidence of communicable diseases. Unfortunately, the Western diet, characterized by high energy density, more refined grains, and highly processed foods, is also frequently accompanied by decreased physical activity and increases in the incidence and prevalence of noncommunicable diseases such as type 2 diabetes, cardiovascular (CV) disease, obesity, inflammatory bowel disease (IBD), and certain cancers. Consequently, it is important to view the impact of diet and nutrition on health from various perspectives: to prevent deficiency, to promote adequacy, and to prevent or reduce the risk for acquiring diseases associated with excess intakes, such as obesity, diabetes, and CV disease.

Advances in our understanding of the roles of some nutrients such as vitamin D, polyunsaturated fatty acids (PUFAs), and fiber have changed our focus from recommendations about preventing deficiency to recommendations about nutritional intake associated with optimal health. The 2006 World Health Organization (WHO) growth charts, recommended *for all infants and children until age 2 years,* are not only descriptive but also prescriptive on how children with adequate nutrition and healthcare should grow. Identifying and providing appropriate and adequate nutrition in infancy and childhood are critical to supporting normal growth and development, as well as providing the foundation for lifelong health and well-being.

DIETARY REFERENCE INTAKES

The **dietary reference intakes (DRI)** were established by the Food and Nutrition Board of the U.S. Institute of Medicine (IOM), currently known as the National Academy of Medicine (NAM), to provide guidance on the nutrient needs for individuals and groups across different life stages and according to gender (Tables 60.1-60.3 and see Tables 60.5 and 60.6).

The DRI represent a series of indicators that are used as a basis for macronutrient and micronutrient intake recommendations for healthy populations within the United States and Canada. The DRI also serve as an estimation of the Dietary Guidelines for Americans 2020-2025 (DGA) Daily Nutritional Goals. DRI indicators include the estimated

Table 60.1 Equations to Estimate Energy Requirements

INFANTS AND YOUNG CHILDREN: EER (KCAL/DAY) = TEE + ED	
0-3 mo	EER = (89 × weight [kg] − 100) + 175
4-6 mo	EER = (89 × weight [kg] − 100) + 56
7-12 mo	EER = (89 × weight [kg] − 100) + 22
13-36 mo	EER = (89 × weight [kg] − 100) + 20
CHILDREN AND ADOLESCENTS 3-18 YR: EER (KCAL/DAY) = TEE + ED	
BOYS	
3-8 yr	EER = 88.5 − (61.9 × age [yr] + PA × [(26.7 × weight [kg] + (903 × height [m])] + 20
9-18 yr	EER = 88.5 − (61.9 × age [yr] + PA × [(26.7 × weight [kg] + (903 × height [m])] + 25
GIRLS	
3-8 yr	EER = 135.3 − (30.8 × age [yr] + PA [(10 × weight [kg] + (934 × height [m])] + 20
9-18 yr	EER = 135.3 − (30.8 × age [yr] + PA [(10 × weight [kg] + (934 × height [m])] + 25

EER, Estimated energy requirement; TEE, total energy expenditure; ED, energy deposition (energy required for growth /new tissue accretion).
PA indicates the physical activity coefficient:
For boys:
PA = 1.00 (sedentary, estimated physical activity level 1.0-1.4); PA = 1.13 (low active, estimated physical activity level 1.4-1.6); PA = 1.26 (active, estimated physical activity level 1.6-1.9); PA = 1.42 (very active, estimated physical activity level 1.9-2.5)
For girls:
PA = 1.00 (sedentary, estimated physical activity level 1.0-1.4); PA = 1.16 (low active, estimated physical activity level 1.4-1.6); PA = 1.31 (active, estimated physical activity level 1.6-1.9); PA = 1.56 (very active, estimated physical activity level 1.9-2.5)

Table 60.3 Dietary Reference Intakes: Macronutrients

FUNCTION	LIFE STAGE GROUP	RDA OR AI* (g/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION
TOTAL DIGESTIBLE CARBOHYDRATE				
RDA based on its role as the primary energy source for the brain AMDR based on its role as a source of kcal to maintain body weight	*Infants* 0-6 mo 7-12 mo *Children* >1 yr *Pregnancy* ≤18 yr 19-30 yr	 60* 95* 130 175 175	Major types: starches and sugars, grains, and vegetables (corn, pasta, rice, potatoes, and breads) are sources of starch. Natural sugars are found in fruits and juices. Sources of added sugars: soft drinks, candy, fruit drinks, desserts, syrups, and sweeteners.†	No defined intake level for potential adverse effects of total digestible carbohydrate is identified, but the upper end of the AMDR was based on decreasing risk of chronic disease and providing adequate intake of other nutrients. It is suggested that the maximal intake of added sugars be limited to providing no more than 10% of energy.
TOTAL FIBER				
Improves laxation, reduces risk of coronary artery (heart) disease, assists in maintaining normal blood glucose levels	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 yr *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr	 ND ND 19* 25* 31* 38* 38* 26* 26* 25* 28* 28*	Includes dietary fiber naturally present in grains (e.g., oats, wheat, unmilled rice) and functional fiber synthesized or isolated from plants or animals and shown to be of benefit to health.	Dietary fiber can have variable compositions; therefore it is difficult to link a specific source of fiber with a particular adverse effect, especially when phytate is also present in the natural fiber source. As part of an overall healthy diet, a high intake of dietary fiber will not produce deleterious effects in healthy persons. Occasional adverse GI symptoms are observed when consuming some isolated or synthetic fibers, but serious chronic adverse effects have not been observed because of the bulky nature of fibers. Excess consumption is likely to be self-limiting; therefore UL was not set for individual functional fibers.
TOTAL FAT				
Energy source When found in foods, is a source of ω3 and ω6 PUFAs Facilitates absorption of fat-soluble vitamins	*Infants* 0-6 mo 7-12 mo 1-18 yr	 31* 30* Insufficient evidence to determine AI or EAR; see AMDR, Table 60.2.	*Infants:* Human milk or infant formula *Older children:* Butter, margarine, vegetable oils, whole milk, visible fat on meat and poultry products, invisible fat in fish, shellfish, some plant products such as seeds and nuts, bakery products.	UL is not set because there is no defined intake of fat at which adverse effects occur. High fat intake will lead to obesity. Upper end of AMDR is also based on reducing risk of chronic disease and providing adequate intake of other nutrients.† Low fat intake (with high carbohydrate) has been shown to increase plasma triacylglycerol concentrations and decrease HDL cholesterol.
ω6 POLYUNSATURATED FATTY ACIDS				
Essential component of structural membrane lipids, involved with cell signaling Precursor of eicosanoids Required for normal skin function	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 yr *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr *Lactation* ≤18 yr 19-21 yr	 4.4* 4.6* 7* 10* 12* 16* 17* 10* 11* 12* 13* 13* 13* 13*	Nuts, seeds; vegetable oils such as soybean, safflower, corn oil.	There is no defined intake of ω6 level at which adverse effects occur. Upper end of AMDR is based on the lack of evidence that demonstrates long-term safety and human in vitro studies that show increased free radical formation and lipid peroxidation with higher amounts of ω6 fatty acids. Lipid peroxidation is thought to be a component of atherosclerotic plaques.

Continued

Table 60.3 Dietary Reference Intakes: Macronutrients—cont'd

FUNCTION	LIFE STAGE GROUP	RDA OR AI* (g/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION
ω3 POLYUNSATURATED FATTY ACIDS				
Involved with neurologic development and growth Precursor of eicosanoids	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 yr *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr *Lactation* ≤18 yr 19-21 yr	 0.5* 0.5* 0.7* 0.9* 1.2* 1.6* 1.6* 1.0* 1.1* 1.1* 1.4* 1.4* 1.3* 1.3*	Vegetable oils (e.g., soybean, canola, flaxseed oil); fish oils, fatty fish, walnuts†; smaller amounts in meats and eggs.	No defined intake levels for potential adverse effects of ω3 PUFAs are identified. Upper end of AMDR is based on maintaining appropriate balance with ω6 fatty acids and the lack of evidence that demonstrates long-term safety, along with human in vitro studies that show increased free radical formation and lipid peroxidation with higher amounts of PUFAs. Because the longer-chain *n*-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are biologically more potent than their precursor, linolenic acid, much of the work on adverse effects of this group of fatty acids has been on DHA and EPA. Lipid peroxidation is thought to be a component in the development of atherosclerotic plaques.
SATURATED AND TRANS FATTY ACIDS				
The body can synthesize its needs for saturated fatty acids from other sources.		No dietary requirement	Saturated fatty acids are present in animal fats (meat fats and butter fat) and coconut and palm kernel oils. Trans fat: stick margarines, foods containing hydrogenated or partially hydrogenated vegetable shortenings	There is an incremental increase in plasma total and LDL cholesterol concentrations with increased intake of saturated or trans fatty acids; therefore saturated fat intake should be limited to <10% with no trans fat.†‡
CHOLESTEROL				
		No dietary requirement	Sources: liver, eggs, foods that contain eggs (e.g., cheesecake, custard pie)	
PROTEIN AND AMINO ACIDS‡				
Major structural component of all cells in the body Functions as enzymes, in membranes, as transport carriers, and as some hormones During digestion and absorption, dietary protein is broken down to amino acids, which become the building blocks of these structural and functional compounds Nine indispensable amino acids must be provided in the diet; the body can make the other amino acids needed to synthesize specific structures from other amino acids	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr ≥19 yr *Females* 9-13 yr ≥14 yr ≤18 yr 19-21 yr Pregnancy and lactation	 9.1* **11.0** **13** **19** **34** **52** **56** **34** **46** **46** **71**	Proteins from animal sources (e.g., meat, poultry, fish, eggs, milk, cheese, yogurt) provide all nine indispensable amino acids in adequate amounts and are considered "complete proteins." Protein from plants, legumes, grains, nuts, seeds, and vegetables tend to be deficient in ≥1 of the indispensable amino acids and are called "incomplete proteins." Vegan diets adequate in total protein content can be made "complete" by combining sources of incomplete protein, which lack different indispensable amino acids.	No defined intake levels for potential adverse effects of protein are identified. Upper end of AMDR was based on complementing AMDR for carbohydrate and fat for the various age-groups. Lower end of AMDR is set at approximately the RDA.

Note: Starred (*) numbers are Adequate Intake (AI) **bold** numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97–98% of members in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying with confidence the percentage covered by this intake.

AMDR is the range of intake for a particular energy source that is associated with reduced risk of chronic disease while providing intakes of essential nutrients. With consumption in excess of the AMDR, there is a potential for increasing the risk of chronic diseases and/or insufficient intakes of essential nutrients.

ND amounts are not determinable because of a lack of data regarding adverse effects in this age-group and concern with regard to a lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

†2015–2020 Dietary Guidelines for Americans. U.S. Department of Health and Human Services. https://health.gov/dietaryguidelines/2015/.

‡Based on 1.5 g/kg/day for infants, 1.1 g/kg/day for 1-3 yr, 0.95 g/kg/day for 4-13 yr, 0.85 g/kg/day for 14-18 yr, 0.8 g/kg/day for adults, and 1.1 g/kg/day for pregnant (using pre-pregnancy weight) and lactating women.

AI, Adequate intake; AMDR, acceptable macronutrient distribution range; EAR, estimated average requirement; GI, gastrointestinal; HDL, high-density lipoprotein; LDL, low-density lipoprotein; ND, not determinable; PUFAs, polyunsaturated fatty acids; RDA, recommended dietary allowance; UL, upper limit of normal.

Institute of Medicine. 2005. Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids. https://doi.org/10.17226/10490.
Adapted and reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, DC.

average requirement (EAR), the recommended dietary allowance (RDA), and the tolerable upper limit of intake (UL) (Figs. 60.1 and 60.2). In addition, the concept of the DRI is also applicable to the estimated energy requirement (EER) and the acceptable macronutrient distribution range (AMDR).

The EAR is an estimated average of the daily nutrient intake required to meet the nutritional needs of 50% of the population; it is applied to the assessment of a population's intake. The RDA provides an estimate of the minimum daily average intake for a nutrient that meets the nutritional needs for more than 97% of individuals in a population, and it can be used as a guideline for individuals to avoid deficiency. When an EAR cannot be derived, an RDA cannot be calculated; therefore an **adequate intake (AI)** is developed as a guideline for individuals based on the best available data and scientific consensus. The UL denotes the highest average daily intake with no associated adverse health effects for almost all individuals in a given population. Figure 60.2 shows the relationships among EAR, RDA, and UL.

ENERGY

Energy balance constitutes both caloric intake, most often derived from food, *and* metabolic caloric expenditure. An imbalance between energy intake and energy expenditure can lead to undesirable health consequences. *Inadequate* energy intake can lead to weight faltering, catabolism of body tissues (e.g., fat and muscle), diminished immunity, and increased morbidity and mortality. For infants, children, and adolescents, acute or chronic energy deficits can adversely affect

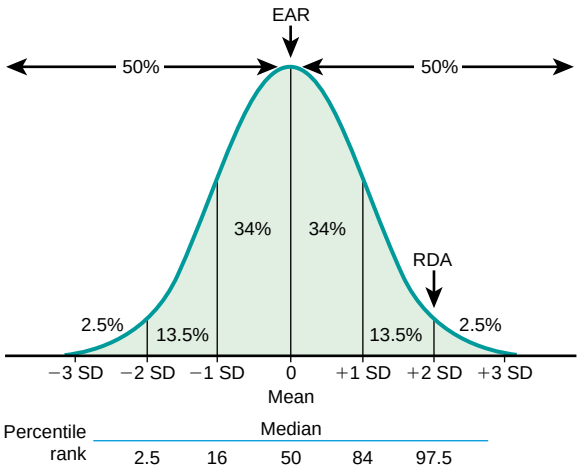

Fig. 60.1 Dietary reference intakes. Normal requirement distribution of hypothetical nutrient showing percentile rank and placement of the estimated average requirement (EAR) and the recommended dietary allowance (RDA) on the distribution; SD, standard deviation.

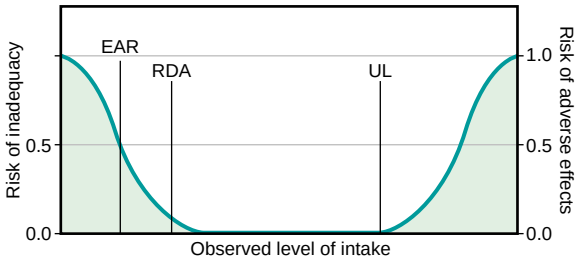

Fig. 60.2 Dietary reference intakes: The relationship among the estimated average requirement (EAR), the recommended dietary allowance (RDA), and the tolerable upper limit of intake (UL). This figure shows that the EAR is the intake at which the risk of inadequacy is estimated to be 0.5 (50%). The RDA is the intake at which the risk of inadequacy would be very small, only 0.02-0.03 (2–3%). At intakes between the RDA and the UL, the risk of inadequacy and of excess are estimated to be close to 0.0. At intakes above the UL, the potential risk of adverse effects can increase.

motor, cognitive, and behavioral development. *Excess* energy intake can increase the risk for obesity and obesity-related metabolic disease. Energy balance in adults is associated with maintenance of weight status. Positive energy balance is required in children to support growth. Components of energy expenditure in adults include the *basal metabolic rate* (BMR), which is primarily determined by lean body mass; the *thermal effect* of food (e.g., energy required for digestion and absorption); *energy* for thermoregulation; and *energy* for physical activity. Energy needs are increased during infancy, childhood, pregnancy, and lactation, necessitating increased energy intakes during these life stages.

The 2020–2025 DGA provides important nutrition and health topics applicable to each life stage, including data on estimates of caloric intake for healthy persons. The exact daily caloric requirement varies according to an individual's age, gender, height, weight, and physical activity, among other factors. Weight loss, weight maintenance, and weight gain depend on calories consumed and calories expended in the context of caloric needs.

The **estimated energy requirement (EER)** for infants, children, and adolescents is the average dietary energy intake predicted to maintain energy balance, ensure adequate growth and development, and provide for a desirable level of physical activity. It considers age, gender, weight, stature, and level of physical activity (see Table 60.1). The EER was determined based on empirical research in healthy persons at different levels of physical activity and is estimated by equations that account for both *total energy expenditure* (TEE) and *energy deposition* (ED) for healthy growth. EERs for infants, relative to body weight, are approximately twice those for adults because of the increased metabolic rate and energy requirements for weight maintenance and growth.

The EER was not devised for, and does not necessarily apply to, children with acute or chronic diseases who may have altered energy requirements due to chronic infection or inflammation, malabsorption, febrile illnesses, chronic lung disease, congenital heart disease, or other conditions. In these situations, **energy requirements** are typically higher when compared with healthy matched peers. Conversely, in some conditions, individuals may be hypometabolic and thus require less energy than expected (e.g., hypothyroidism, hypothalamic obesity conditions, Down syndrome, and certain syndromic or monogenic obesity disorders). Individual energy needs for healthy persons based on age, gender, height, weight, activity level, pregnancy, or lactation status can be approximated using online tools, such as the DRI Calculator for Healthcare Professionals, available at https://www.nal.usda.gov/human-nutrition-and-food-safety/dri-calculator.

Dietary nutrients that provide energy include *fats* (approximately 9 kcal/g), *carbohydrates* (4 kcal/g), and *protein* (4 kcal/g). These nutrients are called **macronutrients**. If alcohol is consumed, it also contributes to energy intake (7 kcal/g). The EER does not specify the relative energy contributions of macronutrients. Once the minimal intake of each macronutrient is attained (e.g., sufficient protein intake to meet specific amino acid requirements, sufficient fat intake to meet linoleic acid and α-linolenic acid needs for brain development), the remainder of the intake is used to meet energy requirements, with some degree of freedom and interchangeability among fat, carbohydrate, and protein. This forms the basis for the **acceptable macronutrient distribution ranges (AMDRs)**, expressed as a function of total energy intake (see Table 60.2).

FAT

Fat is the most calorically dense macronutrient, providing approximately 9 kcal/g. For infants, human milk and formula are the main dietary sources of fat, whereas older children obtain fat from animal products, vegetable oils, margarine, and nuts and seeds. The AMDR for fats is 30–40% of total energy intake for children 1-3 years and 25–35% for children 4-18 years of age. In addition to being energy dense, lipids provide essential fatty acids that have structural and functional roles (e.g., cholesterol moieties are precursors for cell membranes, hormones, and bile acids). Fat intake also facilitates absorption of fat-soluble vitamins (vitamins A, D, E, and K). Both roles are relevant to neurologic and ocular development (see Table 60.3).

Dietary fats include phospholipids; free fatty acids; monoglycerides, diglycerides, and triglycerides; and sterols. **Triglycerides** are the most common form of dietary fat and are composed of one glycerol molecule with three fatty acids. They are found in both animal and vegetable fats. In addition, simple sugars (i.e., refined grains and high-sugar drinks) can be converted to triglycerides in the liver. In general, dietary fatty acids can be classified as saturated, unsaturated, and more specifically, as monounsaturated or polyunsaturated. Dietary saturated fatty acids, found primarily in animal fat and dairy products as well as some vegetable fats (e.g., coconut and palm oil), can be synthesized endogenously by the body and thus are not required in the diet. **Medium-chain triglycerides (e.g., MCT oil)** are beneficial for those suffering from malabsorptive disorders resulting in steatorrhea because of their direct absorption from the gastrointestinal (GI) tract into the bloodstream via the portal vein, bypassing the need for pancreatic and biliary secretory components. The dietary saturated fatty acids most commonly consumed include myristic (C14), palmitic (C16), and steric acid (C18).

Trans fatty acids are a type of unsaturated fat having undergone hydrogenation that alters the configuration of its double bond(s). They are found primarily in processed foods such as margarines and shortenings and are nonessential. A small amount of naturally occurring trans fats can be found in animal products and human breast milk. **Monounsaturated fatty acids** are typically found in certain plants and their derived oils (e.g., avocado oil, olive oil, canola) and in some animal fats. Because monounsaturated fatty acids can be synthesized by the liver, they are considered nonessential to the diet. **Polyunsaturated fatty acids (PUFAs)** are fatty acids not able to be synthesized de novo in the body and are necessary for maintenance of growth, skin integrity, aspects of central nervous system development, and other essential physiologic functions such as regulation of gene transcription, immunity, and inflammation. These dietary essential fatty acids include linoleic (C18:2,W6,9) and linolenic acid (C18:3,W3,6,9), and they are discussed in more detail later.

Neither monounsaturated nor polyunsaturated fatty acids contribute adversely to plasma cholesterol levels. However, dietary saturated fatty acids (found primarily in animal fat and dairy products), trans fats (found in hydrogenated margarines and oils), and **cholesterol** increase the low-density lipoprotein (LDL) fraction of serum cholesterol, which is a risk factor for the development of atherosclerosis. Autopsy studies demonstrate that atherosclerosis begins early in childhood, even in infancy. Therefore dietary advice to optimize CV health should be given starting from age 2 years, when sufficient fat intake to sustain growth and brain development is less of a concern. **It is recommended that saturated fat make up less than 10% of total daily calories in the diet for those age 2 years and above**, with increased focus on consumption of monounsaturated and polyunsaturated fats. **Dietary trans fatty acids are to be avoided**, particularly artificial trans fatty acids in the form of partially hydrogenated oils, which are no longer considered Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration (FDA). Figure 60.3 shows the dietary contributions of saturated fat for those age 1 year and above.

Because saturated and monounsaturated fats can be synthesized endogenously to support adequate structural and physiologic requirements, there is no AI or RDA set for these dietary components. Trans fats, which *have no known health benefits in humans,* also do not have an AI or RDA defined. A UL has not been set for cholesterol, saturated, or trans fats because there is a continuous positive linear association between intake of these fats and increased risk for CV disease, without a threshold level. Diets low in saturated fats without trans fats are therefore preferred. **For optimal CV health in the general population, rather than limiting fat intake, advice should focus in most cases**

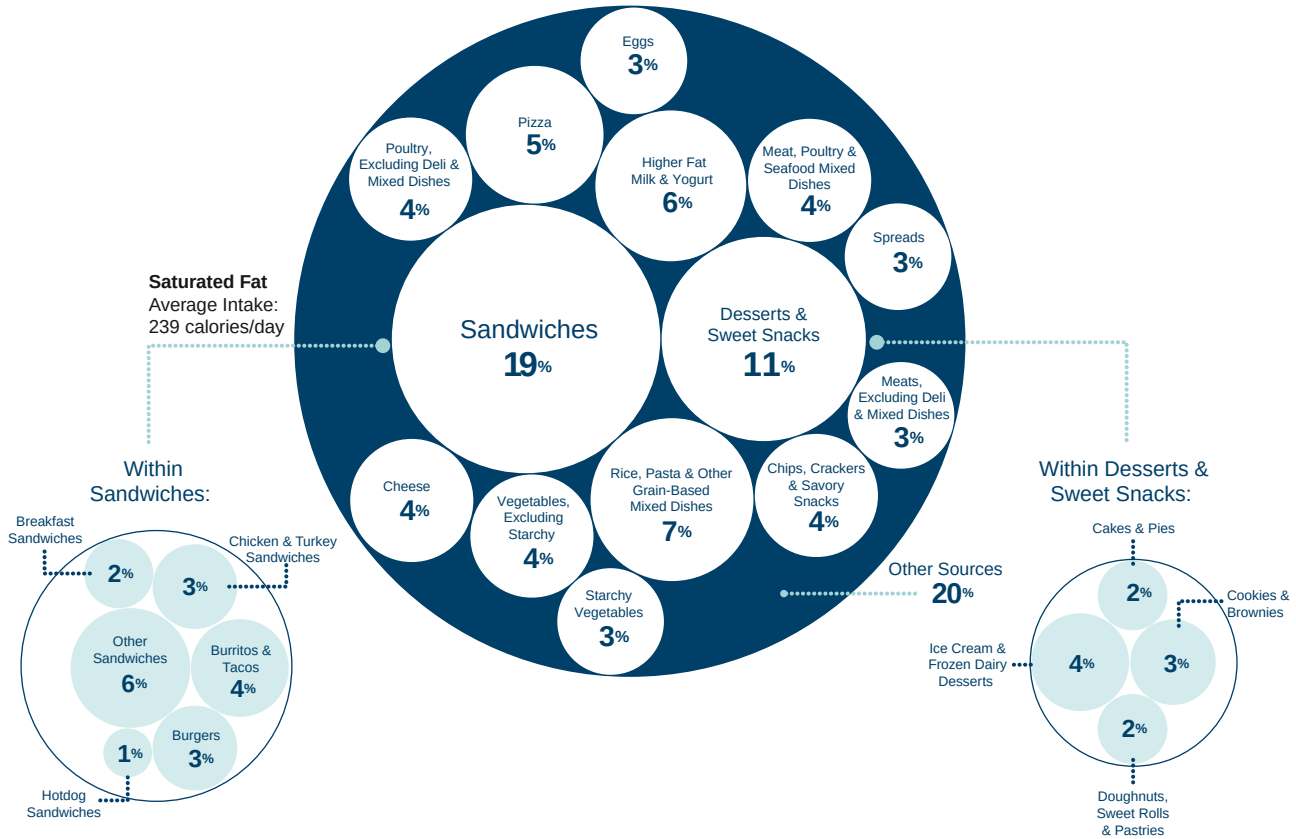

Fig. 60.3 Top sources and average intakes of saturated fat: U.S. population age 1 year and older. Estimates based on 2-day dietary intake data, weighted, from What We Eat in America (WWEIA), National Health and Nutrition Examination Survey (NHANES), 2013-2016. (*From Dietary Guidelines for Americans. 2020-2025, Chapter 1: Nutrition and Health Across the Lifespan. Fig. 1.11. https://www.dietaryguidelines.gov/sites/default/files/2020-12/Dietary_Guidelines_for_Americans_2020-2025.pdf.*)

on changing the type of fat consumed. Because of their high energy density, excessive intake of all types of fatty acids has the potential to increase the risk of obesity.

Humans are incapable of synthesizing the precursor ω3 (α-linolenic acid [ALA]) and ω6 (linoleic acid [LA]) long-chain PUFAs and depend on diet for these two essential fatty acids. Walnut, canola, and flaxseed oil are good sources of ALA. Good sources of LA include safflower and sunflower oil. Essential fatty acids are enzymatically elongated and desaturated into longer-chain fatty acids (LC-PUFAs) that serve essential physiologic roles in the body. ALA can be converted to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). LA is converted to arachidonic acid (ARA). The conversion of ALA to EPA and DHA and of LA to ARA is influenced by many factors, including type and amounts of dietary fats and by enzymatic substrate affinity among competing ω3, ω6, ω9, saturated, and trans fatty acids. Approximately 0.5% of dietary ALA is converted to DHA, and 5% of ALA intake is converted to EPA; therefore dietary intake of LC-PUFAs is an important determinant of serum and tissue DHA and EPA status.

LC-PUFAs such as DHA and ARA have a variety of cellular structural and functional roles; they influence membrane fluidity and gene expression and modulate the inflammatory response. ARA and DHA are present in breast milk and reflect maternal intake. They are often supplemented in infant formulas and are important for optimal growth and development. DHA is highly concentrated in the retina and is involved in the visual evoked response in infants.

Risk factors for **essential fatty acid deficiency** (i.e., deficiency of ALA and LA) include severe fat malabsorption, prematurity, and administration of fat-free parenteral nutrition. Deficiency can develop within 2-4 weeks of inadequate intake. Essential fatty acid deficiency of LA is associated with desquamating skin rashes, alopecia, thrombocytopenia, impaired immunity, and growth deficits, but is rare in the general population. Deficiency of ALA has been associated with paresthesias, weakness, impaired gait, impaired vision, hemorrhagic folliculitis, and impaired wound healing.

The biologic activity and health benefits of ALA are thought to be derived from its elongation products EPA and DHA. Consistent with the findings of limited conversion of ALA to EPA and DHA, the DRI stipulates that up to 10% of the AI for ω3 PUFA (ALA being the major dietary constituent) can be replaced by DHA and EPA to support normal neural development and growth. The ratio of dietary intake of each type of PUFA influences their relative amounts in different tissue compartments. **A dietary ω6:ω3 PUFA ratio of 4-5:1 may be associated with improved health outcomes, compared with the current 15-30:1 ratio typically observed in U.S. diets**. In general, ω6 fatty acids tend to have more proinflammatory effects and ω3 fatty acids more antiinflammatory effects, which have potential implications for adjunctive nutritional management of chronic inflammatory conditions.

PROTEIN

Protein and amino acids have structural and functional roles in every cell in the body. Dietary protein intake is required to maintain and replenish the turnover of protein and to meet amino acid needs for growth. Dietary protein also provides approximately 4 kcal/g as an energy substrate when intake is in excess of needs or derived from endogenous sources during periods of catabolism. Inadequate energy intake or inadequate protein intake increases catabolism of body protein reservoirs (i.e., lean body mass) for energy and free amino acids required to support normal physiologic function. Without adequate daily dietary protein intake, endogenous sources will be mobilized at the expense of function. Negative energy balance (weight loss) is associated with an obligatory negative nitrogen balance. Nitrogen from protein turnover is primarily excreted in urine and stool.

Increased protein intake of up to 20–30% may be required during hypermetabolic states, as well as in those infants and children recovering from malnutrition. Certain conditions may require a modest increase in protein intake, including conditions with high protein turnover, such as cystic fibrosis, inflammatory conditions, critical illnesses, extensive burn injuries, compensated liver disease, and postsurgical states including bariatric surgery (e.g., laparoscopic sleeve gastrectomy and Roux-en-Y gastric bypass). Premature infants also require increased protein intakes due to increased needs related to accelerated growth rates. In addition, athletes engaging in resistance, muscle-building training may have increased total protein needs of approximately 1.2-2.0 g/kg/day to prevent loss of lean body mass and to maintain nitrogen balance. Importantly, the increased protein intake in these situations must occur in the context of adequate energy intake in order for protein deposition to occur, thus ensuring that protein is not used or catabolized for energy. Moderate to severe protein-energy malnutrition (PEM), although relatively rare in the non-institutionalized U.S. population, is more common in low-resource settings. Mild PEM occurs more commonly in the United States, leading children not to meet weight targets on growth curves. PEM impairs brain, immune system, and intestinal mucosal functions (see Chapters 62 and 64).

The DRI for protein is provided in Table 60.3. Numerous factors influence dietary requirements for protein, including gender, age, growth stage, pregnancy, lactation, the presence of illness, the nutritional adequacy of an individual's diet, and genetics. The most important determinant of protein requirements is energy intake because insufficient energy intake will lead to protein catabolism to maintain energy balance, effectively increasing protein intake requirements. The EAR and RDA take into account protein required for growth and maintenance, but the RDA accounts for variation in requirements for a particular population that may exist as a result of differences in maintenance needs, protein accrual rates, and the efficiency of dietary protein accrual. Thus the RDA exceeds the EAR and most protein needs for individuals of a specific group.

The average intake of protein from poultry, meat, eggs, nuts, seeds, and soy products differs by age and gender. According to the 2020–2025 DGA and based on National Health and Nutrition Examination Survey (NHANES) data from 2015 to 2016, the average daily intake of protein for males and females age 2-4 years and 5-8 years is within recommended ranges. In children age 9-13 years, average protein intake barely meets the lower end of recommended intake for both males and females. For adolescents 14 years of age and above, males have average daily protein intakes within the recommended range; that for females falls short of the minimum recommended daily intake. A UL for protein has not been set because of insufficient data; however, excessively high intakes can result in increased urinary calcium excretion that may increase the risk of renal calculi. **Intake of protein or specific amino acids needs to be limited in some health conditions**, such as renal disease, decompensated liver disease, and metabolic diseases such as phenylketonuria and maple syrup urine disease, in which specific amino acids can be toxic. Conclusive evidence for harm in *otherwise healthy* individuals from high protein intakes is lacking. Protein intake necessary to meet micronutrient needs, especially during the first 2 years of postnatal life, will typically exceed recommended protein intakes, thus requiring micronutrient supplementation to prevent insufficiency or deficiency.

The amino acid content of dietary protein is also important. The standard by which a protein's quality is judged is its ability to support adequate growth. Certain amino acids are **indispensable/essential**, and humans depend on dietary sources to meet adequacy and prevent deficiency. Certain amino acids are termed **conditionally indispensable**, meaning they can be endogenously produced but require an exogenous source (i.e., diet) in certain disease conditions or during a certain life stage. An example would be the increased requirements for cysteine, tyrosine, and arginine in newborns because of enzyme immaturity (Table 60.4). DRI recommendations regarding protein intake assume adequate provision of indispensable amino acids and high digestibility. Human milk contains both the indispensable and conditionally indispensable amino acids and therefore meets the protein requirements for infants. Breast milk is considered the optimal protein source for infants and is the reference amino acid composition by which biologic quality is determined for infants. If a single amino acid in a food protein source is low or absent but is required to support normal metabolism, that specific amino acid becomes the limiting nutrient in that food. Animal protein, unlike plant protein, contains sufficient indispensable

Table 60.4 Indispensable, Dispensable, and Conditionally Indispensable Amino Acids in the Human Diet

INDISPENSABLE	DISPENSABLE	CONDITIONALLY INDISPENSABLE*	PRECURSORS OF CONDITIONALLY INDISPENSABLE
Histidine†	Alanine	Arginine	Glutamine/glutamate, aspartate
Isoleucine	Aspartic acid	Cysteine	Methionine, serine
Leucine	Asparagine	Glutamine	Glutamic acid/ammonia
Lysine	Glutamic acid	Glycine	Serine, choline
Methionine	Serine	Proline	Glutamate
Phenylalanine		Tyrosine	Phenylalanine
Threonine			
Tryptophan			
Valine			

**Conditionally indispensable* is defined as requiring a dietary source when endogenous synthesis cannot meet metabolic need.
†Although histidine is considered indispensable, unlike the other 8 indispensable amino acids, it does not fulfill the criteria of reducing protein deposition and inducing negative nitrogen balance promptly on removal from the diet.
Adapted from Otten JJ, Hellwig JP, Meyers LD (eds). *Dietary Reference Intakes: The Essential Guide to Nutrient Requirements.* Washington, DC: Institute of Medicine, National Academies Press; 2006.

amino acids and typically is more digestible (>95%) than plant-source proteins (70–80%).

To ensure appropriate growth and to promote satiety, children should consume the recommended amount of protein. Specific recommendations for appropriate dietary protein sources to meet indispensable amino acid requirements are available for groups adopting specific diets, such as vegetarians and vegans. Including mixtures of protein sources (e.g., legumes and corn) and using a variety of food sources to provide all of the required amino acids are strategies advocated for vegetarians and vegans (see Chapter 61).

CARBOHYDRATES

Carbohydrates are abundant in many foods, including cereals, grains, fruits, and vegetables, and provide approximately 4 kcal/g of energy. Dietary carbohydrates include *monosaccharides,* which contain one sugar molecule (e.g., glucose, fructose, galactose); *disaccharides,* which contain two sugar molecules (e.g., sucrose, lactose, maltose); *oligosaccharides* or *polysaccharides,* which contain multiple sugar molecules in a chain or complex configuration (e.g., starch, nonstarch polysaccharides like fiber); and *sugar alcohols.* Dietary carbohydrates are absorbed across the intestinal epithelium and converted to glucose in the liver. Glucose serves as the essential energy source for erythrocytes and the central nervous system and is a major energy source for all other cells. The requirements for carbohydrates are based on the average minimum amount of glucose used by the brain. Chronic low carbohydrate intake (e.g., less than 10% of total caloric intake) results in ketosis. Although a UL for carbohydrates has not been set, a maximal intake of <10% of total energy intake from *added* sugars, such as syrups and other caloric *sweeteners,* has been proposed in the 2020–2025 DGA.

Added sugars do not contribute essential nutrients and function to sweeten foods and beverages. Naturally occurring sugars, such as in milk (lactose) or fruits (fructose), are not included. Higher intakes of added sugar can displace other **macronutrients and micronutrients** and increase the risk for nutrient deficiency and excessive energy intake. There is no benefit from consuming added sugars as discretionary calorie intake. The excess calories from added sugars may displace more nutrient-dense foods and make it difficult to meet nutrient needs while remaining within the recommended total caloric intake.

The recommended AMDR for carbohydrates is based on data suggesting a risk for coronary artery disease (CAD) with diets high in refined carbohydrates and low in fat (see Table 60.2). These diets, compared with diets with higher fat intake, result in high triglyceride levels, low high-density lipoprotein (HDL) cholesterol, and small LDL cholesterol particles and are associated with an increased risk of CAD, especially in sedentary overweight individuals. Diets within the AMDR for carbohydrates and fats minimize the risks of diabetes, obesity, and CAD. Diets with less than the minimum AMDR for carbohydrate most likely do not meet the AI for fiber (see Table 60.3).

Most carbohydrates are present as starches or sugars in food. Simple sugars (monosaccharides and disaccharides) are often added to foods and beverages during food preparation, processing, and packaging to enhance their palatability and also act as preservatives. Sugar-sweetened beverages, including nondiet soft drinks, juice drinks, iced tea, and sport drinks, are major contributors to added sugars in the diet of U.S. children and adolescents (Fig. 60.4). Added sugars are associated with increased risk for obesity, diabetes, and dental caries. Fructose is one such added sugar in the form of *high-fructose corn syrup,* which is ubiquitous in the U.S. diet. Added fructose increases HDL and triglyceride production in the liver and serum uric acid, which increases systolic blood pressure and is associated with nonalcoholic fatty liver disease and metabolic syndrome. Excessive fructose intake, such as in the form of fruit juices, may be associated with diarrhea, abdominal pain, and failure to thrive in children. Fructose consumed in whole fruits rarely contributes to these side effects because its systemic absorption and metabolic effects are mitigated by the fact that it is complexed with fiber.

The **glycemic index** is a measure of peak blood glucose concentration 2 hours after ingestion of a given food compared with a reference standard (slice of white bread). The glycemic index has predictable effects on blood glucose, hemoglobin A_{1C}, insulin, triglycerides, and HDL cholesterol. *Lower-glycemic-index foods are recommended and may reduce the risk of insulin resistance and CV disease.* Examples of low-glycemic-index foods include oat bran, muesli, barley, carrots, nonstarchy vegetables, and most fruits.

FIBER

Fiber consists of *nondigestible* carbohydrates (i.e., nonstarch polysaccharides and nonpolysaccharides such as lignins), mostly derived from plant sources, such as whole grains, fruits, and vegetables, that escape digestion and reach the colon almost 100% intact. Fiber can be classified as fermentable and nonfermentable. Fermentable fibers are found in beans, fruits, and products containing oats or psyllium, and nonfermentable fiber is found in whole grains and vegetables. The DRI classification considers total fiber intake to be composed of **dietary fiber** (nondigestible carbohydrates and lignins intrinsic to plants that are fermented by colonic bacteria) and **functional fiber** (nondigestible carbohydrates isolated from plants or manufactured for use as dietary supplements). Although functional fibers may improve constipation and glucose absorption, they do not contain the other beneficial phytochemicals and nutrients of naturally occurring fiber found in whole foods. Functional fibers have been added to cereals, salad dressings, soups, baked goods, and meal replacements with the aim of increasing fiber intake.

Dietary fiber may help reduce intestinal cell dysplasia by diluting toxins, carcinogens, and tumor promoters; decreasing transit time, thereby reducing colonic mucosal exposure; and promoting toxin expulsion in the fecal stream. Dietary fiber that is resistant to colonic

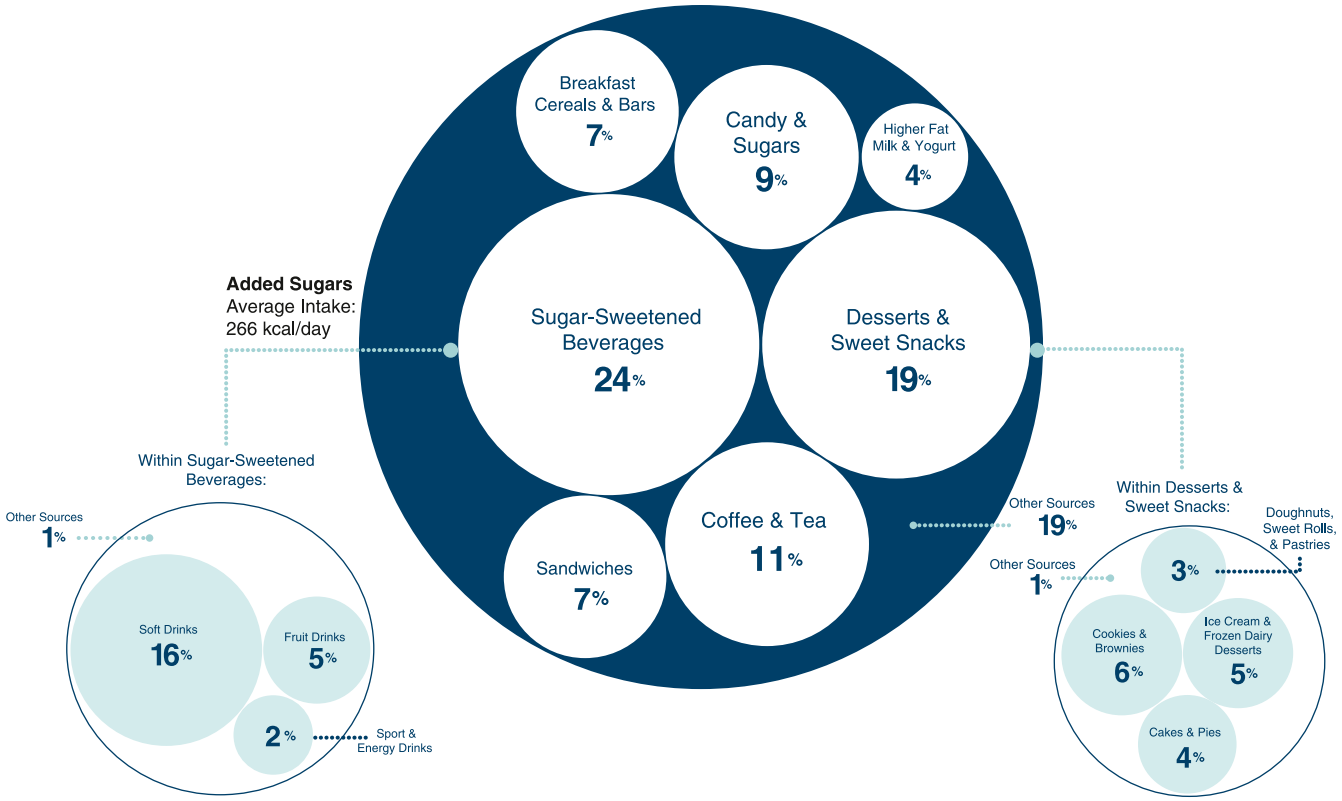

Fig. 60.4 Top sources and average intakes of added sugars: U.S. population age 1 year and older. Estimates based on 2-day dietary intake data, weighted, from What We Eat in America (WWEIA), NHANES, 2013-2016. (*From the Dietary Guidelines for Americans, 2020-2025, Chapter 1: Nutrition and Health Across the Lifespan. Fig. 1.10.* https://www.dietaryguidelines.gov/sites/default/files/2020-12/Dietary_Guidelines_for_Americans_2020-2025.pdf.)

degradation may also play a role in maintaining and promoting stool bulk and in regulating intraluminal pressure and colonic wall resistance, disordered colonic motility, or both. Lack of certain types of dietary fiber is associated with constipation and diverticulosis.

All types of dietary fiber slow gastric emptying and promote satiety, and thus may help to regulate appetite. Dietary fiber may decrease the rate of release and absorption of simple sugars and may help regulate blood sugar concentration by lowering postprandial blood glucose levels. Dietary fiber has a low glycemic index and may have a beneficial effect on insulin sensitivity. Fiber also binds luminal cholesterol and reduces absorption and enterohepatic circulation of the cholesterol in bile salts (e.g., with the intake of more viscous forms of dietary fiber, such as pectin). Guar gum, oat products, and pectin (i.e., fermentable/viscous fiber) lower serum cholesterol, whereas nonfermentable/nonviscous fiber (e.g., flax, wheat bran) may reduce serum triglycerides. Fiber such as psyllium, resistant dextrins, and resistant starch may lower both serum LDL cholesterol and triglycerides. Low fiber intake in Western society has been associated with the increasing incidence and prevalence of diabetes, obesity, CV disease, colon cancer, and IBD.

There is a dynamic interplay between the colonic bacterial milieu and the diet. The metabolic fate of fiber is influenced primarily by colonic bacteria, which render it susceptible to fermentation, depending on the structure of the fiber (e.g., pectin, oat bran). Common by-products of colonic fermentation include carbon dioxide, methane (in addition to other gases), **oligofructose** (also known as a *prebiotic,* a substrate that nourishes beneficial commensal GI microbiota), and **short-chain fatty acids (SCFAs)**. The common SCFAs produced by fermentation include acetate, butyrate, and propionate. SCFAs influence colonic physiology by stimulating colonic blood flow and fluid and electrolyte uptake. Butyrate is the preferred fuel for the colonocyte and may have a role in maintaining the normal phenotype in these cells. Good sources of fiber include beans, peas, leafy and cruciferous vegetables, fruits, and whole grains. The observed benefits of diets rich in fruits and vegetables may be mediated by the fiber they contain and also by the other compounds and micronutrients (e.g., polyphenols, carotenoids) they contain.

Data are insufficient to establish an EAR for dietary fiber. AI for dietary fiber has been established based on the intake levels associated with reducing risk for CV disease and in lowering or normalizing serum cholesterol (see Table 60.3). Several recommendations address dietary fiber intake in children based on body weight or as a proportion of daily calories consumed. The IOM recommends an AI for fiber of 14 g per 1,000 kcal of energy consumed (see Table 60.3), which for younger children may be unrealistic to achieve. *The equation for the range of recommended daily fiber intake in grams = Age (years) + 5 to 10 grams per day.* The recommendations do not specify type of fiber and predate the newer definitions of fiber.

A UL has not been established for fiber, which is not thought to be harmful to human health. Some types of fiber, such as fermentable oligosaccharides, may exert symptoms on the basis of their digestibility, by-product formation, and interactions with GI microbiota. Excessive intake of **fermentable oligosaccharides** (e.g., fructooligosaccharides such as onions), **disaccharides** (e.g., lactose), **monosaccharides** (e.g., fructose), and **polyols** (e.g., sorbitol) (aka **FODMAPs**) is associated with increased risk for GI symptoms along the functional abdominal pain, functional GI disorders (IBS), and IBD. **Restricted intake or substitution with lower-FODMAP foods may be beneficial.** Substitutions within the same food groups can shift from a high-FODMAP diet to a low-FODMAP diet, which may provide GI symptom relief. For example, substituting cucumber for celery would be exchanging a high-FODMAP food for a low-FODMAP food. Dietary management for some conditions may put certain children at risk of low fiber intake. Gluten-free diets used for celiac disease are often low in fiber. In such cases, gluten-free sources of fiber should be recommended, such as tapioca, flax, corn, rice, sorghum, and quinoa.

MICRONUTRIENTS

See Chapters 66-72.

Vitamins and minerals, the dietary **micronutrients**, are essential for growth and development and contribute to a host of physiologic functions. Many U.S. children may have suboptimal intake of iron, zinc, potassium, calcium, and vitamins D, E, and K, and excess intake of sodium. Dietary recommendations for micronutrients were originally established to prevent deficiency and currently also include the impact of micronutrients on long-term health outcomes (Table 60.5). Food fortification is an effective strategy to prevent some nutrient deficiencies and has been successfully implemented to prevent iodine, folate, and vitamin D deficiencies.

The DRI for 0-6 months for all micronutrients are AIs, because data are considered to be insufficient to establish an EAR on which an RDA would be based. The AI for the first 6 months of postnatal life is based on the daily mean nutrient intake supplied by human milk for healthy, full-term infants who are exclusively breastfed. For approximately the first 6 months of postnatal life for healthy term infants, an adequately nourished mother produces human milk with adequate amounts of the majority of micronutrients; exceptions are iron and zinc, concentrations of which are unrelated to maternal intake. In the early postnatal months, infants rely on body stores and iron available from the relatively high erythron (especially with delayed cord clamping), and thus the actual dietary requirement for iron is very modest. Infants born prematurely and/or with evidence of fetal growth restriction are likely to have low iron stores at birth and thus may need exogenous iron earlier than 6 months. Zinc concentrations in human milk decline sharply over the first 3-4 months of lactation and are insufficient to meet needs by approximately 6 months. Thus after about 6 months, sources of both iron and zinc are required from complementary foods, such as pureed meats, fortified foods (e.g., infant cereals), or from supplements.

Iron

Iron requirements are relatively higher during infancy and early childhood than later in life and are higher for menstruating females than for males of similar age-groups (see Chapter 72). Iron from animal protein is more bioavailable than that found in animal-source foods such as milk or plant sources because it is already incorporated into heme moieties in blood and muscle. Iron deficiency is the most common micronutrient deficiency in the world and is associated with iron-deficiency anemia and neurocognitive deficits in some children.

Zinc

Zinc deficiency is estimated to affect millions of children in low-resource settings and is associated with increased risk for impaired linear growth (stunting), impaired immune function, and increased risk for respiratory and diarrheal diseases. In high-resource settings, mild deficiency may occur in older infants and toddlers if dietary choices do not include meat or fortified products. Whole grains, legumes, and other high-protein plant sources contain good amounts of zinc, but the absorption bioavailability will be lower compared to animal-source foods.

Vitamin D

Vitamin D insufficiency is more common than previously thought in infants and children. Vitamin D is central to calcium and bone metabolism but is also an important determinant of various nonosseous health outcomes (see Chapter 69). Children of all ages with darker skin and those who do not consume fortified dairy products should be considered for screening for vitamin D deficiency. The DRI for vitamin D is based on its effects on calcium status and bone health. The goal is to achieve serum 25-hydroxyvitamin D levels >50 nmol/L (30 ng/dL). Breast milk is a poor source of vitamin D. The American Academy of Pediatrics (AAP) recommends total vitamin D intake of 400 IU/day for infants (0 to <12 months). A supplement is recommended for all breastfed infants to ensure sufficient intake. The RDA of vitamin D is currently 600 units daily for healthy children 1-18 years of age.

Calcium

Calcium is key to bone health. Adequacy is determined in part by bone mineral content and bone mineral density (BMD). The main storage organs for calcium are the bones and teeth. Bone mineral accretion occurs primarily during childhood, with peak bone mass being achieved by the second to third decade of life. Calcium recommendations include a change from an AI to RDA, in terms of strength of evidence for recommendations, and increased UL in 9- to 18-year-olds (Table 60.6). There are no adequate biomarkers to assess calcium status in healthy children because serum calcium is tightly regulated (regardless of intake and total body calcium) by changes in parathyroid hormone and calcitriol levels. Maintaining adequate serum calcium level despite inadequate intake could come at the expense of BMD. Therefore in the long term, reduced BMD could serve as a surrogate marker of chronic calcium intake and status. It is important to note other determinants of BMD are age, gender, genetic-ethnic factors, hormonal status, physical activity, and weight. Assessments of calcium status should include calcium intake in the diet. It is also important to educate families on additional and alternative sources of calcium (including calcium supplementation) if calcium intake is determined to be low.

Electrolytes

Potassium (K^+) and sodium (Na^+) are the main intracellular and extracellular cations, respectively, and are involved in transport of fluids and nutrients across the cellular membrane. The AI for potassium is related to its effects in maintaining a healthy blood pressure, reducing risk for nephrolithiasis, and supporting bone health. Moderate potassium deficiency occurs even in the absence of hypokalemia and can result in increased blood pressure, stroke, and other CV disease.

For people at increased risk of hypertension and who are salt sensitive, reducing sodium intake and increasing potassium intake is advised. Leafy green vegetables, vine fruits (e.g., tomatoes, eggplant, zucchini, pumpkin), and root vegetables (e.g., yams, beets) are good sources of potassium (see Table 60.6). People with impaired renal function may need to reduce potassium intake, because hyperkalemia can increase the risk for fatal cardiac arrhythmias among these patients.

Most dietary sodium (i.e., sodium chloride, or table salt) in the United States is found in processed foods, breads, and condiments (Fig. 60.5). Sodium salt (NaCl) is added to foods to serve as a preservative and enhance palatability. Sodium has an AI, but given the risk of table salt–related hypertension, an UL has also been set. The UL threshold may be even lower in certain populations, who on average may be more sodium salt sensitive, and for those with hypertension or preexisting renal disease. Dietary sodium intake also displaces potassium intake. Elevated sodium:potassium ratios can increase the risk for nephrolithiasis. Intakes of <2,300 mg sodium (approximately 1 tsp of table salt) per day are recommended. The average daily salt intake for most people in the United States and Canada exceeds both the AI and UL. *For populations with or at risk of hypertension and renal disease, sodium intake should be decreased to <1,500 mg/day and potassium intake increased to >4,700 mg/day.* For persons with hypertension, additional dietary guidelines are available from the **Dietary Approaches to Stop Hypertension (DASH) eating plan.**

WATER

The daily water requirement and water content as a proportion of body weight are highest in infants and decrease with age. Water intake is achieved with liquid and food intake, and losses include excretion in the urine and stool, as well as insensible and evaporative losses through the skin and respiratory tract. An AI has been established for water (see Table 60.6). Special considerations are required by life stages and by BMR, physical activity, body proportions (surface area to volume), environment, and underlying medical conditions. Breast milk and infant formula provide adequate water, and additional water or other fluid intake is not required until complementary foods are introduced. Water contains no calories, but the concern is that additional water intake in young infants will decrease breast milk intake and displace the intake of essential nutrients during this phase of rapid rate of growth and high metabolic activity. The relatively higher fluid needs of

Table 60.5 Dietary Reference Intakes for Vitamins

NUTRIENT	FUNCTION	LIFE STAGE GROUP	RDA OR AI	UL	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION	SPECIAL CONSIDERATIONS

		14-18 yr	**65**	1,800			
		19-21 yr	**75**	2,000			
		Pregnancy (mg/day)					
		≤18 yr	**80**	1,800			
		19-21 yr	**85**	2,000			
		Lactation (mg/day)					
		≤18 yr	**115**	1,800			
		19-21 yr	**120**	2,000			
Vitamin E (α-tocopherol) α-tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, RRS-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements It does not include the *2S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements	A metabolic function has not yet been identified. Vitamin E's major function appears to be as a nonspecific chain-breaking antioxidant.	*Infants* (mg/day)			Vegetable oil, unprocessed cereal grains, nuts, fruit, vegetables, meat	No evidence of adverse effects from consuming vitamin E naturally occurring in food. Adverse effects from supplements may include hemorrhagic toxicity. UL applies to any form of α-tocopherol obtained from supplements, fortified foods, or a combination of these.	Persons receiving anticoagulant therapy are at risk of excess bleeding when taking vitamin E supplements in doses greater than 1,000 mg/day.

		Lactation (μg/day)					
		≤18 yr	75*	ND			
		19-21 yr	90*	ND			

Note: Starred (*) numbers are adequate intake (AI) and **bold** numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97–98% of members in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying with confidence the percentage covered by this intake.

UL is the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Because of a lack of suitable data, ULs could not be established for potassium, water, or inorganic sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

ND amounts are not determinable because of a lack of data on adverse effects in this age-group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

*RDA for vitamin D in IU/day: 400 if <1 yr age, 600 if >1 yr, lactating, or pregnant.

AI, Adequate intake; GI, gastrointestinal; ND, not determinable; PLP, pyridoxal phosphate; PMP, pyridoxamine phosphate; PNP, pyridoxine phosphate; RDA, recommended dietary allowance; UL, upper limit of normal.

Data from Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride, 1997; Dietary reference intakes for thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline, 1998; Dietary reference intakes for vitamin C, vitamin E, selenium, and carotenoids, 2000; Dietary reference intakes for vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc, 2001; Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids, 2002/2005; Dietary reference intakes for calcium and vitamin D, 2011. These reports may be accessed via www.nap.edu

Table 60.6 Dietary Reference Intakes for Select Micronutrients and Water

NUTRIENT	FUNCTION	LIFE STAGE GROUP	AI (mg/day)	UL (mg/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION	SPECIAL CONSIDERATIONS
Sodium	Maintains fluid volume outside of cells and thus normal cell function	*Infants*			Processed foods with added sodium chloride (salt), benzoate, phosphate; salted meats, bread, nuts, cold cuts; margarine; butter; salt added to foods in cooking or at the table. Salt is about 40% sodium by weight.	Hypertension, increased risk of cardiovascular disease and stroke	AI is set based on ability to obtain a nutritionally adequate diet for other nutrients and to meet the needs for sweat losses for persons engaged in recommended levels of physical activity. Persons engaged in activity at higher levels or in humid climates resulting in excessive sweating might need more than the AI. UL applies to apparently healthy persons without hypertension; it thus may be too high for persons who already have hypertension.
		0-6 mo	120	ND			
		7-12 mo	370	ND			
		Children					
		1-3 yr	1,000	1,500			
		4-8 yr	1,200	1,900			
		Males					
		9-13 yr	1,500	2,200			
		14-21 yr	1,500	2,300			
		Females					
		9-13 yr	1,500	2,200			
		13-21 yr	1,500	2,300			
		Pregnancy and Lactation					
		≥14 yr	1,500	2,300			
Chloride	With sodium, maintains fluid volume outside of cells and thus normal cell function	*Infants*			Processed foods with added table salt, benzoate, phosphate; salted meats, nuts, cold cuts; margarine; butter; salt added to foods in cooking or at the table. Salt is about 60% chloride by weight.	In concert with sodium, results in hypertension	Chloride is lost, usually with sodium, in sweat and in vomiting and diarrhea. AI and UL are equimolar in amount to sodium because most of sodium in diet comes as table salt.
		0-6 mo	180	ND			
		7-12 mo	570	ND			
		Children					
		1-3 yr	1,500	2,300			
		4-8 yr	1,900	2,900

		13-21 yr	2,300	3,600			
		Pregnancy and Lactation					
		≥14 yr	2,300	3,600			
Potassium	Maintains fluid volume inside/outside of cells and thus normal cell function; acts to blunt the rise of blood pressure in response to excess sodium intake and decrease markers of bone turnover and recurrence of kidney stones	*Infants*			Fruits and vegetables, dried peas, dairy products, meats, nuts	None documented from food alone, but potassium from supplements or salt substitutes can result in hyperkalemia and possibly sudden death if excess is consumed by persons with chronic renal insufficiency (kidney disease) or diabetes	Persons taking drugs for cardiovascular disease such as ACE inhibitors, ARBs, or potassium-sparing diuretics should be careful not to consume supplements containing potassium and might need to consume less than the AI.

Table 60.6 Dietary Reference Intakes for Select Micronutrients and Water—cont'd

NUTRIENT	FUNCTION	LIFE STAGE GROUP	AI (mg/day)	UL (mg/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION	SPECIAL CONSIDERATIONS
Iron	Critical component of enzymes, cytochromes, myoglobin, and hemoglobin	*Infants*			Heme sources: meat, poultry, fish Nonheme sources: dairy, eggs, plant-based foods like whole grains, nuts, seeds, legumes, and leafy greens, breads, cereals, breakfast foods	GI distress	Persons with decreased gastric acidity may be at increased risk for deficiency. Cow's milk is a poor source of bioavailable iron and is not recommended for children <1 yr old. Neurocognitive deficits have been reported in infants with iron deficiency. RDA for females increases with menarche related to increased losses during menstruation. Vegans and vegetarians might require iron supplementation or intake of iron-fortified foods. GI parasites can increase iron losses via GI bleeds. Iron supplements can interfere with zinc absorption, and vice versa; if supplements are being used, the doses should be staggered.
		0-6 mo	0.27	40

Table 60.6 Dietary Reference Intakes for Select Micronutrients and Water—cont'd

Water	Maintains homeostasis in the body Allows transport of nutrients to cells and removal and excretion of waste products of metabolism	*Infants* (L/day)		None set	All beverages, including water Moisture in foods High-moisture foods include watermelon, meats, and soups	No UL because normally functioning kidneys can handle >0.7 L (24 oz) of fluid per hour. Symptoms of water intoxication include hyponatremia, which can result in heart failure, and rhabdomyolysis (skeletal muscle tissue injury), which can lead to kidney failure.	Recommended intakes for water are based on median intakes of generally healthy persons who are adequately hydrated. Persons can be adequately hydrated at levels above or below the AIs provided; AIs provided are for total water in temperate climates. All sources can contribute to total water needs: beverages (tea, coffee, juice, soda, drinking water) and moisture found in foods. Moisture in food accounts for about 20% of total water intake. Thirst and consumption of beverages at meals are adequate to maintain hydration.
		0-6 mo	0.7

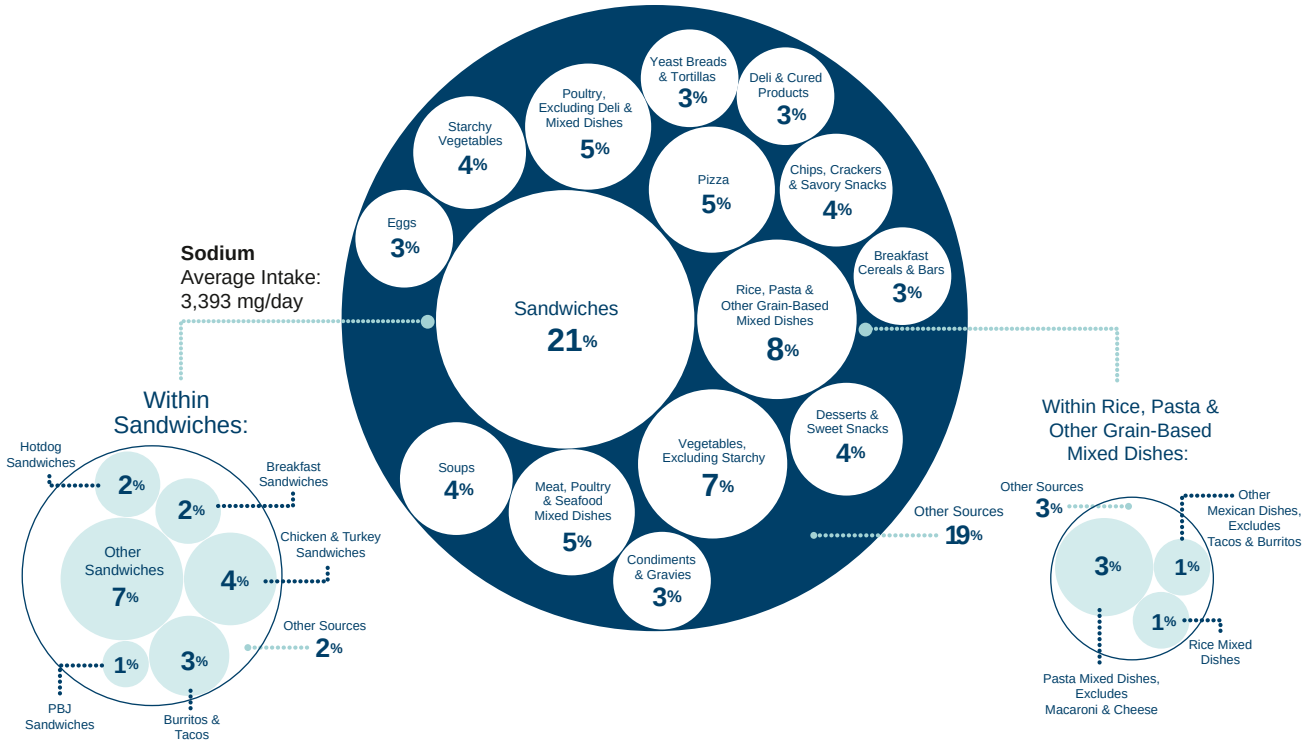

Fig. 60.5 Top sources and average intakes of sodium: U.S. population age 1 and older. Estimates based on 2-day dietary intake data, weighted, from What We Eat in America (WWEIA), National Health and Nutrition Examination Survey (NHANES), 2013-2016. (*From Dietary Guidelines for Americans. 2020-2025, Chapter 1: Nutrition and Health Across the Lifespan. Fig 1.12.* https://www.dietaryguidelines.gov/sites/default/files/2020-12/Dietary_Guidelines_for_Americans_2020-2025.pdf.)

Table 60.7 Growth Chart Comparisons for Measuring Growth from Birth to 20 Years

GROWTH CHART	AGE RANGE	GROWTH METRICS	INSUFFICIENT GROWTH PERCENTILE	EXCESSIVE GROWTH PERCENTILE	BMI STATUS PERCENTILE
World Health Organization, 2006	Birth to 2 yr	Weight, length, weight-for-length, and head circumference	<2.3rd	>97.7th	—
U.S. Centers for Disease Control and Prevention, 2000	2-20 yr	Weight, height, body mass index (BMI)	<5th	>95th	Under (<5th) Normal (5-85th) Over (85-95th) Obese (>95th) Severe obesity (≥120% of 95th or ≥35 kg/m^2)

infants and young children can be explained in part by the high ratio of body surface area to volume in infancy, high respiratory rate, and rapid growth.

The consequences of inadequate fluid intake include impaired thermoregulation and heat dissipation, reduced activity tolerance and performance, and reduced intravascular fluid and dehydration. Inadequate fluid intake may be reflected by decreased urine output. These deficits can result in an increased compensatory heart rate, hypotension, and syncope, and if uncorrected, renal injury or nephrolithiasis. "Free water" is defined as water in the body that can be removed by ultrafiltration and in which substances can be dissolved. Excess free water intake is usually better tolerated by healthy adults than by younger children, who are at increased risk for water intoxication. Hyponatremia can result when water and sodium are out of balance, such as excess free water intake coupled with inadequate sodium intake. Fluid intake requirements and restrictions are also influenced by any underlying renal and hormonal disorders, including diabetes, the syndrome of inappropriate antidiuretic hormone secretion (SIADH), and diabetes insipidus.

MEASURING NUTRITIONAL ADEQUACY

The U.S. Centers for Disease Control and Prevention (CDC) and AAP recommend the use of the WHO charts to monitor growth of all infants and children (human milk–fed and infant formula–fed) from birth to 2 years, and the use of the CDC 2000 growth charts for children 2-20 years (see Chapters 19 and 27). The WHO growth charts are derived from longitudinal and cross-sectional data obtained from a sample of healthy breastfed infants and children (0-2 years) who were receiving adequate nutritional intake and medical care in Brazil, Ghana, India, Norway, Oman, and the United States. Consequently, the WHO/CDC 0-2 year growth charts are considered *standards* and describe the ideal growth of adequately nourished healthy children under best-care practices. The CDC 2-20 year charts are considered *references* and describe the population's average growth and distribution.

In the clinical setting, the 2.3rd and 97.7th percentiles on the WHO growth charts are used to identify *insufficient* and *excessive* growth from birth to 2 years, respectively. In contrast, the 5th and 95th percentiles are recommended for the equivalent identification in the CDC growth charts from 2 to 20 years (Table 60.7). Note that length, weight, and

weight-for-length are used in the WHO growth charts from birth to 2 years. *Body mass index* (BMI) can be calculated but is not recommended for use in children <2 years. Stature, weight, and BMI are used in the CDC 2000 growth charts from 2 to 20 years of age. These charts can be used to categorize children as *underweight* (<5th BMI percentile), normal weight (5-85th), overweight (85-95th), and obese (≥95th BMI percentile).

Severe obesity is defined as BMI ≥120% of the 95th percentile or BMI ≥35 kg/m^2 (whichever is lower). This assessment corresponds to approximately the 99th percentile or a BMI *z* score ≥2.33. Severe obesity that exceeds the 99th percentile is tracked on a specialized percentile curve for obesity. Furthermore, adult classification is used for BMI ≥27 kg/m^2 in adolescents over age 18 for consideration of medication and bariatric surgery.

It is important to consider the limitations in the use of WHO and CDC growth charts for certain populations such as premature infants, children with certain genetic disorders (e.g., Turner syndrome, Down syndrome, Wolf-Hirschhorn syndrome, achondroplasia) and children with cerebral palsy. Specific growth charts addressing the unique growth characteristics of these children are available from various resources, including the AAP.

Chapter 61

Feeding Healthy Infants, Children, and Adolescents

Katherine J. Barrett, Stephanie P. Gilley, Matthew A. Haemer, Nancy F. Krebs, and Susan L. Johnson

Early feeding experiences can support the development of healthy eating habits, optimal growth and development, and prevention of chronic disease throughout the life course. Childhood nutrition is known to play a role in the origin of adult diseases such as type 2 diabetes, hypertension, obesity, and metabolic syndrome. To support development and to prevent chronic disease, appropriate feeding practices are best established in the neonatal period and continued throughout childhood and adolescence to adulthood. Healthful feeding in children requires partnerships between family members, the healthcare system, schools, the community, and policy makers.

FEEDING DURING THE FIRST YEAR OF LIFE

Breastfeeding

The American Academy of Pediatrics (AAP) and World Health Organization (WHO) have declared breastfeeding and the administration of human milk to be the ideal practice for infant feeding and nutrition. Breastfeeding has documented short- and long-term medical and neurodevelopmental advantages and rare contraindications (Tables 61.1, 61.2, and 61.3). The AAP and the WHO recommend that infants be exclusively fed human breast milk for approximately 6 months. Breastfeeding ideally should be continued with the introduction of complementary foods until 24 months of age or longer, if mutually desired by the mother and infant. We recognize that there are some lactating individuals who do not identify as women/mothers and may prefer the use of other terms, including the use of chestfeeding in lieu of breastfeeding. This is a consideration that a practitioner may need to make when speaking to a family member who uses these alternative terms. The success of breastfeeding initiation and continuation depends on multiple factors, such as education about breastfeeding, hospital breastfeeding practices and policies, routine and timely follow-up care, family and societal support, and the health of the mother (Tables 61.4 and 61.5). Breastfeeding support from both professionals and lay individuals has a positive impact on breastfeeding success, and the importance of such support cannot be overstated.

Table 61.1 Selected Beneficial Properties of Human Milk Compared with Infant Formula

FACTOR	ACTION
ANTIBACTERIAL FACTORS	
Secretory IgA	Specific antigen-targeted antiinfective action
Lactoferrin	Immunomodulation, iron chelation, antimicrobial action, antiadhesive, trophic for intestinal growth
κ-Casein	Antiadhesive, bacterial flora
Oligosaccharides	Prevention of bacterial attachment
Cytokines	Antiinflammatory, epithelial barrier function
GROWTH FACTORS	
Epidermal growth factor	Luminal surveillance, repair of intestine
Transforming growth factor (TGF)	Promotes epithelial cell growth (TGF-β) Suppresses lymphocyte function (TGF-β)
Nerve growth factor	Promotes neural growth
ENZYMES	
Platelet-activating factor (PAF)–acetylhydrolase	Blocks action of PAF
Glutathione peroxidase	Prevents lipid oxidation
Nucleotides	Enhance antibody responses, bacterial flora

Adapted from Hamosh M. Bioactive factors in human milk. *Pediatr Clin North Am.* 2001;48:69–86.

Feedings are initiated soon after birth unless medical conditions preclude them. Mothers can be encouraged to feed at both breasts at each feeding, starting with the breast offered second at the last feeding. For optimal milk production, it is preferable to fully empty the first breast before moving to the second breast, rather than partially emptying both sides. It is not unusual for an infant to fall asleep after the first breast and refuse the second. Table 61.6 summarizes patterns of milk supply in the first week. Pacifiers may help prevent sudden infant death syndrome in breastfed infants, but it is not recommended to introduce until breastfeeding is well established and should not be used to try to increase time between feeds or in lieu of a feed in a baby showing hunger cues.

Breastfeeding is a learned skill for both mother and infant, and support from a provider knowledgeable in breastfeeding is critical, especially as milk production is established in the first few weeks postpartum. It is helpful to instruct new mothers about infant hunger cues and correct nipple latch, positioning of the infant on the breast, and feeding frequency. It is also suggested that someone trained in lactation observe a feeding to evaluate positioning, latch, milk transfer, maternal responses, and infant satiety. Attention to these issues during the newborn period allows dialog with the mother and family and can prevent problems that could occur with improper technique or knowledge of breastfeeding. Discussions about normal infant feeding, infant elimination patterns, breast engorgement, breast care, and maternal nutrition are important aspects of the hospital discharge process. A follow-up appointment with a lactation specialist is recommended within 24-48 hours after hospital discharge. The AAP recommends that exclusively breastfed infants start supplementation with vitamin D (10 mcg, or 400 IU) by 2 weeks of life.

Table 61.2 Absolute and Relative Contraindications to Breastfeeding Because of Maternal Health Conditions

MATERNAL HEALTH CONDITION	DEGREE OF RISK
HIV and HTLV infection	In the United States, breastfeeding is contraindicated. In other settings, health risks of not breastfeeding must be weighed against the risk of transmitting the virus to the infant.
Tuberculosis infection	Direct breastfeeding is contraindicated until completion of approximately 2 wk of appropriate maternal therapy.
Varicella-zoster infection	Infant should not have direct contact with active lesions. Infant should receive immune globulin.
Herpes simplex infection	Breastfeeding is contraindicated with active herpetic lesions of the breast.
CMV infection	May be found in milk of mothers who are CMV seropositive. Transmission through human milk causing symptomatic illness in term infants is uncommon.
Hepatitis B infection	Infants routinely receive hepatitis B immune globulin and hepatitis B vaccine if mother is HBsAg positive. No delay in initiation of breastfeeding is required.
Hepatitis C infection	Breastfeeding is not contraindicated.
COVID-19	Maternal infection is not a contraindication for breastfeeding or feeding expressed milk.
Ebola	Confirmed maternal Ebola infection is a contraindication to breastfeeding and expressed milk.
Brucellosis	Active untreated brucellosis is a contraindication to breastfeeding and expressed milk.
Live vaccines	Smallpox and yellow fever live-virus vaccines are contraindicated for breastfeeding mothers.
Alcohol intake	Limit maternal alcohol intake to <0.5 g/kg/day (for a woman of average weight—this is the equivalent of 2 cans of beer, 2 glasses of wine, or 2 oz of liquor).
Cigarette smoking	Discourage cigarette smoking, but smoking is not a contraindication to breastfeeding.
Marijuana usage	Metabolites, including tetrahydrocannabinol, are detectable in breast milk. Marijuana usage is not recommended but is not a strict contraindication to breastfeeding.
Chemotherapy, radiopharmaceuticals	Breastfeeding is generally contraindicated.

CMV, Cytomegalovirus; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus.

Table 61.3 Conditions for Which Human Milk May Have a Protective Effect

INFANT		MOTHER
• Diarrhea • Otitis media • Urinary tract infection • Necrotizing enterocolitis • Septicemia • Infant botulism • Insulin-dependent diabetes mellitus • Celiac disease	• Crohn disease • Lymphoma • Leukemia • Recurrent otitis media • Atopy • Hospitalizations for respiratory illness • Sudden infant death syndrome • Obesity	• Uterine atony • Breast cancer • Ovarian cancer • Cardiovascular disease • Obesity • Type 2 diabetes

Table 61.4 Ten Hospital Practices to Encourage and Support Breastfeeding*†

1. Have a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help women initiate breastfeeding within 1 hour of birth.
5. Show women how to breastfeed and how to maintain lactation, even if they are separated from their newborns.
6. Give newborns no food or drink other than breast milk unless medically indicated.
7. Practice rooming-in; allow mothers and newborns to remain together 24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no pacifiers or artificial nipples to breastfeeding infants.‡
10. Foster the establishment of breastfeeding support groups and refer to them on discharge from the hospital or birth center.

COMPONENTS OF SAFE POSITIONING FOR THE NEWBORN WHILE SKIN-TO-SKIN**

1. Infant's face can be seen.
2. Infant's head is in "sniffing" position.
3. Infant's nose and mouth are not covered.
4. Infant's head is turned to one side.
5. Infant's neck is straight, not bent.
6. Infant's shoulders and chest face mother.
7. Infant's legs are flexed.
8. Infant's back is covered with blankets.
9. Mother-infant dyad is monitored continuously by staff in the delivery environment and regularly on the postpartum unit.
10. When mother wants to sleep, infant is placed in bassinet or with another support person who is awake and alert.

*The 1994 report of the Healthy Mothers, Healthy Babies National Coalition Expert Work Group recommend that the UNICEF-WHO Baby Friendly Hospital Initiative be adapted for use in the United States as the United States Breastfeeding Health Initiative, using the adapted 10 hospital practices noted.
†Data from Baby-Friendly USA. Guidelines and evaluation criteria for facilities seeking baby-friendly designation. Sandwich, MA: Baby Friendly USA; 2010. Available at https://www.babyfriendlyusa.org/for-facilities/practice-guidelines/. Accessed 10 November 2022. From ACOG Committee Opinion. Optimizing support for breastfeeding as part of obstetric practice. *Obstet Gynecol.* 2018;132(4):e187–e195, Boxes 1 and 2, pp. e191–e192.
‡The American Academy of Pediatrics endorsed the UNICEF-WHO Ten Steps to Successful Breastfeeding, but does not support a categorical ban on pacifiers because of their role in reducing the risk of sudden infant death syndrome and their analgesic benefit during painful procedures when breastfeeding cannot provide the analgesia.
**Data from Ludington-Hoe SM, Morgan K. Infant assessment and reduction of sudden unexpected postnatal collapse risk during skin-to-skin contact. *Newborn Infant Nurs Rev.* 2014;14:28–33.

Nipple pain is one of the most common complaints of breastfeeding mothers in the immediate postpartum period. Poor infant positioning and improper latch are the most common reasons for nipple pain beyond the mild discomfort felt early in breastfeeding. If the problem persists and the infant refuses to feed, evaluation for **nipple candidiasis** is indicated. If candidiasis is present, the nipples can be treated with an antifungal cream that is wiped off of the breast before feeding, and the infant is treated with an oral antifungal medication.

Tongue-tie (ankyloglossia) has been associated with nipple pain, poor latching, and poor weight gain in breastfed and bottle-fed infants. Ankyloglossia is defined as a lingual frenulum that attaches close to the anterior tongue tip and is estimated to be present in 4–11% of newborns. *Frenotomy* is a minor surgical procedure with few complications

Table 61.5 Recommendations on Breastfeeding Management for Healthy Term Infants

1. Exclusive breastfeeding for about 6 months
   - Breastfeeding preferred; alternatively, expressed mother's milk or donor breast milk
   - To continue for 2 years or beyond as long as mutually desired by mother and child
   - Complementary foods rich in iron, zinc, and other micronutrients should be introduced at about 6 mo of age
2. Peripartum policies and practices that optimize breastfeeding initiation and maintenance should be compatible with the AAP and Academy of Breastfeeding Medicine Model Hospital Policy and include the following:
   - Direct skin-to-skin contact with mothers immediately after delivery until the first feeding is accomplished and encouraged throughout the postpartum period
   - Delay in routine procedures (weighing, measuring, bathing, blood tests, vaccines, and eye prophylaxis) until after the first feeding is completed
   - Delay in administration of intramuscular vitamin K until after the first feeding is completed but within 6 hr of birth
   - Ensure 8-12 feedings at the breast every 24 hr
   - Ensure formal evaluation and documentation of breastfeeding by trained caregivers (including position, latch, milk transfer, examination) at least once for each nursing shift
   - Give no supplements (water, glucose water, commercial infant formula, or other fluids) to breastfeeding newborn infants unless medically indicated using standard evidence-based guidelines for the management of hyperbilirubinemia and hypoglycemia
   - Avoid routine pacifier use in the postpartum period
   - Begin daily oral vitamin D drops (400 IU) at hospital discharge
3. All breastfeeding infants should be seen by a pediatrician within 48-72 hr after discharge from the hospital
   - Evaluate hydration and elimination patterns
   - If weight >7% below birthweight or there is additional weight loss on day 5 or later, providers should consider more frequent follow-ups and/or referral to a lactation consultant.
   - Discuss maternal/infant issues
   - Observe feeding
4. Mother and infant should sleep in proximity to each other to facilitate breastfeeding
5. Pacifier should be offered, while placing infant in back-to-sleep-position, no earlier than 3-4 weeks of age and after breastfeeding has been established

From American Academy of Pediatrics (AAP). Breast-feeding and the use of human milk. *Pediatrics.* 2012;129:e827–e841.

Table 61.6 Patterns of Milk Supply

DAY OF LIFE	MILK SUPPLY
Day 1	Some milk (~5 mL) may be expressed.
Days 2-4	Lactogenesis; milk production increases.
Day 5	Milk present; fullness and leaking are felt.
Day 6 onward	Breasts should feel "empty" after feeding.

Adapted from Neifert MR. Clinical aspects of lactation: promoting breastfeeding success. *Clin Perinatol.* 1999;26:281–306.

and has been used as a treatment option for ankyloglossia with increasing frequency despite *insufficient evidence* that it improves breastfeeding outcomes, making its use somewhat controversial. Most infants with ankyloglossia have no feeding problems, and most infants with nursing problems do not have ankyloglossia. Providing a feeding evaluation and assessment of latch while monitoring weight over the course of 2-3 weeks may be more valuable than proceeding immediately to frenotomy. During that time many feeding issues resolve, thus avoiding unnecessary frenotomy.

Engorgement may occur in the second stage of lactogenesis (typically days 3-10 postpartum) and is characterized by the breasts feeling firm, overfilled, and sometimes painful. Incomplete removal of milk as a result of ineffective breastfeeding technique or infant illness can cause engorgement. Breastfeeding immediately at signs of infant hunger can prevent this from occurring. To reduce engorgement, breasts may be softened before infant feeding with a combination of hot compresses and manual expression of milk. To reduce inflammation and pain, between feedings mothers can wear a supportive bra, apply cold compresses, and take oral nonsteroidal antiinflammatory drugs (NSAIDs).

Mastitis occurs in 2–3% of lactating women and is usually unilateral, manifesting with localized warmth, tenderness, edema, and erythema after the second postdelivery week. Sudden onset of breast pain, myalgia, and fever with fatigue, nausea, vomiting, and headache can also occur. Organisms implicated in mastitis include *Staphylococcus aureus, Escherichia coli,* group A streptococcus, *Haemophilus influenzae, Klebsiella pneumoniae,* and *Bacteroides* species. Diagnosis is confirmed by physical examination. Treatment is with oral antibiotics (most commonly dicloxacillin or cephalexin) and analgesics, while at the same time promoting breastfeeding or emptying of the affected breast. A **breast abscess** is a much less common complication of mastitis, but it is a more serious infection that requires intravenous antibiotics and incision and drainage, along with continued breast emptying. Washing hands thoroughly before breastfeeding or pumping, especially after changing the baby's diapers, can help minimize risk for breast infections.

Insufficient milk intake, dehydration, and jaundice in the infant can occur within the first weeks of life. In fact, retrospective studies suggest higher rates of hospitalization—primarily caused by jaundice and poor weight gain—in the first month of life for breastfed versus formula-fed babies, highlighting the *critical importance of lactation support*. Breastfed neonates feed 8-12 times a day. Signs that milk intake is not adequate include lethargy, delayed stooling, decreased urine output, weight loss >10% of birthweight, hypernatremic dehydration, inconsolable crying, and increased hunger. Insufficient milk intake may be caused by inadequate milk production and/or health conditions in the infant that prevent proper breast stimulation. Careful attention to prenatal history can identify maternal factors associated with low milk production (for example, obesity, type 2 diabetes, postpartum hemorrhage, or failure of breasts to enlarge during pregnancy or within the first few days after delivery). Excess weight loss or failure to return to birthweight by 7-10 days in an exclusively breastfed infant should trigger an evaluation of breastfeeding effectiveness. Direct observation of breastfeeding can help identify improper technique, and test weighs (weighing the infant before and after feeding) may help assess milk transfer. If a large volume of milk is expressed manually after breastfeeding, the infant might not be extracting enough milk, eventually leading to decreased milk output. Late preterm infants (34-36 weeks) are at particular risk for insufficient milk intake because of weak suck, difficulty coordinating suck and swallow patterns, or medical issues.

Breastfeeding jaundice, also referred to as *suboptimal intake jaundice,* is related to insufficient fluid intake during the first week of life and is a common reason for hospital readmission of healthy breastfed infants (see Chapter 137). Breastfeeding jaundice is associated with dehydration and hypernatremia. Treatment may require supplementation with expressed maternal breast milk, donor milk, or infant formula**.** ***Breast milk*** **jaundice** is a different disorder that causes persistently high serum indirect bilirubin in thriving, healthy, well-fed infants. Breast milk contains inhibitors of glucuronyl transferase and causes enhanced absorption of bilirubin from the gut. Breast milk jaundice becomes evident later than breastfeeding jaundice and generally declines in the second to third week of life. Infants with severe or persistent jaundice or a direct hyperbilirubinemia need evaluation for other medical causes (see Chapter 137). Persistently high bilirubin levels may require treatment with phototherapy without cessation of breastfeeding or changing from breast milk to infant formula for 24-48 hours if phototherapy is not available or if a rapid reduction in total serum bilirubin is urgently needed. Breastfeeding can resume after the decline in serum bilirubin. Parents can be encouraged to continue collecting breast milk during the period the infant is taking formula.

Breast milk collection by pumping is a common practice when the mother and baby are separated and when families wish for other caregivers to engage in infant feeding. Electric breast pumps are generally more efficient and better tolerated by mothers than manual pumps or hand-expression, but not all insurance companies cover electric pumps. Good handwashing and hygiene are important during all steps of pumping. Collection kits should be cleaned with hot soapy water, rinsed, and air-dried after each use. Glass or plastic containers can be used to collect the milk. Fresh milk can be stored at room temperature for up to 4 hours and in the refrigerator for up to 4 days. Expressed breast milk can be frozen and used for up to 6-12 months; frozen milk should be used within 24 hours of thawing. Human milk should never be microwaved. **Paced bottle feeding** helps support breastfeeding during bottle feeds by matching the slower pace of direct breastfeeding.

Growth of the breastfed infant differs from that of the formula-fed infant; the infant's risk for excess weight gain during late infancy may be associated with bottle feeding (whether formula or expressed human milk). The WHO growth charts are based on growth patterns of healthy breastfed infants through the first year of life. The infants were selected based on being breastfed, having good healthcare, an absence of socioeconomic constraints, and nonsmoking mothers, so that they reflect the growth pattern of breastfed infants in optimal conditions and can be used as prescriptive standards rather than as normative reference curves. Charts are available for growth monitoring. The Centers for Disease Control and Prevention (CDC) recommends use of the WHO growth charts for infants from birth to 2 years and CDC growth charts for ages 2 to 20 years (see Chapter 27).

Formula Feeding

Despite efforts to promote exclusive breastfeeding through 6 months, only ~55% of women in the United States continue any breastfeeding at 6 months. Parental preferences are the most common reason for using infant formula and may relate to return to work, perceived poor milk supply, lack of support, or other factors. Most parents make their infant feeding choices early in pregnancy. However, infant formula is also indicated for infants whose intake of breast milk is contraindicated for infant factors (e.g., inborn errors of metabolism) or maternal factors (see Table 61.2). In addition, infant formula may be used as a supplement to support inadequate weight gain in breastfed infants, though often formula is used to supplement based upon caregiver perception of benefit rather than medical necessity.

Infant formulas marketed in the United States are safe and nutritionally adequate as the sole source of nutrition for healthy infants for the first 6 months of life. Infant formulas are available in ready-to-feed, concentrated liquid, and powder forms. Ready-to-feed products generally provide 19-20 kcal/30 mL (1 oz) and approximately 64-67 kcal/100 mL. Concentrated liquid products, when diluted according to instructions, and powder formulas, when mixed according to instructions (typically 2 ounces of water plus one scoop of powder), will result in similar caloric density.

Although infant formulas are manufactured in adherence to good manufacturing practices and are regulated by the U.S. Food and Drug Administration (FDA), there are potential safety issues. Ready-to-feed and concentrated liquid formulas are commercially sterile, but powder preparations are not. Although the number of bacterial colony-forming units per gram (CFU/g) of powder formula is generally lower than allowable limits, outbreaks of infections with *Cronobacter sakazakii* (previously *Enterobacter sakazakii*) have been documented, especially in premature infants. The powder preparations can contain other coliform bacteria but have not been linked to disease in healthy term infants. Care must be taken to follow the mixing instructions to avoid overdilution or underdilution, to use clean water, and to use the specific scoops provided by the manufacturer because scoop sizes vary. Water that has been boiled must cool fully to prevent degradation of heat-labile nutrients, specifically vitamin C. Well water should be tested regularly for bacteria and toxin contamination. Testing may also identify high lead concentrations in water flowing through pipes installed before 1986. Municipal water can contain variable concentrations of fluoride, and if the concentrations are higher than 2.0 mg/L, use of bottled water that is defluoridated is preferred to avoid possible toxicity and tooth discoloration.

Proper handwashing is important before preparing formula for the infant. Formula storage guidelines vary based on preparation. Once opened, ready-to-feed and concentrated liquid containers can be covered and stored in the refrigerator for no longer than 48 hours. Manufacturer guidelines recommend storing powder formula in a cool, dry place but not in the refrigerator; once opened, cans can be covered with the original plastic cap or aluminum foil, and the powdered product used within 4 weeks. The CDC recommends using prepared formula within 24 hours, regardless of type. The CDC further recommends using formula within 2 hours of removal from the refrigerator and within 1 hour from the start of a feed. Prepared formula stored in the refrigerator can be warmed by placing the container in warm water for about 5 minutes. Formula should *never* be heated in a microwave because it can heat unevenly and result in burns, despite appearing to be at the right temperature when tested.

Formula feedings are ideally provided ad libitum, with the goal of achieving growth and development to the child's genetic potential. The usual intake to allow a weight gain of 20-30 g/day in the first 2-3 months of life is approximately 140-180 mL/kg/day, although some may require intake outside this range. The average rate of weight gain declines from 3 to 12 months of age (see Chapters 27 and 64). **Overfeeding** with resultant rapid weight gain increases the risk for developing obesity and is to be prevented. **Paced bottle feeding** may help avoid overfeeding.

COW'S MILK PROTEIN–BASED FORMULAS

Intact cow's milk protein–based formulas are appropriate for most term infants. There are nutritional differences between formula and breast milk, although the effects of these differences on long-term health are unknown. Formulas contain 10-35 times higher iron compared with breast milk and higher zinc, sodium, and vitamin D. Most formulas in the United States also contain considerably higher protein than in mature breast milk. This concentration is designed to meet the needs of the youngest infants but may lead to excess protein intake for older infants and has been associated with increased risk of obesity. In contrast, breast milk protein content decreases over time to match needs. Protein concentration and composition differences between human milk and cow's milk–based formulas result in different plasma amino acid profiles in infants on different feeding patterns, but clinical significance has not been demonstrated.

Fat provides 40–50% of the energy in cow's milk–based formulas and is primarily from plant and animal oils. Fat blends are better absorbed than dairy fat and provide saturated, monounsaturated, and polyunsaturated fatty acids (PUFAs). All infant formulas are supplemented with long-chain PUFAs, specifically docosahexaenoic acid (DHA) and arachidonic acid (ARA). DHA and ARA are found at varying concentrations in human milk and vary by geographic region and maternal diet. The DHA and ARA added to formulas are derived from single-cell microfungi and microalgae and are classified as "generally recognized as safe" (GRAS) for use in infant formulas at approved concentrations and ratios. Long-term studies are lacking on the relationship between routine supplementation of formula with long-chain PUFAs and physical, neurodevelopmental, or visual outcomes of term infants.

Lactose is the major carbohydrate in breast milk and in standard cow's milk–based formulas for term infants. Formulas for term infants may also contain modified starch or other complex carbohydrates like prebiotic oligosaccharides similar to those in human milk.

SOY PROTEIN–BASED FORMULAS

Soy protein–based formulas on the market are all free of cow's milk–based protein and lactose. They meet the vitamin, mineral, and electrolyte guidelines from the AAP and the FDA for feeding term infants. In term infants, although soy protein–based formulas have been used to provide nutrition resulting in normal growth patterns, there are few indications for use in place of cow's milk–based formula. Indications for soy formula include galactosemia, preference for a vegetarian diet, and hereditary lactase deficiency, because

soy-based formulas are lactose free. Most healthy infants with acute gastroenteritis can be managed after rehydration with continued use of breast milk or cow's milk–based formulas and do not require a lactose-free formula. However, soy protein–based formulas may be indicated when documented secondary lactose intolerance occurs. Soy protein–based formulas have no advantage over cow's milk protein–based formulas as a supplement for the breastfed infant, unless the infant has one of the indications noted previously. Soy protein–based formulas are *contraindicated for preterm infants* because of concerns about protein quality and aluminum content. The routine use of soy protein–based formula has no proven value in the prevention or management of infantile colic, fussiness, or atopic disease. Infants with documented cow's milk protein–induced enteropathy or enterocolitis often are also sensitive to soy protein and should be fed using an extensively hydrolyzed or amino acid–based formula.

PROTEIN HYDROLYSATE FORMULAS

Protein hydrolysate formulas may be partially hydrolyzed, containing oligopeptides with a molecular weight of <5,000 daltons (range 3,000-10,000 Da), or extensively hydrolyzed, containing peptides with a molecular weight <3,000 Da. These formulas are lactose free and can include medium-chain triglycerides, making them useful in infants with gastrointestinal malabsorption caused by cystic fibrosis, short bowel syndrome, prolonged diarrhea, or hepatobiliary disease. **Partially hydrolyzed protein** formulas have fat blends similar to cow's milk–based formulas, and carbohydrates are supplied by corn maltodextrin or corn syrup solids. Because the protein is only partially hydrolyzed, these formulas are not appropriate for infants who are allergic to cow's milk protein. There is insufficient evidence to recommend use of hydrolyzed formulas to prevent atopic dermatitis or other atopic diseases in high-risk infants. **Extensively hydrolyzed formulas** are recommended for infants intolerant to cow's milk or soy proteins.

AMINO ACID FORMULAS

Amino acid (elemental) formulas are peptide-free formulas that contain mixtures of essential and nonessential amino acids. They are designed for infants with cow's milk–based protein allergy who fail to thrive on extensively hydrolyzed protein formulas. The effectiveness of amino acid formulas to prevent atopic disease has not been studied.

OTHER FLUIDS IN INFANTS AND TODDLERS

Neither breastfed nor formula-fed infants require additional water unless dictated by a specific condition involving excess water loss, such as diabetes insipidus. Vomiting and spitting up are common in healthy infants. When weight gain and general well-being are noted, no change in formula is necessary. Whole cow's milk can impair iron absorption and is not recommended for infants younger than 12 months. Nondairy, very low-protein milks are also inadequate to meet infant nutritional needs. Prune or apple juice may be used in small amounts for treatment of constipation, but juice is not recommended for routine consumption in infants. Infants with vomiting caused by gastroenteritis may need to consume an oral electrolyte solution but will need close monitoring and ideally will consume the solution for less than 24 hours. Goat milk is not an appropriate substitution for formula. Goat milk has been shown to cause significant electrolyte disturbances and anemia because it has low folic acid concentrations. Likewise, homemade formulas, which typically involve a combination of raw cow, raw goat, or plant-based milk, cod liver oil, molasses, and other ingredients, cannot be considered safe for infant feeding. Mixing homemade formula incorrectly can put unnecessary stress on a newborn's kidneys and intestines and may not provide sufficient calories or micronutrients. Infants and young children are also particularly susceptible to infections such as *Escherichia coli*, *Campylobacter*, *Listeria*, *Brucella*, and *Salmonella* found in **raw or unpasteurized milk**.

COMPLEMENTARY FEEDING

The timely introduction of complementary foods (solid and liquid foods other than breast milk or formula, also called **weaning foods**) during infancy is important for nutritional and developmental reasons (Table 61.7). The AAP recommends exclusive breastfeeding for about the first 6 months, after which nutrient requirements cannot be met by breastfeeding alone. Table 61.7 summarizes the AAP recommendations for introducing complementary foods, though nearly 25% of parents do not adhere to current guidelines (e.g., introducing complementary foods too early or introducing inappropriate foods, such as cow's milk, in children under 12 months).

Complementary foods should be introduced around 6 months and be varied to ensure adequate macronutrient and micronutrient intake. Although there is not currently evidence to promote a recommended order in which to introduce foods, information about important nutrients is included here. Additionally, a wide variety of textures is important for oral motor development, typically starting with pureed or very soft (easy to mash with the gums) foods. This is also a good time to establish consistent eating routines, including providing predictable meal and snack times for solid foods, eating in a safe dedicated space (such as in a highchair at the family table), and eating with family members to the extent possible. Continued breastfeeding up to 24 months of age and use of infant formula until 12 months is encouraged.

Some complementary foods are more nutritionally beneficial than others. *Iron- and zinc-rich foods* (such as fortified infant cereals, age-appropriate meats, eggs, and legumes) are especially important for breastfed infants, whose iron and zinc stores decline over time and are not sufficiently replaced through consumption of breast milk. Yogurt and cheese (including soy-based products) without added sugars are appropriate for infants receiving complementary foods, but full-fat cow's milk as a replacement for infant milk is inappropriate before 12 months. In addition to honey and unpasteurized consumables, foods and beverages with added sugars and those high in sodium are not recommended. Overconsumption of energy-dense complementary foods (e.g., cakes, cookies, fried foods, and sugar-sweetened beverages) can lead to excessive weight gain in infancy, increasing the risk of obesity in childhood.

Early introduction of peanuts and eggs around 4-6 months helps to prevent the development of food allergies. Although data are limited for other highly allergenic foods, the strength of current evidence suggests that introducing other allergenic foods early in complementary

Table 61.7 Important Principles for Weaning

- Begin around 6 mo of age.
- Introduce one new food at a time.
- Choose foods that provide key nutrients and help meet energy needs.
- Iron-containing foods (meat, iron-supplemented cereals) are required, especially for breastfed infants.
- Zinc intake should be encouraged with foods such as meat, dairy products, and fortified infant cereal.
- Phytate intake should be low to enhance mineral absorption.
- By 7-8 mo infants should be consuming foods from all food groups.
- Between 9 and 12 mo of age, encourage a cup rather than a bottle.
- Fluids other than breast milk, formula, and water should be discouraged.
- Breast milk can continue up to 24 mo of age; cow's milk can be introduced at 12 mo of age and up to 24 oz/day of cow's milk can be consumed if breastfeeding is discontinued.
- Give no more than 4 oz/day of 100% fruit juice; no sugar-sweetened beverages.
- Encourage routine mealtimes and responsive feeding, watching for and responding to the child's hunger and satiety cues.

Adapted from American Academy of Pediatrics. *Pediatric Nutrition Handbook*, 8th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2019.

feeding may prevent IgE-mediated food allergies. The most recent guidelines from the American Academy of Allergy, Asthma, and Immunology recommend early introduction of the top 9 highly allergenic foods (dairy, soy, eggs, peanuts, tree nuts, sesame, wheat, fish, and shellfish) for all children, especially those at higher risk for atopic disease. For more information, see Chapter 192.

TRANSITION TO MILK

Whole cow's milk can be introduced at 12 months, and formula-fed children are transitioned to milk at this time. In children 12-24 months, for whom overweight or obesity is a concern or who have a family history of obesity, dyslipidemia, or cardiovascular disease, the use of reduced-fat milk may be appropriate. Otherwise, whole milk is recommended until age 24 months, after which changing to 1% milk helps reduce overall dietary intake of fat if this is a concern. The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) does not provide 2% or whole milk for children over 24 months unless authorized by a medical provider. Regardless of the type, all animal milk consumed should be pasteurized because of the infection risk with raw or unpasteurized milk, as discussed earlier.

Nondairy alternatives to milk from plant-based (e.g., soy, hemp, pea, oat, rice) and nut-based (e.g., almond, cashew, peanut) sources are popular. When counseling parents, it is important to emphasize that the overall nutritional content and quality of plant-based milk alternatives is not equivalent to cow's milk. Although most are fortified with vitamin A, vitamin D, and calcium, only some soy-, hemp-, and pea-based milk alternatives have comparable protein content, and all products have inferior protein quality. Many plant-based products have added oils and sugars. No nondairy alternative milks are appropriate substitutions for infant formula or breast milk in infants. Nut-based milks may be suitable for toddlers ≥12 months of age without allergies who have an otherwise adequate diet. Nondairy (vegan) milks vary between products; a careful assessment of ingredients, including protein and micronutrient fortification, must be determined.

RESPONSIVE FEEDING

Responsive feeding begins in infancy and is associated with desirable growth outcomes. Responsive feeding refers to recognizing and responding to children's signs of hunger and satiety in a timely and developmentally appropriate manner. Parents are encouraged to learn to recognize signs of hunger (e.g., child leans forward or reaches for food, or opens mouth when offered food) and satiety (e.g., child closes mouth or turns away from food) in infants who receive solid foods so that they can respond appropriately.

The period from 6 months to 15 months is characterized by acquisition of self-feeding skills as the infant learns to grasp finger foods, use a spoon, and eat soft foods (Table 61.8). Around 12 months of age, the child learns to drink from a cup, and bottle weaning around 12-15 months is recommended. To prevent dental caries, bedtime bottles should be discouraged, and it is best that cups contain only water outside of mealtimes. Sugar-sweetened beverages and 100% fruit juice are not recommended for infants less than 12 months. Cups without a lid or with a straw rather than a hard spout are preferred.

Baby-led weaning (BLW) typically refers to allowing infants to self-feed soft (often well-cooked) solid or table foods from the very beginning of complementary feeding. Presently, many parents are choosing to give their infants finger foods rather than, or in combination with, purees. There is little evidence that BLW leads to improved nutrient status, weight gain, or food acceptance longitudinally. In general, all food textures, including purees, are encouraged to be included in the infant's diet. Parents should be counseled on avoidance of foods that are common choking hazards.

FEEDING TODDLERS AND PRESCHOOL-AGED CHILDREN

Toddlerhood is a period when eating behaviors and healthful habits can be established, and it is often a confusing and anxiety-generating period for parents. Important goals of early childhood nutrition are to offer foods that are developmentally appropriate and to begin to foster healthful eating habits that will last a lifetime. Growth after the first year slows dramatically, appetite decreases, motor activity increases, and children naturally become leaner until they reach an adiposity nadir at 4-6 years. Using growth charts to illustrate adequate growth and provide guidance about typical behavior and eating habits can help allay parents' concerns if they are explained in a way that parents can understand (Table 61.9). Eating behavior can be erratic, and children can appear distracted from eating as they explore the environment. Young children may consume a limited variety of foods, and it is common for children to "like" a particular food for a period and then reject the favored food. It can take many offers before children become familiar with and decide to try a novel food, and it is important to help children learn about food without expectations regarding how much they will eat.

Table 61.8 Feeding Skills Birth to 36 Months

AGE (mo)	FEEDING/ORAL SENSORIMOTOR SKILLS
Birth to 4-6	Nipple feeding, breast or bottle Hand on bottle during feeding (2-4 mo) Maintains semiflexed posture during feeding Promotion of infant-parent interaction
6-9 (transition feeding)	Head and neck control Feeding more in upright position Spoon-feeding thin, pureed foods Both hands to hold bottle Finger feeding of easily dissolvable solids introduced Vertical munching of easily dissolvable solids
9-12	Cup drinking Eats lumpy, mashed food Finger feeding for easily dissolvable solids Chewing includes rotary jaw action
12-18	Self-feeding; grasps spoon with whole hand Holds cup with two hands Drinking with four to five consecutive swallows Holding and tipping bottle
>18-24	Swallowing with lip closure Self-feeding predominates Chewing broad range of food Up-down tongue movements
24-36	Circulatory jaw rotations Chewing with lips closed One-handed cup holding and open cup drinking with no spilling Using fingers to fill spoon Eating wide range of solid food Total self-feeding, using fork

Recommended Intake and Serving Sizes

Toddlers and preschool-aged children usually eat three healthy meals and one to two snacks daily. Recommended daily amounts for each food group can be found in Table 61.10. Toddlers and preschool children often fail to meet the recommended servings of fruits, vegetables, and fiber, whereas intakes of food with fat and added sugar are excessive. Recommended serving sizes of fruits, vegetables, and grains are approximately the size of the child's fist, and a serving size of protein can be the size of the child's palm. It is important to be mindful that some children become overwhelmed when large portions are offered, fearing that they will be expected to finish the entire portion. If parents are concerned about their children eating enough vegetables, giving vegetables at the beginning of the meal has been shown, in some circumstances, to be an effective strategy for increasing vegetable consumption in preschool children. Milk continues to be an important

Table 61.9 Suggested Language for Discussing Growth Charts with Families

UNDERWEIGHT	NORMAL WEIGHT	OVERWEIGHT OR OBESE
• Looking at how your child's weight is matched for their height, only 2 of 100 children are at a weight that is lower at the same height. • Your child's weight for their height is lower than what is generally thought to be healthy. • BMI looks at the way height and weight are balanced with each other. Currently your child's BMI is too low, which has a higher risk of developing health problems related to weight.	• Looking at how your child's weight is matched for their height, 75 of 100 children are at a weight that is lower at the same height. • Your child's weight and height are matched for each other in a way that is generally thought to be healthy. • If you were to line up 100 children of the same age by weight, your child would be right in the middle.	• Looking at how your child's weight is matched for their height, 99 of 100 children are at a weight that is lower at the same height. • Your child's weight for their height is heavier than what is generally thought to be healthy. • BMI looks at the way height and weight are balanced with each other. Currently your child's BMI is too high, which has a higher risk of developing health problems related to weight.

Table 61.10 Recommended Daily Amounts for Children

	TODDLERS AGES 12-23 MO	CHILDREN AGES 2-8 YR	CHILDREN AGES 9 YR AND OLDER
Calories per day*	700-1,000	1,000-1,400	1,600-3,200
Vegetables	⅔-1 cup	1-1½ cups	2-4 cups
Fruits	½-1 cup	1-1½ cups	1½-2½ cups
Grains	1¾-3 ounces	3-5 ounces	5-10 ounces
Dairy	1⅔-2 cups	2-2½ cups	3 cups
Protein foods	2 ounces	2-4 ounces	5-7 ounces
Oils	9-13 grams	15-17 grams	22-51 grams

*Calorie needs may be higher for children who are active far above typical levels for age. Additionally, calorie needs may change on a daily basis as children experience illness, growth spurts, and variations in activity.

Adapted from the U.S. Department of Agriculture and U.S. Department of Health and Human Services. *Dietary Guidelines for Americans, 2020-2025*, 9th Edition. December 2020. Available at DietaryGuidelines.gov.

source of nutrition, particularly protein, fat, calories, and vitamin D, and it is recommended that children consume up to 2-3 cups (16-24 ounces) per day (see Table 61.10). Sugar-sweetened beverages like soda, sports drinks, sweetened tea, or fruit punch are not recommended. Toddlers ages 12 months and older can be given up to 4 oz/day of 100% fruit juice. Grapefruit juice can affect medications metabolized by CYP34A (e.g., antifungals such as fluconazole and ketoconazole, antiretrovirals, erythromycin, clarithromycin, fluoxetine, and amiodarone).

Feeding Practices

In the second year of life, self-feeding is learned, becomes the norm with time, and provides more opportunities for the family to eat together. Self-feeding also provides the child with the autonomy to self-regulate their intake. Child feeding is an interactive process, especially because children receive cues regarding appropriate eating behaviors from parents. Parents are encouraged to notice and comment on positive and ignore negative eating behaviors unless the behavior jeopardizes the health and safety of the child. Parents should avoid pressuring young children to eat, particularly pressuring them to eat larger, adult-sized portions. Instead, parents are encouraged to focus on acceptance of a wide variety of healthful foods. In addition, parents are encouraged to eat the same foods with their toddlers to model positive eating behaviors such as trying and consuming healthful foods.

The 2-year-old child can progress from small pieces of soft finger foods to prepared table foods with care. They can also learn how to eat with utensils (as culturally appropriate) over the preschooler period. The young child is not capable of completely chewing and swallowing chewy or hard foods, and hard foods present a choking risk. Hard candies, nuts, popcorn, and raw carrots should be avoided before age 4 years. Foods like hot dogs, sausages, and grapes can be sliced lengthwise to avoid choking. Caregivers should always be vigilant and present during feeding, and the child placed in a highchair or booster seat. The AAP discourages eating in the presence of distractions such as television, tablets, mobile devices, and other screens and eating in a car where an adult cannot adequately observe and assist the child.

FEEDING SCHOOL-AGED CHILDREN AND ADOLESCENTS

MyPlate

The U.S. Department of Agriculture (USDA) MyPlate (www.myplate.gov) is a basis for building an optimal diet for children and adults (Fig. 61.1). MyPlate is based on the 2020 **Dietary Guidelines for Americans**. MyPlate provides a visual representation of the different food groups and portion sizes designed for the general public. The website provides recipes, weight management strategies, and tools to track calories and physical activity goals. A personalized eating plan based on these guidelines provides, on average over a few days, all the essential nutrients necessary for health and growth, while limiting nutrients associated with chronic disease development. MyPlate can also be used as an interactive tool for customized recommendations based on age, sex, physical activity, and for some populations, weight and height. Print materials from the USDA are also available for families without internet access.

The MyPlate model emphasizes making half the plate vegetables and fruits, prioritizing whole grains, and eating protein from both animal and plant sources. A separate dairy section is included. Physical activity recommendations to achieve a healthful energy balance are not visually displayed but are provided on the website. MyPlate has removed foods that have low nutritional value, such as sugar-sweetened beverages and sweetened baked goods.

In the United States, the vast majority of children and adolescents do not consume a diet that follows the recommendations of MyPlate. The intake of high-calorie/low-nutrient-density foods is much higher than recommended, with frequent consumption of sugar-sweetened beverages (e.g., soda, juice drinks, iced tea, sport drinks), snack foods,

Fig. 61.1 MyPlate food guide. *(From U.S. Department of Agriculture: http://www.myplate.gov/.)*

Table 61.11 Revised National School Lunch Program and School Breakfast Program Recommendations

1. Portion sizes of food are to be based on age-grade groups.
2. School lunches and breakfasts will have a minimum and maximum calorie level, maximum saturated fat content, and a maximum sodium content.
3. Foods must contain zero grams of trans fat per serving.
4. The inclusion of unsaturated vegetable oils is encouraged within calorie limits.
5. Vegetables and fruits are not interchangeable.
6. Vegetable offerings at lunch must include cup equivalent of the following: dark-green vegetables, bright-orange vegetables, and legumes.
7. No more than half of fruit servings may be in the form of juice.
8. At least one half of bread/grain offered must be whole grain.
9. Milk must be fat free if flavored and either fat free or 1% fat if plain.
10. Students must select a fruit option at breakfast with their meal and either a fruit or a vegetable at lunch for the meal to be reimbursable.

Adapted from the National Academies of Engineering, Science and Medicine. *School Meals: Building Blocks for Healthy Children*. Washington, DC: National Academies Press; 2010.

high-fat meat (e.g., bacon, sausage), and high-fat dairy products (e.g., cheese, ice cream). Intake of dark-green and orange vegetables (vs fried white potatoes), whole fruits, reduced-fat dairy products, and whole grains is typically lower than recommended (see Table 61.10 for recommendations). Other common unhealthful eating habits include consuming larger-than-recommended portion sizes; preparing foods with added fat, sugar, or salt; skipping breakfast and/or lunch; grazing; consuming packaged snack foods; and following fad diets. MyPlate offers a helpful and customer-friendly tool to assist pediatricians counseling families on optimal eating plans for short- and long-term health.

Diet quality tends to decline with child age, and ensuring that children and adolescents consume sufficient nutrient-dense foods is a challenge for many parents. The vast majority of children and adolescents consume more than the recommended amounts of added sodium, saturated fats, and added sugars, with ~17% of calorie intake coming from highly processed packaged foods. Frequent snacking and consumption of sugar-sweetened beverages are major contributors to this excess and are valuable targets for dietary counseling. Among adolescents, night eating may be an important source of lower-quality food intake that may be missed during a standard diet recall. In the United States, nearly 85% of adolescents consume caffeinated beverages. Although moderate consumption (up to 2.5 mg/kg/day, equivalent to 6 ounces of coffee for a 30-kg child) is generally considered safe, higher levels of caffeine consumption are associated with impaired sleep and with negative physiologic, emotional, and behavioral outcomes.

NUTRITION ISSUES OF IMPORTANCE ACROSS PEDIATRIC AGES

Eating at Home

At home, parents control much of what children and adolescents eat because they typically shop for groceries and monitor which foods are available in the household. Home food availability is associated with child dietary intake: availability of foods such as fruits, vegetables, and dairy has been associated with intake of those foods, whereas availability of foods such as sugar-sweetened beverages is associated with lower diet quality. Parents can help to influence children's healthy food choices by modeling healthful eating behaviors themselves. Dietary counseling includes encouraging parents to make healthier food choices available and attractive at home and part of routine family meals. Improved diet quality for children is associated with regular family meals while sitting at a table (vs eating alone or watching a TV or other screen), perhaps because of increased opportunities for *positive parenting* during meals. Although there are many reasons families may be unable to provide an ideal meal setting (busy schedules, parents working multiple jobs, no kitchen table), family meals at predictable times are encouraged to the extent families are able.

Another important aspect of *food parenting* is helping children learn to be mindful of and respond to internal cues of hunger and satiety. This can be a challenge for some families who have children with a propensity to overeat or to eat in response to nonhunger signals (such as eating as an emotional response). Parents can support their children to eat at a slower pace and to chew their food properly. Useful strategies when the child is still hungry after a meal include a 15- to 20-minute pause (to allow the child to engage in another activity) before providing a second serving or offering foods that are insufficiently consumed, such as vegetables, whole grains, or fruits.

Eating in Childcare and School Settings

Many U.S. toddlers and preschool children attend formal or informal childcare and receive meals and snacks in this setting. There is wide variation in the quality of food offered (if food is provided) and level of mealtime supervision. Parents are encouraged to assess the quality of the food and supervision by asking questions, visiting the center, and taking part in parent committees. Free or reduced-price snacks and meals are provided in childcare centers for low- and medium-income communities through the **USDA Child and Adult Care Food Program**. Participating programs are required to provide meals and snacks that meet meal regulations set by the USDA, enabling a certain level of food quality. However, many centers and schools still struggle to provide high-quality meals and snacks due to cost.

The National School Lunch Program and the School Breakfast Program provide low-cost meals to millions of children. Guidelines for meals are taken from the Dietary Guidelines for Americans. Recommendations include the use of age-grade portion sizes and the amounts of vegetables and fruits, grains, and fats (Table 61.11). Among the necessary components of these programs are training and equipment for school food service staff, school community engagement, parent education, and food industry involvement. Parents are encouraged to assist their child with food choices at school. If children bring their lunch from home, lunch should include, at a minimum, a fruit and/or vegetable, a whole grain, and a protein source. Parents can be directed to www.myplate.gov for healthful lunch ideas. Additionally, parents are encouraged to be aware of school and classroom parties and work with teachers and other parents to ensure children have access to healthy choices.

Eating Outside the Home

The number of meals eaten outside the home or brought home from takeout restaurants continues to increase among all age-groups in the United States. The increased convenience of this meal pattern is undermined by the generally lower nutritional value of the meals compared with home-cooked meals. Typically, meals from fast-food or casual restaurants are of large portion size; are dense in calories; and contain large amounts of saturated fat, salt, and sugar and low amounts of whole grains, fruits, and vegetables. Although an increasing number of restaurants offer healthier alternatives, the vast majority of what is consumed at restaurants does not fit MyPlate recommendations. Parents are encouraged to evaluate menu labels when available, select the healthiest available options, and consider sharing meals to supplement children's meals, which often comprise highly palatable options with low nutrient density.

With increasing age, more meals and snacks are also consumed during peer social gatherings at friends' houses and parties. When a large part of a child's or adolescent's diet is consumed on these occasions, diet quality can suffer because food offerings are typically of low nutritional value. Parents and pediatricians need to guide children and teens in navigating these occasions while maintaining a healthful diet and enjoying meaningful social interactions. These occasions may also be opportunities for teens to consume alcohol; consequently, adult supervision is important.

Food Environment

Environmental and social challenges can make it difficult for families to make healthful food choices. Although *taste* is the main determinant of food choice, many other complex factors influence that choice, including cost, availability, accessibility, convenience, and marketing strategies, including shelf placement and special pricing. Recognizing the context of food and lifestyle choices can help providers understand lack of changes or "poor adherence" to dietary recommendations and can decrease the frustration often experienced by the pediatricians who might otherwise "blame the victim" for behavior that is not entirely under their control. Local and national efforts to improve access to fresh and unprocessed foods are ongoing but often struggle to address broader issues such as cost or time to prepare foods at home.

Responsive Feeding and Contingent Feeding Practices

Responsive feeding entails recognizing and responding to children's hunger and satiety cues in an age-appropriate and developmentally appropriate way across all stages of childhood and adolescence (Table 61.12). It also includes providing routines and structure with clear expectations (e.g., providing meals and snacks at scheduled intervals with a variety of healthy foods to choose from) and a warm emotional context that promotes positive interactions about food and eating. Responsive feeding strategies can include encouraging children to eat foods that are healthful, teaching them about various foods, and involving them in the selection and preparation of meals. Allowing children to select (within reason) how much to eat of each offered food encourages children to listen to internal cues of hunger and satiety.

It is common for parents to use food as a reward or sometimes withdraw preferred foods as punishment. Most parents use this practice occasionally, and some use it systematically, starting at young ages. The practice is also commonly used in other settings, such as in childcare, school, or even athletics. Although it is a good idea to limit some unhealthful but desirable foods to special occasions, using food as a reward can be problematic. Making access to food contingent on an accomplishment increases the desirability of that food. Conversely, pressuring children to consume some healthful foods renders those foods less desirable. Therefore phrases such as, "Finish your vegetables, and you will get ice cream for dessert" can result in establishing unhealthful eating habits once the child has more autonomy in food choices. Parents are encouraged to choose items other than food as rewards, such as stickers, inexpensive toys or sporting equipment, additional time for a favorite activity, special family events, or collectible items. Similar types of behavior are also seen in schools and extracurricular events, and parents are encouraged to work with teachers and coaches to identify appropriate alternative rewards.

Table 61.12 Responsive Feeding Recommendations

WAYS TO PROMOTE RESPONSIVE FEEDING	WHAT TO AVOID
• Have set meal and snack times and a consistent place to eat. • Select and provide healthful snack and meal options. • Allow child to decide what to eat and how much. • Sit and eat with the child. • Encourage child to try what is on the plate. • Notice when child attempts to try a food: "You tried your broccoli," or "good job trying your broccoli."	• Allow child to "graze" or eat small bites throughout the day. • Allow child to eat whatever they want. • Make child eat all of the food on their plate. • Leave child to eat by themselves. • Offer the child a (food) reward for eating their food. • Offer person praise to child: "You are a good person for trying your broccoli."

Cultural Considerations in Nutrition and Feeding

Food choices, food preparation, eating patterns, and infant feeding practices all have very deep cultural roots. Beliefs, attitudes, and practices related to food and eating are some of the most important components of cultural identity (Fig. 61.2). In multicultural societies, high dietary variability can be observed. In a world where global marketing forces tend to reduce geographic differences in the types and brands of food that are available, most families are still influenced by their cultural background, especially during family meals at home. Therefore pediatricians are encouraged to become familiar with the dietary characteristics of various cultures in their community, so that they can identify the potential nutritional benefits and concerns related to their patients' diets and address concerns in a nonjudgmental way.

Vegetarianism

Vegetarianism is the practice of following a diet that excludes animal flesh foods, including beef, pork, poultry, fish, and shellfish. There are several variations on the vegetarian diet, some of which also exclude eggs and/or some products produced from animal labor, such as dairy products and honey. Another expression used for different varieties of vegetarianism is **plant-based diets**.

It is important to ask parents or adolescents about their diets when they report following a vegetarian, vegan, or plant-based diet, because these terms may mean different restrictions for different families. Vegetarian and vegan diets, with extensive knowledge and forethought, can be safely followed by children. Some people practice diets that are even more restrictive, such as those that exclude foods from the allium family (e.g., onion, garlic, chives) or include only raw foods cooked below a certain temperature. The safety of these *more restrictive diets,* which can be very limited in macronutrients and micronutrients, has not been studied in children, and these more restrictive diets are not recommended. Although being on a vegetarian or vegan diet does not appear to increase the risk of an eating disorder, some teenagers with disordered eating may choose such diets to aid in limiting their caloric intake.

Vegetarianism, or following a plant-based diet, is considered a healthful and viable diet: both the U.S. Academy of Nutrition and Dietetics and the Dietitians of Canada have found that a properly planned and well-balanced vegetarian diet can satisfy the nutritional goals for all stages of life. Recommendations for healthy vegetarian dietary patterns at all ages can be found in the 2020 Dietary Guidelines for Americans. Families may benefit from consultation with a registered dietitian to ensure all nutrient requirements are being met.

Compared with meat-based diets, vegetarian diets tend to have lower intakes of saturated fat, cholesterol, and animal protein and relatively higher levels of complex carbohydrates, fiber, magnesium, potassium,

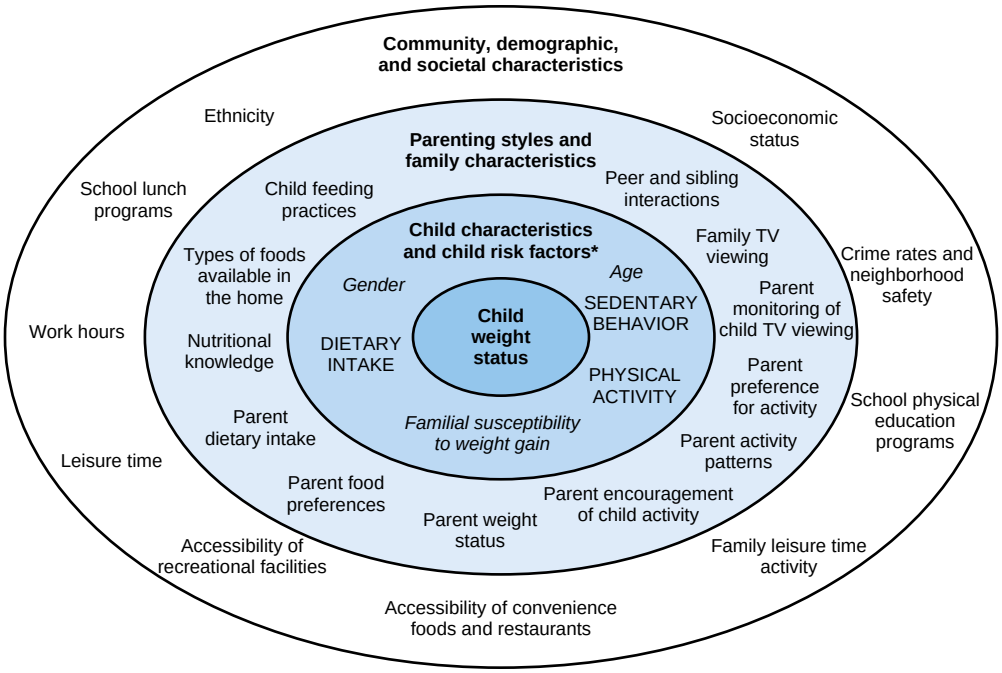

Fig. 61.2 A conceptual framework of the context of food and lifestyle choices. Child risk factors (shown in uppercase lettering) refer to child behaviors associated with the development of overweight. Characteristics of the child (shown in italic lettering) interact with child risk factors and contextual factors to influence the development of overweight (i.e., moderator variables). *(From Davison KK, Birch LL. Childhood overweight: a contextual model and recommendations for future research. Obes Rev. 2001;2:159–171. © 2001 The International Association for the Study of Obesity.)*

folate, vitamins C and E, and phytochemicals. Vegetarians tend to have a lower body mass index, cholesterol level, and blood pressure and are at decreased risk for cancer and ischemic heart disease. Specific nutrients of concern in vegetarian diets include the following:

- **Iron** (see Chapter 72): Vegetarian diets may have similar levels of iron intake as nonvegetarian diets, but iron from plant sources has lower bioavailability than iron from meat sources. Additionally, iron absorption may be inhibited by other dietary constituents, such as phytate (found in leafy green vegetables and whole grains). Iron stores are lower in vegetarians and vegans than in nonvegetarians, and iron deficiency is more common in vegetarian and vegan women and children. Plant-based foods rich in iron include iron-fortified cereals, black beans, cashews, kidney beans, lentils, oatmeal, raisins, black-eyed peas, soybeans, sunflower seeds, chickpeas, molasses, chocolate, and tempeh. Iron absorption from plants is increased when consumed with vitamin C–containing foods (e.g., bell peppers, citrus fruits, strawberries, tomatoes, broccoli). Periodic monitoring of iron stores may be valuable in vegan and vegetarian children and adolescents with low iron intake.
- **Vitamin B_{12}:** Plants are not a good source of B_{12} (see Chapter 67.7). Vegetarians may consume vitamin B_{12} through dairy products and eggs; vegans need fortified foods or supplements. Breastfeeding by B_{12}-unsupplemented vegan mothers can place an infant at risk for vitamin B_{12} deficiency. Only some infant liquid multivitamins contain B_{12}. Vegan children and adolescents may need assessment of vitamin B_{12} levels if supplementation is inconsistent.
- **Fatty acids:** Vegetarians and vegans may be at risk for insufficient eicosapentaenoic acid (EPA) and DHA. The inclusion of sources of linolenic acid (a precursor of EPA and DHA), such as walnuts, soy products, flaxseed oil, and canola oil, is recommended.
- **Calcium and vitamin D:** Without supplementation, vegan diets can be low in calcium and vitamin D, putting vegans at risk for impaired bone mineralization (see Chapter 69). Monitoring serum 25-hydroxyvitamin D levels can identify patients with deficiency (<30 ng/mL) and start supplementation. Calcium sources include leafy greens with low oxalate, such as broccoli, kale, and Chinese cabbage. Calcium and vitamin D are found in some fortified plant-based milks and yogurts and some brands of orange juice.
- **Zinc:** The bioavailability of zinc in plant sources tends to be low because of the presence of phytates and fiber that inhibit zinc absorption (see Chapter 72). Zinc is found in soy products, legumes, grains, cheese, and nuts.
- **Iodine:** Plant-based diets can be low in iodine, and vegetarians and vegans who do not consume iodized salt or sea vegetables (which have variable iodine content) may be at risk of iodine deficiency. The exclusive use of noniodized salt such as Himalayan, sea, or kosher salts could further increase that risk. Iodized salt is not typically used in processed foods such as crackers, although some bread products are fortified with iodine.

Families may also choose to restrict specific foods in the form of elimination diets to prevent allergies or to treat real or presumed gastrointestinal disorders. Figure 61.3 provides an approach to elimination/restrictive diets.

Organic Food

Organic food is defined as produce and ingredients grown without the use of synthetic pesticides, synthetic fertilizers, sewage sludge, genetically modified organisms, or ionizing radiation. Animals that produce organic meat, poultry, eggs, and dairy products are not given antibiotics or growth hormones. In the United States, certification must be obtained, and USDA regulations must be followed to market food as "organic."

Genetically modified organisms (GMOs) in themselves are not thought to be harmful to consume. However, GMOs are modified to be resistant to the effects of herbicides, including glyphosate and 2,4-dichlorophenoxyacetic acid (2,4-D), which give GMOs a selective growth advantage and facilitate use of these chemicals. Glyphosate and 2,4-D have been designated by the International Agency for Research on Cancer as probable and possible human carcinogens, respectively. Therefore higher concentrations of these chemicals in GMO foods are of concern.

Parents may prefer organic foods to feed children secondary to concerns regarding chemical and hormonal content of animals and produce. Although nutritional differences between organic and conventional foods have been reported (e.g., higher levels of PUFAs, α-tocopherol, and iron and lower levels of cadmium, selenium, and

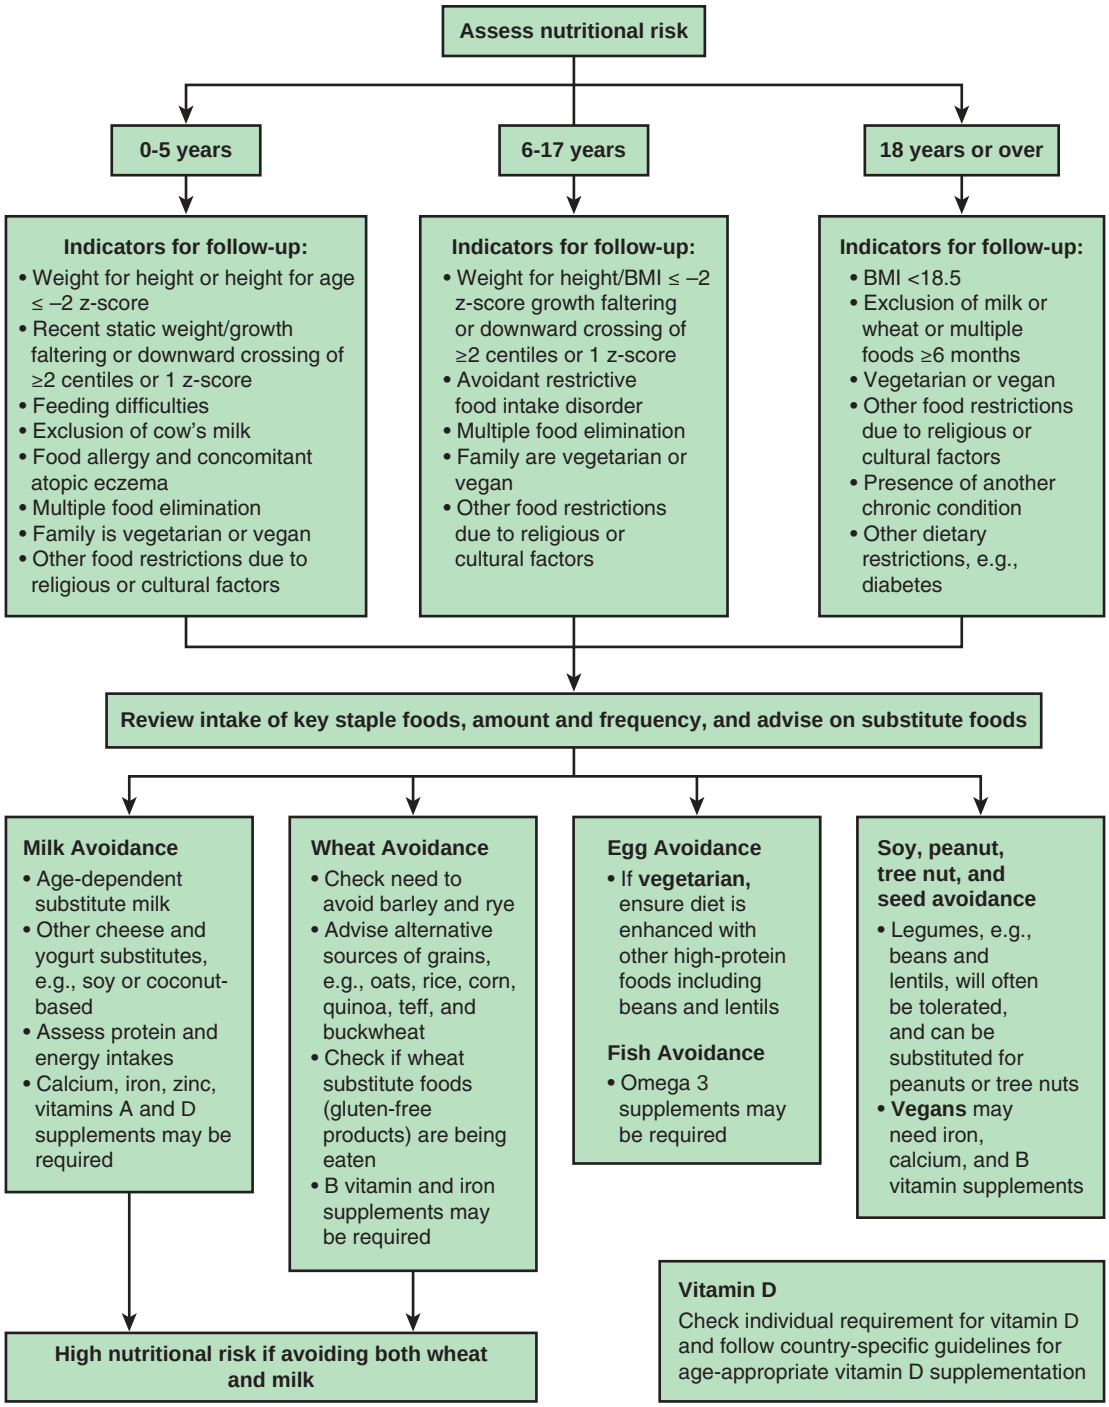

Fig. 61.3 Approach to evaluate risk for adverse elimination diets. BMI, Body mass index. *(Modified from Skypala IJ, McKenzie R. Nutritional issues in food allergy. Clin Rev Allergy Immunol. 2019;57:166–178, Fig. 1, p. 172.)*

iodine), they may not be clinically relevant. Similarly, children consuming organic foods have lower levels of pesticides in their urine compared with those consuming nonorganic foods, but it remains unclear whether such a reduction is clinically meaningful. However, other chemicals in the environment, such as the endocrine disruptors bisphenol-A and phthalates (found in plastics), are best avoided. A high frequency of organic food ingestion has been associated with a lower risk of cancer in adults.

Nutritional Supplements

The use of nutritional supplements as complementary or alternative medicine is increasing, despite limited data on safety and efficacy, especially in children. Many parents assume that if a food or supplement is "natural" or "organic," there is no potential for risk and some potential for benefit. However, adverse effects of some dietary supplements have been documented, and some supplements have been discovered to contain common allergens. In the United States, dietary supplements, including botanical and herbal products, are regulated differently from medications. Manufacturers do not have to prove safety or efficacy before marketing the supplement; the potential for adverse effects, inefficacy, unnecessary cost, and contamination is therefore high. It can be difficult to compete against the aggressive marketing of food supplements. Medical professionals must also compete against advice from people without a scientific background and those with significant conflicts of interest, particularly on the internet.

Pediatricians may be asked whether a child needs to receive a daily multivitamin. Many children do not follow all the guidelines of MyPlate, and parents and pediatricians may be tempted to use multivitamin supplements to fill gaps. The average U.S. diet provides more than a sufficient amount of most nutrients. Therefore multivitamins are recommended only where there is concern for dietary inadequacy, especially when intake of one of the major food groups is very limited or absent (fruits, vegetables, proteins, whole grains, dairy or equivalent). Using vitamin supplements as a support while working to expand dietary variety can help avoid micronutrient deficiencies in cases of dietary restriction whether due to food selectivity or for health, cultural, or religious reasons.

Food Safety

Food safety issues are an important aspect of feeding infants, children, and adolescents. In addition to choking hazards and food allergies, pediatricians and parents need to be aware of food safety issues related to infectious agents and environmental contaminants. **Food poisoning** with bacteria, viruses, or their toxins is most common with raw or undercooked food, such as meat, poultry, eggs, and seafood, or cooked foods that have not been handled or stored properly. Unwashed fruits and vegetables may also be contaminated. The specific bacteria and viruses involved in food poisoning are described in Chapter 259. Many chemical contaminants, such as heavy metals, pesticides, and organic compounds, are present in various foods, usually in small amounts. Because of concerns regarding their child's neurologic development and cancer risk, many questions arise from parents, especially after media coverage of isolated incidents. A recurring debate is the balance between the benefits of seafood for the growing brain and cardiovascular health and the risk of mercury contamination from consuming large, predatory fish species. The **Food Safety Modernization Act** provides the FDA with authority to have stricter control over food production and distribution, including requirements that manufacturers develop food safety plans. A good source of information for patients and parents can be found at www.foodsafety.gov. Other reliable sources of information include the websites of the U.S. Environmental Protection Agency (EPA), FDA, and CDC.

Preventive Nutrition Counseling in Pediatric Primary Care

An important part of the primary care well child visit focuses on nutrition and growth because most families turn to pediatric healthcare providers for guidance on child nutrition. Preventive nutrition is one of the cornerstones of preventive pediatrics and a critical aspect of anticipatory guidance. The first steps of nutrition counseling are nutritional status assessments, primarily achieved through growth monitoring and dietary intake assessment. Although **dietary assessment** is somewhat simple in infants who have a relatively monotonous diet, it is more challenging at older ages. The goals of dietary assessment in the primary care setting need to include an idea of the eating patterns (time, location, and environment) and usual diet. A basic assessment of the child's intake includes evaluating meal routine, dietary diversity (ensuring that a child eats foods from all food groups, namely vegetables, fruits, whole grains, sources of iron and protein, and low-fat or nonfat dairy products), and consumption of sugar-sweetened beverages, including 100% fruit juice. Pediatricians can encourage regularly scheduled meals and one or two healthy snacks (depending on the child's age) with avoidance of grazing, particularly on foods and beverages that are energy dense but of low nutritional value. For more ambitious goals of dietary assessment, referral to a registered dietitian with pediatric experience is recommended.

After understanding the child's usual diet, existing or anticipated nutritional problems can be addressed, such as diet quality, dietary habits, and portion size. Most nutritional issues, such as overeating or poor food choices, are not solely the result of lack of parents' knowledge but can be the result of access, availability, and economic factors. Therefore nutrition education alone is insufficient in these situations, and pediatricians need to acquire training in behavior-modification techniques such as motivational interviewing (see Chapter 18) or refer to specialists to assist their patients in engaging in healthful feeding and eating behaviors. The physical, cultural, and family environment in which the child lives must be considered so that nutrition counseling is relevant and changes feasible (see Fig. 61.2). The phone app ChangeTalk from the AAP provides free training on motivational interviewing for the prevention and treatment of pediatric obesity.

One important aspect of nutrition counseling is providing families with sources of additional information and behavioral change tools. Although some handouts are available from government agencies, the AAP, and other professional organizations for families without internet access, an increasing number of families rely on the internet to find nutrition information. Therefore pediatricians need to become familiar with common websites so that they can point families to reliable and unbiased sources of information. Perhaps the most useful websites for children are the AAP and USDA MyPlate sites and those of the CDC, FDA, National Institutes of Health, The National Academies, and Food and Nutrition Board for government sources. Other professional resources include the American Heart Association and Academy of Nutrition and Dietetics. Unfortunately, there are websites that provide biased or even dangerous information. Examples include dieting sites, sites that openly promote dietary supplements or other food products, and the sites of "nonprofit" organizations that are mainly sponsored by food companies or that have other social or political agendas.

Food Security and U.S. Food Assistance Programs

Food insecurity is defined as the state of being without reliable access to a sufficient quantity of affordable, nutritious food. In 2016, minoritized households were 1.5 to almost 2 times more likely to be food insecure than the national average of 12.3%. Children in food-insecure homes are more likely to have medical problems, including asthma and depression, and are more likely to seek emergency medical care. Patients from all backgrounds can experience food insecurity, and selective screening risks reinforcing bias and missing children in need. Answering "often true" or "sometimes true" (versus "never") to the following two-question screen has a sensitivity of 97% and specificity of 83% for identifying food insecurity: For the last 12 months: (1) "We worried whether our food would run out before we got money to buy more." (2) "The food we bought just didn't last, and we didn't have money to get more."

Several programs exist in the United States to help meet the needs of families experiencing food insecurity. One of the most utilized federal programs is the **Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)**. This program provides nutrition supplements to a large proportion of pregnant and postpartum women and children up to their fifth birthday. One of its strengths is that families regularly visit a WIC nutritionist, who can be a useful resource for nutritional counseling. For older children, federal programs provide school lunches, breakfasts, and after-school meals, as well as daycare and summer nutrition. Lower-income families are also eligible for the **Supplemental Nutrition Assistance Program (SNAP)**, formerly known as the Food Stamp Program. This program provides funds directly to families to purchase various food items in regular food stores. **Food insecurity screening should be universal in clinical settings.** Eligibility criteria for both WIC and SNAP can be found on the programs' federal websites.

Chapter 62

Nutrition, Food Security, and Health

Jason M. Nagata and Christine M. McDonald

MALNUTRITION AS THE INTERSECTION OF FOOD INSECURITY AND HEALTH INSECURITY

Undernutrition is usually an outcome of three factors, often in combination: household food supply insecurity, suboptimal childcare practices, and restricted access to or use of health and water/sanitation services. In famine and emergency settings, food shortage is the foremost factor, but in many countries with widespread undernutrition, food production or access to food might not be the most limiting factor. More important causes might be repeated childhood infections, especially diarrheal diseases associated with an unsanitary environment, poor infant and young child feeding practices, or various challenges that may prevent families from using quality maternal and child health services. Figure 62.1 shows some of the many causal factors on the pathway to undernutrition and how they extend from household and community levels to national/international levels. Inequitable distribution of resources because of political, economic, and agricultural policies often denies families their right to adequate land, water, food, healthcare, education, and a safe environment, all of which can influence nutritional status.

Families with few economic resources who know how to care for their children and are enabled to do so can often use available food and health services to produce well-nourished children. If food resources and health services are not available in a community, not used, or not accessible to some families, children might become undernourished. Undernutrition is not confined to low-income countries. It has been noted in chronically ill patients in neonatal and pediatric intensive care units in high-income countries and among patients with burns, human immunodeficiency virus (HIV) infection, tuberculosis, cystic fibrosis, chronic diarrhea syndromes, malignancies, bone marrow transplantation, and inborn errors of metabolism (see Chapter 64). Severe malnutrition has been reported in affluent communities in infants whose families believe in fad diets and in infants with food allergies fed nutritionally inadequate foods such as rice "milk," which has a very low protein and micronutrient content (Figs. 62.2 and 62.3; also see Fig. 61.3).

FOOD SECURITY

Food security exists when all people, at all times, have access to sufficient, safe, nutritious food to maintain a healthy and active life. Four main dimensions of food security can be identified: availability, access, utilization, and stability. **Availability** refers to the *supply* of food, reflecting the level of food production, food stocks, and net trade. **Access** is typically defined at the household level, reflecting purchasing power, household food production, and food/cash transfers received through social "safety net" programs. The **utilization** dimension recognizes that even when a household has access to food, it is not necessarily shared equitably within a household. **Stability** refers to being "food secure" at all times: Examples of situations that affect stability are the "lean seasons" before a harvest, natural disasters, political unrest, and rising food prices. To be food secure, all four dimensions must be met simultaneously.

Measuring Food Insecurity

The most commonly used measurement of food insecurity is *undernourishment* (chronic hunger), which is the proportion of the population who are unable to meet daily energy requirements for light activities. It is an estimate calculated by the **Food and Agriculture Organization (FAO)** based on country-level food balance sheets. It does not take nutrient adequacy into account, but has the advantage of being available for almost all countries annually (although with a time lag) and assists in monitoring global trends. In addition, FAO measures food access by asking individuals about their experiences over the last 12 months, such as whether they ran out of food or skipped meals. The responses are graded from mild to severe food insecurity. This relatively simple monitoring tool, the **Food Insecurity Experience Scale**, provides timely information to guide decision-making at national and local levels.

In 2020, the FAO estimated that between 720 and 811 million people, or approximately 9.9% of the world's population, were undernourished. More than half of the world's undernourished were found in

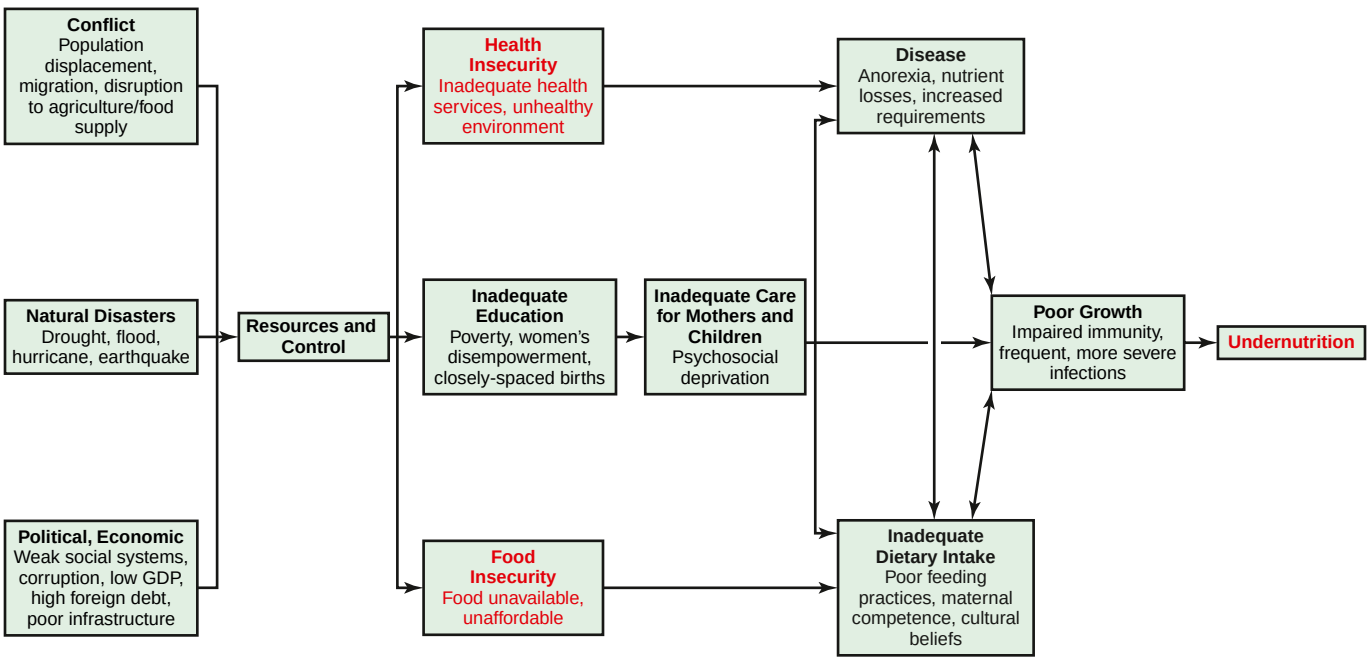

Fig. 62.1 Basic, underlying, and immediate causes of undernutrition.

Fig. 62.2 A 14-month-old girl with "flaky paint" dermatitis. *(From Katz KA, Mahlberg MH, Honig PJ, et al. Rice nightmare: Kwashiorkor in 2 Philadelphia-area infants fed Rice Dream beverage. J Am Acad Dermatol. 2005;52:S69–S72.)*

Fig. 62.3 Paired, transverse, homogeneous, and smooth bordered lines noted in all fingernails suggestive of Muehrcke lines in an infant fed diluted cow's milk since birth. Muehrcke lines are an apparent leukonychia most often associated with hypoalbuminemia. *(From Williams V, Jayashree M. Muehrcke lines in an infant. J Pediatr. 2017;189:234.)*

Asia, and more than one third were found in Africa. The majority are rural poor people subsisting on small plots of land or hired as laborers and urban poor people who lack the means to grow or buy food. Alongside the 768 million people who are underfed are 1.9 billion who are overweight or obese, reflecting global inequalities and the "double burden of malnutrition" in low- and middle-income countries.

Nutrition, Food Security, and Poverty

Household food security tracks income closely. With rising incomes, very poor households first increase their dietary energy intake to avert hunger. If incomes rise further, there is a shift to more expensive staple foods and then to a more varied diet with a greater proportion of energy from animal sources, fruits/vegetables, and fats/sugars and less from cereals, roots, and tubers. National economic growth tends to be accompanied by reductions in stunting, but economic growth can pass by poor persons if they work in unaffected sectors or are unable to take advantage of new opportunities because of lack of education, access to credit, or transportation, or if governments do not channel resources accruing from economic growth to healthcare, education, social protection, and other public services and infrastructure. There is good evidence that economic growth reduces poverty but does not necessarily reduce undernutrition.

Table 62.1 Global Food Security and Nutrition Targets

ZERO HUNGER CHALLENGE OBJECTIVES	WORLD HEALTH ASSEMBLY GLOBAL NUTRITION TARGETS FOR 2025
1. Access to an adequate and stable food supply for all 2. Elimination of stunting in children <2 yr, and no malnutrition in pregnancy and early childhood 3. Sustainable food systems 4. Doubling of smallholder productivity and income, particularly for women 5. No loss or waste of food and responsible consumption	1. A 40% reduction in the number of stunted children <5 yr 2. A 50% reduction in anemia in women of reproductive age 3. A 30% reduction in low birthweight 4. No increase in childhood overweight 5. Increase exclusive breastfeeding rates to at least 50% in the first 6 mo 6. Reduce and maintain childhood wasting to <5%

Food Security and Nutrition Targets

The period of the Millennium Development Goals (MDGs) ended in 2015. All developing regions except sub-Saharan Africa achieved the target to halve the proportion of people living in extreme poverty, with the proportion falling from 47% in 1990 to 14% in 2015. Reductions in hunger were broadly consistent with those of poverty reduction, and rates of undernourishment in developing regions fell from 23% in 1990 to 13% in 2015. The prevalence of underweight among children under 5 years (another MDG indicator of "hunger") fell from 29% in 1990 to 15% in 2015 for the developing regions combined. Rural children are almost twice as likely to be underweight as urban children, and the poorest quintile is almost 3 times as likely to be underweight as the richest quintile.

Eradicating poverty and hunger continue to be core targets of the **Sustainable Development Goals**, as agreed by 193 countries of the United Nations General Assembly in September 2015, and are to be achieved by 2030. In addition, in 2012 the World Health Assembly agreed to six global nutrition targets to be reached by 2025, measured against a 2010 baseline, and the United Nations Secretary-General launched the **Zero Hunger Challenge** with five objectives that "would boost economic growth, reduce poverty and safeguard the environment" and "would foster peace and stability" (Table 62.1).

Future Food Security

Between now and 2050 the world's population is expected to exceed 9 billion, and an increase in the food supply of 70–100% will be needed to feed this larger, more urban, and more affluent populace. Over this same period, the world's food supply is expected to diminish unless action is taken. Accelerating the decline in fertility rates and reducing overconsumption are basic but difficult actions to bridge the gap between increasing demand and diminishing supply. Equally challenging actions include limiting climate disruption, increasing the efficiency of food production, reducing waste, and reducing the demand for meat and dairy foods. The COVID-19 pandemic significantly disrupted food systems and exacerbated food insecurity globally.

- *Limit climate disruption.* Drought, floods, and other extreme weather events are becoming more prevalent and destroy crops and livestock, often on a huge scale. Rising sea levels will lead to loss of productive land through inundation and salinization. Acidification of oceans will reduce marine harvests. Because curbing greenhouse gas emissions is essential to minimize climate disruption, the goals are (1) to cut fossil fuel use by at least half of present levels by 2050 so as to reduce carbon dioxide (CO_2) emissions and (2) change livestock husbandry and agronomic practices to reduce methane and nitrous oxide (N_2O) emissions.
- *Increase efficiency of food production.* Expanding the area of agricultural land to any large extent (e.g., by deforestation) is not a sustainable option because of adverse consequences on ecosystems and biodiversity, although some expansion of food production could be

achieved by switching good-quality land away from first-generation biofuels. For example, almost 40% of the U.S. corn harvest in 2016–2017 went to biofuels. Efforts to increase the intensity of production need to be environmentally sustainable. These include optimizing yields by soil and water conservation, removal of technical and financial constraints faced by farmers, and breeding resource-efficient crops and livestock that are also climate resilient and pest/disease resistant.

- *Reduce waste.* Approximately 30–40% of food is wasted, between harvesting and the market, during retail, at home, and in the food service industry. Better transport and storage facilities in developing countries, less stringent sell-by dates, lower cosmetic standards for fruits and vegetables, and ending supersized portions would help reduce waste.
- *Change diets.* As wealth increases, so does the demand for processed foods, meat, dairy products, and fish. About one third of global cereal production is fed to animals, so reducing consumption of meat from grain-fed livestock and increasing the proportion derived from the most efficient sources (pigs and poultry) would allow more people to be fed from the same amount of land.

UNDERNUTRITION

The greatest risk of undernutrition (underweight, stunting, wasting, and micronutrient deficiencies) occurs in the first 1,000 days, from conception to 24 months of age, and this early effect on growth and development can have adverse consequences on health, intellectual ability, school achievement, work productivity, and earnings in later life. Governments and agencies are therefore advised to focus interventions on this critical window of opportunity.

Measurement of Undernutrition

The term **malnutrition** encompasses both ends of the nutrition spectrum, undernutrition as well as overweight and obesity. Many poor nutritional outcomes begin in utero and are manifest as low birthweight (LBW, <2,500 g). Preterm birth and fetal growth restriction are the two main causes of LBW, with prematurity relatively more common in richer countries and fetal growth restriction relatively more common in lower-income countries.

Nutritional status is often assessed in terms of anthropometry (Table 62.2). International standards of normal child growth under optimum conditions from birth to 5 years have been established by the World Health Organization (WHO). To compile the standards, longitudinal data from birth to 24 months of healthy, breastfed, term infants were combined with cross-sectional measurements of children ages 18-71 months. The standards allow normalization of anthropometric measures in terms of *z* scores (standard deviation [SD] scores). A *z* score is the child's height (weight) minus the median height (weight) for the child's age and sex divided by the relevant SD. The standards are applicable to all children everywhere, having been derived from a large, multicountry study reflecting diverse ethnic backgrounds and cultural settings.

Height-for-age (or length-for-age for children <2 years) is a measure of linear growth, and a deficit represents the cumulative impact of adverse events, usually in the first 1,000 days from conception, that result in *stunting,* or chronic undernutrition. A low height-for-age typically reflects socioeconomic disadvantage. A low **weight-for-height**, or *wasting*, usually indicates acute malnutrition. Conversely, a high weight-for-height indicates *overweight*. **Weight-for-age** is the most commonly used index of nutritional status, although a low value has limited clinical significance because it does not differentiate between wasting and stunting. Weight-for-age has the advantage of being somewhat easier to measure than indices that require height measurements. In humanitarian emergencies and some community or outpatient settings, **mid-upper arm circumference** is used as a screening tool to identify wasted children (Fig. 62.4).

Body mass index (BMI) is calculated by dividing weight in kilograms by the square of height in meters. For children, BMI is age and gender specific. **BMI-for-age** can be used from birth to 20 years and is a screening tool for *thinness* (less than −2 SD), *overweight* (between +1 SD and +2 SD), and *obesity* (greater than +2 SD). To diagnose obesity, additional measures of adiposity are desirable because a high BMI can result from high muscularity and not only from excess subcutaneous fat.

Table 62.2 Classification of Undernutrition

CLASSIFICATION	INDEX	GRADING
Gomez (underweight)	90–75% of median weight-for-age	Grade 1 (mild)
	75–60%	Grade 2 (moderate)
	<60%	Grade 3 (severe)
Waterlow (wasting)	90–80% of median weight-for-height	Mild
	80–70%	Moderate
	<70%	Severe
Waterlow (stunting)	95–90% of median height-for-age	Mild
	90–85%	Moderate
	<85%	Severe
WHO (wasting)	< −2 to > −3 SD weight-for-height	Moderate
	< −3	Severe
WHO (stunting)	< −2 to > −3 SD height-for-age	Moderate
	< −3	Severe
WHO (wasting) (for age-group 6-59 mo)	115-125 mm mid-upper arm circumference	Moderate
	<115 mm	Severe

SD, Standard deviation; WHO, World Health Organization.

Micronutrient deficiencies are another dimension of undernutrition. Those of particular public health significance are vitamin A, iodine, iron, and zinc deficiencies.

Vitamin A deficiency is caused by a low intake of retinol (in animal foods) or its carotenoid precursors, mainly beta-carotene (in orange-colored fruits and vegetables and dark-green leaves) (see Chapter 66). The prevalence of *clinical deficiency* is assessed from symptoms and signs of xerophthalmia (principally night blindness and Bitot spots). *Subclinical deficiency* is defined as serum retinol concentration ≤0.70 µmol/L. Vitamin A deficiency is the leading cause of preventable blindness in children. It is also associated with a higher morbidity and mortality among young children.

Iodine deficiency is the world's leading cause of preventable intellectual impairment (see Chapter 72). An enlarged thyroid (goiter) is a sign of deficiency. Severe deficiency in pregnancy causes fetal loss and permanent damage to the brain and central nervous system in surviving offspring (cretinism). It can be prevented by iodine supplementation before conception or during the first trimester of pregnancy. Postnatal iodine deficiency is associated with impaired mental function and growth stunting. The median urinary iodine concentration in children age 6-12 years is used to assess the prevalence of deficiency in the general population, and a median of <100 µg/L indicates insufficient iodine intake.

Iron-deficiency anemia is common in childhood either from low iron intakes or poor absorption, or as a result of illness or parasite infestation (see Chapter 72). Women also have relatively high rates of anemia as a result of menstrual blood loss, pregnancy, low iron intake, poor absorption, and illness. Hemoglobin cutoffs to define anemia are 110 g/L for children 6-59 months, 115 g/L for children 5-11 years, and 120 g/L for children 12-14 years. Cutoffs to define anemia are 120 g/L for nonpregnant women, 110 g/L for pregnant women, and 130 g/L for men.

Zinc deficiency increases the risk of morbidity and mortality from diarrhea, pneumonia, and possibly other infectious diseases (see Chapter 72). Zinc deficiency also has an adverse effect on linear growth. Deficiency at the population level is assessed from dietary zinc intakes or serum zinc concentrations. For children under 10 years of age, serum zinc cutoffs of <65 µg/dL and <57 µg/dL are used to define zinc deficiency according to whether the blood sample was obtained in the morning or afternoon, respectively. For females 10 years of age or older, cutoffs of <70 µg/dL, <66 µg/dL, and <59 µg/dL are used depending on whether the blood sample was obtained in the morning in a fasted state, the morning in a nonfasted state, or in the afternoon in a nonfasted state, respectively.

Prevalence of Undernutrition

It is estimated that approximately 14.6% of births worldwide in 2015 were LBW. Rates of LBW are highest (48%) in southern Asia, which are twice those of sub-Saharan Africa. Globally, in 2015, 14% of children <5 years of age were *underweight* (weight-for-age < −2 SD). The global prevalence of *stunting* (height-for-age < −2 SD) has declined from 33% in 2000 to 22% in 2017, with the greatest reductions occurring in Asia. Stunting prevalence is highest in the African region (30%). *Wasting* (weight-for-height < −2 SD) affects 7% of children <5 years, with minimal change in prevalence over the past 2 decades. These figures represent 149 million stunted children and 50 million wasted children under 5 years of age. Asia carries most of the global burden of underweight children because of the combination of large population size and high prevalence. In 2017, 55% of all stunted children and 69% of all wasted children lived in Asia. Africa carries most of the remaining global burden.

Approximately 29% of children under 5 years of age in low- and middle-income countries (LMICs) suffer from vitamin A deficiency. Nationally representative data on the zinc status of children are sparse, but an estimated 17% of the global population is believed to be at risk of inadequate zinc intake. The estimated prevalence of anemia in children and women of reproductive age in 2016 was 42% and 33%, respectively. Iron deficiency is considered to be the primary cause of anemia in 25–42% and 50–60% of anemia cases among children and women, respectively. Universal salt iodization has made great strides in reducing the global burden of iodine deficiency. However, mild to moderate iodine deficiency remains a public health concern in 25 countries.

Consequences of Undernutrition

The most profound consequence of undernutrition is premature death (Table 62.3). Fetal growth restriction together with suboptimal breastfeeding in the first month of life contribute to 19% of all deaths in children <5 years (1.3 million deaths/year). When the effects of stunting, wasting, and deficiencies of vitamin A and zinc are also considered, these six items jointly contribute to 45% of global child deaths (3.1 million deaths/year), and many more are disabled or stunted for life. Anemia contributes to over one quarter of maternal deaths.

Table 62.3 Global Deaths in Children <5 Years Attributed to Nutritional Conditions

CONDITION	ATTRIBUTABLE DEATHS	% OF TOTAL DEATHS <5 YR
(a) Fetal growth restriction (<1 mo)	817,000	11.8
(b) Stunting (1-59 mo)	1,017,000	14.7
(c) Wasting (1-59 mo)	875,000	12.6
(d) Zinc deficiency (12-59 mo)	116,000	1.7
(e) Vitamin A deficiency (6-59 mo)	157,000	2.3
(f) Suboptimal breastfeeding (0-23 mo)	804,000	11.6
Joint effects of (a) + (f)	1,348,000	19.4
Joint effects of all 6 factors	3,097,000	44.7

From Black RE, Victora CG, Walker SP, et al. Maternal and child undernutrition and overweight in low- and middle-income countries. *Lancet.* 2013;382:427–451.

The risk of child death from infectious diseases increases even with mild undernutrition, and as the severity of undernutrition increases, the risk increases exponentially (Table 62.4). Undernutrition impairs immune function and other host defenses; consequently, childhood infections are more severe and longer lasting and more likely to be fatal than the same illnesses in well-nourished children. Infections can adversely affect nutritional status, and young children can quickly enter a cycle of repeated infections and ever-worsening malnutrition. Even for the survivors, physical and cognitive damage as a result of undernutrition can affect their future health and economic well-being. For females, the cycle of undernutrition is passed on to the next generation when undernourished women give birth to LBW babies.

Fetal growth restriction and early childhood undernutrition have consequences for adult chronic illness. LBW is associated with an increased risk of hypertension, stroke, and type 2 diabetes in adults. This increased risk is thought to reflect "fetal programming," a process by which fetal undernutrition leads to permanent changes in the structure and metabolism of organs and systems that manifest as disease in later life. The risk is exacerbated by low weight gain during the first 2 years of life. The increased risk of adult chronic disease from undernutrition early in life is a particular challenge to LMICs with rapid economic growth.

Stunting before age 3 years is associated with poorer motor and cognitive development and altered behavior in later years. The developmental quotient (DQ; see Chapter 28) is reduced by 6-13 points. Iodine and iron deficiencies also lead to loss of cognitive potential. Indications are that children living in areas of chronic iodine deficiency have an average reduction in intelligence quotient (IQ) of 12-13.5 points compared with children in iodine-sufficient areas. Iron deficiency has a detrimental effect on the motor development of children <4 years and on cognition of school-aged children. The estimated deficit is 1.73 IQ points for each 10 g/L decrease in hemoglobin concentration.

Undernutrition can have substantial economic consequences for survivors and their families. The consequences can be quantified in five categories: (1) increased costs of healthcare, either neonatal care for LBW babies or treatment of illness for infants and young children; (2) productivity losses (and thus reduced earnings) associated with smaller stature and muscle mass; (3) productivity losses from reduced cognitive ability and poorer school performance; (4) increased costs of chronic diseases associated with fetal and early child malnutrition; and

Table 62.4 Hazard Ratios for All-Cause and Cause-Specific Deaths Associated with Stunting, Wasting, and Underweight in Children <5 Years

STANDARD DEVIATION (SD) SCORE	DEATHS				
	ALL	PNEUMONIA	DIARRHEA	MEASLES	OTHER INFECTIONS
HEIGHT/LENGTH-FOR-AGE					
< −3	5.5	6.4	6.3	6.0	3.0
−3 to < −2	2.3	2.2	2.4	2.8	1.9
−2 to < −1	1.5	1.6	1.7	1.3	0.9
≥ −1	1.0	1.0	1.0	1.0	1.0
WEIGHT-FOR-LENGTH					
< −3	11.6	9.7	12.3	9.6	11.2
−3 to < −2	3.4	4.7	3.4	2.6	2.7
−2 to < −1	1.6	1.9	1.6	1.0	1.7

(5) consequences of maternal undernutrition on future generations. The impact of nutrition on earnings appears to be independent of the effects of childhood deprivation.

Interventions for Undernutrition

Interventions to address child undernutrition can be divided into those that address immediate causes *(nutrition-specific interventions)* and those that address underlying or indirect causes *(nutrition-sensitive interventions)* (Table 62.5). In the short-term, nutrition-specific interventions (e.g., salt iodization) can have substantial impact even in the absence of economic growth, and micronutrient interventions (supplementation and fortification) are consistently ranked as the most cost-effective investment. However, there is increased attention to nutrition-sensitive interventions as the best means of sustainably eliminating malnutrition and to multisectoral policies that harness the synergism between the two types of interventions (e.g., cross-sectoral linkages among agriculture, nutrition, and health).

To reduce the adverse consequences of undernutrition on mortality, morbidity, and cognitive development, interventions must encompass both fetal and postnatal periods. Preventing LBW is essential, with emphasis on prevention of low maternal BMI and anemia, and in the longer term, prevention of low maternal stature. Maternal height is a strong predictor of birth outcomes, and approximately 6.5 million small-for-gestational age (SGA) or preterm births are associated with maternal short stature each year. Other measures include smoking cessation, birth spacing, delaying pregnancy until after 18 years of age, and intermittent preventive treatment of malaria in malaria-endemic areas. In the postnatal period, promotion and support of exclusive breastfeeding is a high priority. Although the Baby Friendly Hospital Initiative has a marked benefit on rates of exclusive breastfeeding in hospitals, postnatal counseling from community workers or volunteers is needed to facilitate continuation of exclusive breastfeeding at home for 6 months (see Chapter 61). Most studies show a lower risk of HIV transmission with exclusive breastfeeding than with mixed breastfeeding. The risk of HIV transmission by breastfeeding is approximately 5–20% depending on duration, but can be reduced to <2% with antiretroviral drugs. Even without antiretroviral drugs, exclusively breastfed children of HIV-infected mothers in low-income countries have lower mortality than nonbreastfed children, because the latter are at increased risk of death from diarrhea and pneumonia.

Table 62.5 Examples of Nutrition-Specific and Nutrition-Sensitive Interventions

NUTRITION-SPECIFIC INTERVENTIONS	NUTRITION-SENSITIVE INTERVENTIONS
• Promotion and support for exclusive breastfeeding for 6 mo, and continued breastfeeding for at least 2 yr • Promotion of adequate, timely, and safe complementary feeding from 6 mo • Increased micronutrient intake through dietary diversity • Micronutrient supplements for pregnant women (iron/folate) and young children (vitamin A, iron, zinc) in deficient areas • Zinc supplements to children during and after diarrhea (10-20 mg/day for 2 wk) • Prevention and treatment of severe acute malnutrition • Crop biofortification, food fortification, salt iodization • Reduced heavy physical activity in pregnancy	• Increased access to affordable, nutritious food; smallholder agriculture; credit and microfinance • Postharvest food processing and preservation • Vaccination against neonatal and childhood illness; access to healthcare • Improved water/sanitation and hygiene (e.g., handwashing with soap) • Education; women's empowerment; gender equality • Social protection (e.g., cash transfers) • Malaria prevention (vector control/bednets); intermittent preventive treatment during pregnancy and in children 3-59 mo • Birth spacing; delaying pregnancy until after 18 yr of age

Interventions to improve infant feeding must be designed for the local setting and thus require careful formative research during their development. Messages should be few, feasible, and

culturally appropriate. For complementary feeding, the introduction of nutrient-rich energy-dense mixtures of foods at 6 months of age and responsive feeding are often emphasized. Where adequate complementary feeding is difficult to achieve and subclinical deficiencies are common, high-dose vitamin A supplementation every 6 months in children 6-59 months of age reduces all-cause mortality and death caused by diarrhea by 12%, and zinc supplementation can reduce 1- to 4-year mortality by 18%, diarrhea incidence by 13%, and pneumonia by 19%. Monitoring of child growth provides an early alert to a nutrition or health problem but is only worthwhile if accompanied by good counseling and growth promotion activities. The impact of growth monitoring and promotion will depend on coverage, intensity of contact, health worker performance and communication skills, adequacy of resources, and the motivation and ability of families to follow agreed actions.

Other Nutritional Interventions

Treatment of vitamin and mineral deficiencies is discussed in Chapters 66-72. Treatment of LBW and intrauterine growth restriction is discussed in Chapter 119.

SEVERE ACUTE MALNUTRITION

Severe acute malnutrition is defined as severe wasting and/or bilateral edema. *Severe wasting* is extreme thinness diagnosed by a weight-for-length (or height) < −3 SD of the WHO Child Growth Standards. In children ages 6-59 months, a mid-upper arm circumference <115 mm also denotes severe acute malnutrition: a color-banded tape (see Fig. 62.4) is a convenient way of screening children in need of treatment.

Bilateral edema is diagnosed by grasping both feet, placing a thumb on top of each, and pressing gently but firmly for 10 seconds. A pit (dent) remaining under each thumb indicates bilateral edema.

This definition of severe acute malnutrition distinguishes wasted/edematous children from those who are stunted because stunted children (although underweight) are not a priority for acute clinical care because their deficits in height and weight cannot be corrected in the short term. The previous name *protein-energy malnutrition* is avoided because it oversimplifies the complex, multifactorial etiology. Other terms are *marasmus* (severe wasting), *kwashiorkor* (characterized by edema), and *marasmic-kwashiorkor* (severe wasting and edema).

Children with severe acute malnutrition have had a diet insufficient in energy and nutrients relative to their needs. The magnitude of the deficits will differ depending on the duration of inadequacy, quantity and diversity of food consumed, presence of antinutrients (e.g., phytate), individual variation in requirements, and number and severity of coexisting infections and their duration. Infections can lead to profound nutrient deficits and imbalances: For example, amino acids are diverted to form acute-phase proteins, potassium, magnesium, vitamin A, and zinc are lost through diarrhea, and losses of glycine and taurine are linked to small bowel bacterial overgrowth. Ingested microbes can cause villous atrophy and loss of nutrients from maldigestion and malabsorption, as well as disruption of gut barrier function leading to microbial translocation, chronic immune activation, and altered gut microbiome (environmental enteric dysfunction). Deficits can also arise from increased nutrient utilization in response to toxins (e.g., cysteine and methionine to detoxify dietary cyanogens).

Children affected by severe acute malnutrition may have different clinical presentations and metabolic disturbances due to variations in the type and extent of deficits and imbalances in their bodies. This heterogeneity is a result of diverse pathways that lead to severe acute malnutrition. Children who develop edematous malnutrition are more likely than nonedematous children to have had exposures that generate oxidative stress and/or to have greater deficits in free radical–scavenging antioxidants (glutathione; vitamins A, C, and E; and essential fatty acids) or cofactors (zinc, copper, selenium).

Table 62.6 Clinical Signs of Malnutrition

SITE	SIGNS
Face	Moon face (kwashiorkor), simian facies (marasmus)
Eye	Dry eyes, pale conjunctiva, Bitot spots (vitamin A), periorbital edema
Mouth	Angular stomatitis, cheilitis, glossitis, spongy bleeding gums (vitamin C), parotid enlargement
Teeth	Enamel mottling, delayed eruption
Hair	Dull, sparse, brittle hair; hypopigmentation; flag sign (alternating bands of light and normal color); broomstick eyelashes; alopecia
Skin	Loose and wrinkled (marasmus); shiny and edematous (kwashiorkor); dry, follicular hyperkeratosis; patchy hyperpigmentation and hypopigmentation ("crazy paving" or "flaky paint" dermatoses); erosions; poor wound healing
Nails	Koilonychia; thin and soft nail plates, fissures, or ridges
Musculature	Muscle wasting, particularly buttocks and thighs; Chvostek or Trousseau sign (hypocalcemia)
Skeletal	Deformities, usually as a result of calcium, vitamin D, or vitamin C deficiencies
Abdomen	Distended: hepatomegaly with fatty liver; ascites may be present
Cardiovascular	Bradycardia, hypotension, reduced cardiac output, small vessel vasculopathy
Neurologic	Global developmental delay, loss of knee and ankle reflexes, impaired memory
Hematologic	Pallor, petechiae, bleeding diathesis
Behavior	Lethargic, apathetic, irritable on handling
Gastrointestinal tract	Atrophy of small intestine mucosa, lactase deficiency common

Modified from Grover Z, Ee LC. Protein energy malnutrition. *Pediatr Clin North Am.* 2009;56:1055–1068.

Clinical Manifestations of Severe Acute Malnutrition (Table 62.6)

Severe wasting is most visible on the thighs, buttocks, and upper arms and over the ribs and scapulae, where loss of fat and skeletal muscle is greatest (Fig. 62.5). Wasting is preceded by failure to gain weight and then by weight loss. The skin loses turgor and becomes loose as subcutaneous tissues are broken down to provide energy. The face may retain a relatively normal appearance, but eventually becomes wasted and wizened. The eyes may be sunken from loss of retroorbital fat, and lacrimal and salivary glands may atrophy, leading to lack of tears and a dry mouth. Weakened abdominal muscles and gas from bacterial overgrowth of the upper gut may lead to a distended abdomen. Severely wasted children are often fretful and irritable.

In **edematous malnutrition** the edema is most likely to appear first in the feet and then in the lower legs. It can quickly develop into generalized edema affecting also the hands, arms, and face (Fig. 62.6). Skin changes typically occur over the swollen limbs and include dark, crackled peeling patches ("flaky paint" dermatosis) with pale skin underneath that is easily infected (see Figs. 62.2 and 62.6). The hair is sparse, easily pulled out, and may lose its curl. In dark-haired children, the hair may turn pale or reddish. The liver is often enlarged with fat. Children with edema are uncomfortable, irritable and/or apathetic, and often refuse to eat.

Fig. 62.5 Child with severe wasting.

Fig. 62.6 Child with generalized edema.

Pathophysiology

When a child's intake is insufficient to meet daily needs, physiologic and metabolic changes take place in an orderly progression to conserve energy and prolong life. This process is called *reductive adaptation*. Fat stores are mobilized to provide energy. Later, protein in muscle, skin, and the gastrointestinal tract is mobilized. Energy is conserved by reducing physical activity and growth, reducing basal metabolism and the functional reserve of organs, and reducing inflammatory and immune responses. These changes have important consequences:

- The liver makes glucose less readily, making the child more prone to hypoglycemia. It produces less albumin, transferrin, and other transport proteins. It is less able to cope with excess dietary protein and to excrete toxins.
- Heat production is less, making the child more vulnerable to hypothermia.
- The kidneys are less able to excrete excess fluid and sodium, and fluid easily accumulates in the circulation, increasing the risk of fluid overload.
- The heart is smaller and weaker and has a reduced output, and fluid overload readily leads to death from cardiac failure.
- Sodium builds up inside cells because of leaky cell membranes and reduced activity of the sodium-potassium pump, leading to excess body sodium, fluid retention, and edema.
- Potassium leaks out of cells and is excreted in urine, contributing to electrolyte imbalance, fluid retention, edema, and anorexia.
- Loss of muscle protein is accompanied by loss of potassium, magnesium, zinc, and copper.
- The gut produces less gastric acid and enzymes. Motility is reduced, and bacteria may colonize the stomach and small intestine, damaging the mucosa and deconjugating bile salts. Digestion and absorption are impaired.
- Cell replication and repair are reduced, increasing the risk of bacterial translocation through the gut mucosa.
- Immune function is impaired, especially cell-mediated immunity. The usual responses to infection may be absent, even in severe illness, increasing the risk of undiagnosed infection.
- Red blood cell mass is reduced, releasing iron, which requires glucose and amino acids to be converted to ferritin, increasing the risk of hypoglycemia and amino acid imbalances. If conversion to ferritin is incomplete, unbound iron promotes pathogen growth and formation of free radicals.
- Micronutrient deficiencies limit the body's ability to deactivate free radicals, which cause cell damage. Edema and hair/skin changes are outward signs of cell damage.

When prescribing treatment, it is essential to take these changes in function into account. Otherwise, organs and systems will be overwhelmed, and death will rapidly ensue.

Principles of Treatment

Figure 62.7 shows the 10 steps of treatment, which are separated into two phases: stabilization and rehabilitation. These steps apply to all clinical forms and all geographic locations, including North America and Europe. The aim of the **stabilization** phase is to repair cellular function, correct fluid and electrolyte imbalance, restore homeostasis, and prevent death from the interlinked triad of hypoglycemia, hypothermia, and infection. The aim of the **rehabilitation** phase is to restore wasted tissues (i.e., catch-up growth). It is essential that treatment proceeds in an ordered progression and that the metabolic machinery is repaired before any attempt is made to promote weight gain. Pushing ahead too quickly risks inducing the potentially fatal "refeeding syndrome" (see Chapter 63).

Caregivers bring children to health facilities because of illness, rarely because of their malnutrition. A common mistake among healthcare providers is to focus on the illness and treat as for a well-nourished child. This approach ignores the deranged metabolism in malnourished children and can be fatal. Such children should be considered as severely malnourished with a complication, and

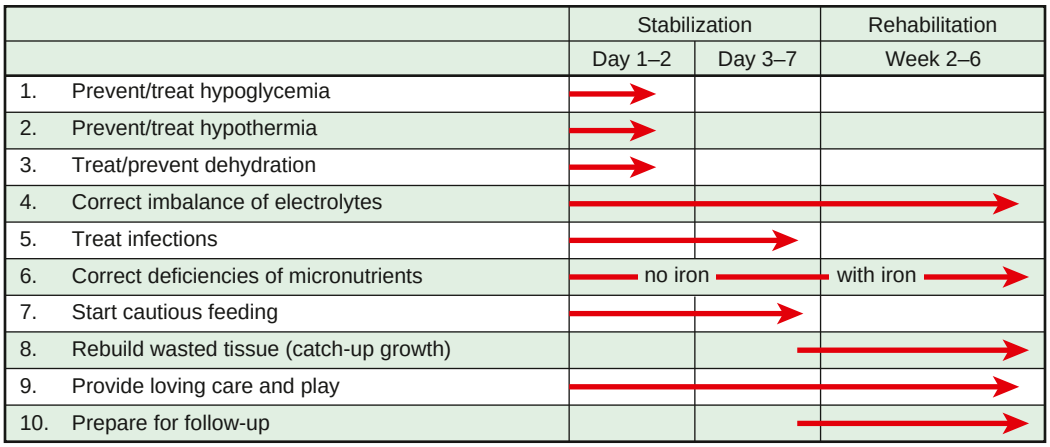

Fig. 62.7 The 10 steps of treatment for severe acute malnutrition and their approximate time frames.

Table 62.7 Emergency Treatment in Severe Malnutrition

CONDITION	IMMEDIATE ACTION
Shock • Lethargic or unconscious *and* • Cold hands *Plus* either: • Slow capillary refill (>3 sec) *or* • Weak fast pulse	1. Give oxygen. 2. Give sterile 10% glucose (5 mL/kg) rapidly by IV injection. 3. Give IV fluid at 15 mL/kg over 1 hr, using: • Ringer lactate with 5% dextrose *or* • Half-normal saline* with 5% dextrose *or* • Half-strength Darrow solution with 5% dextrose • If all these are unavailable, Ringer lactate 4. Measure and record pulse and respirations at the start and every 10 min. If there are signs of improvement (pulse and respiration rates fall), repeat IV drip, 15 mL/kg for 1 more hr. Then switch to oral or nasogastric rehydration with ReSoMal, 5-10 mL/kg in alternate hr (see Table 62.8 step 3). If there are no signs of improvement, assume septic shock and: 1. Give maintenance fluid IV (4 mL/kg/hr) while waiting for blood. 2. Order 10 mL/kg fresh whole blood and transfuse slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood. 3. Give furosemide, 1 mg/kg IV at start of transfusion.
Hypoglycemia Blood glucose <3 mmol/L	See Table 62.8 step 1 for treatment.
Severe dehydration	Do *not* give IV fluids except in shock. See Table 62.8 step 3 for treatment.
Very severe anemia Hgb <4 g/dL	If very severe anemia (or Hgb 4-6 g/dL *and* respiratory distress): 1. Give whole blood 10 mL/kg slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood. 2. Give furosemide 1 mg/kg IV at the start of the transfusion.
Emergency eye care Corneal ulceration	If corneal ulceration: 1. Give vitamin A immediately (age <6 mo: 50,000 IU; 6-12 mo: 100,000 IU; >12 mo: 200,000 IU) 2. Instill 1 drop atropine (1%) into affected eye to relax the eye and prevent the lens from pushing out.

*Some would recommend 5% dextrose in normal saline.
Hgb, Hemoglobin; IV, intravenous(ly).

treatment should follow the 10 steps. *Two other potentially fatal mistakes are to treat edema with a diuretic and to give a high-protein diet in the early phase of treatment.*

Emergency Treatment

Table 62.7 summarizes emergency treatment for malnourished children with shock and other emergency conditions. Note that treatment of shock in these children is different (less rapid, smaller volume, different fluid) from treatment of shock in well-nourished children. However, shock from dehydration and shock from sepsis often coexist and are difficult to differentiate on clinical grounds. Thus the physician must be guided by the response to treatment: children with dehydration respond to IV fluid, whereas those with septic shock will not respond. Because severely malnourished children can quickly succumb to fluid overload, they must be monitored closely.

Stabilization

Table 62.8 summarizes the therapeutic directives for stabilization steps 1-7 (see Fig. 62.7). Giving broad-spectrum antibiotics (Table 62.9) and feeding frequent small amounts of F75 (a specially formulated low-lactose milk with 75 kcal and 0.9 g protein per 100 mL to which potassium, magnesium, and micronutrients are added) will reestablish metabolic control, treat edema, and restore appetite. The parenteral route should be avoided; children who lack appetite should be fed by nasogastric tube, because nutrients delivered within the gut lumen help in its repair. Table 62.10 provides recipes for preparing the special feeds and their nutrient composition. Of the two recipes for F75, one requires no cooking, and the other is cereal based and has a lower osmolality, which may benefit children with persistent diarrhea. F75 is also commercially available; maltodextrins replace some of the sugar, and potassium, magnesium, minerals, and vitamins are already added.

Table 62.8 Therapeutic Directives for Stabilization of Malnourished Children

STEP	PREVENTION	TREATMENT
1. Prevent/treat hypoglycemia blood glucose <3 mmol/L.	Avoid long gaps without food and minimize need for glucose: 1. Feed immediately. 2. Feed every 3 hr day and night (2 hr if ill). 3. Feed on time. 4. Keep warm. 5. Treat infections (they compete for glucose). *Note:* Hypoglycemia and hypothermia often coexist and are signs of severe infection.	**If conscious:** 1. Give 10% glucose (50 mL), or a feed (see step 7), or 1 tsp sugar under tongue, whichever is quickest. 2. Feed every 2 hr for at least first day. Initially give ¼ of feed every 30 min. 3. Keep warm. 4. Start broad-spectrum antibiotics. **If unconscious:** 1. Immediately give sterile 10% glucose (5 mL/kg) rapidly by IV. 2. Feed every 2 hr for at least first day. Initially give ¼ of feed every 30 min. Use nasogastric (NG) tube if unable to drink. 3. Keep warm. 4. Start broad-spectrum antibiotics.
2. Prevent/treat hypothermia axillary <35°C (95°F); rectal <35.5°C (95.9°F).	Keep warm and dry and feed frequently. 1. Avoid exposure. 2. Dress warmly, including head, and cover with blanket. 3. Keep room hot; avoid drafts. 4. Change wet clothes and bedding. 5. Do not bathe if very ill. 6. Feed frequently day and night. 7. Treat infections.	Actively rewarm. 1. Feed. 2. Skin-to-skin contact with caregiver ("kangaroo technique") or dress in warmed clothes, cover head, wrap in warmed blanket, and provide indirect heat (e.g., heater; transwarmer mattress; incandescent lamp). 3. Monitor temperature hourly (or every 30 min if using heater). 4. Stop rewarming when rectal temperature is 36.5°C (97.7°F).
3. Prevent/treat dehydration.	Replace stool losses. 1. Give ReSoMal after each watery stool. ReSoMal (37.5 mmol Na/L) is a low-sodium rehydration solution for malnutrition.	Do *not* give IV fluids unless the child is in shock. 1. Give ReSoMal 5 mL/kg every 30 min for first 2 hr orally or NG tube. 2. Then give 5-10 mL/kg in alternate hours for up to 10 hr. Amount depends on stool loss and eagerness to drink. Feed in the other alternate hour. 3. Monitor hourly and stop if signs of overload develop (pulse rate increases by 25 beats/min and respiratory rate by 5 breaths/min; increasing edema; engorged jugular veins). 4. Stop when rehydrated (≥3 signs of hydration: less thirsty, passing urine, skin pinch less slow, eyes less sunken, moist mouth, tears, less lethargic, improved pulse and respiratory rate).
4. Correct electrolyte imbalance—deficit of potassium and magnesium, excess sodium.		1. Give extra potassium (4 mmol/kg/day) and magnesium (0.6 mmol/kg/day) for at least 2 wk (see Table 62.12). *Note:* Potassium and magnesium are already added in Nutriset F75 and F100 packets.
5. Prevent/treat infections.	Minimize risk of cross-infection. 1. Avoid overcrowding. 2. Wash hands. 3. Give measles vaccine to unimmunized children age >6 mo.	Infections are often silent. Starting on first day, give broad-spectrum antibiotics to all children. 1. For antibiotic choices/schedule, see Table 62.9. 2. Ensure all doses are given, and given on time. 3. Cover skin lesions so that they do not become infected. *Note:* Avoid steroids because they depress immune function.
6. Correct micronutrient deficiencies.	*Note:* Folic acid, multivitamins, zinc, copper, and other trace minerals are already added in Nutriset F75 and F100 packets.	Do *not* give iron in the stabilization phase. 1. Give vitamin A on day 1 (<6 mo 50,000 units; 6-12 mo 100,000 units; >12 mo 200,000 units) if child has any eye signs of vitamin A deficiency or has had recent measles. Repeat this dose on days 2 and 14. 2. Give folic acid, 1 mg (5 mg on day 1). 3. Give zinc (2 mg/kg/day) and copper (0.3 mg/kg/day). These are in the electrolyte/mineral solution and Combined Mineral Vitamin mix (CMV) and can be added to feeds and ReSoMal. 4. Give multivitamin syrup or CMV.
7. Start cautious feeding.		1. Give 8-12 small feeds of F75 to provide 130 mL/kg/day, 100 kcal/kg/day, and 1-1.5 g protein/kg/day. 2. If gross edema, reduce volume to 100 mL/kg/day. 3. Keep a 24-hr intake chart. Measure feeds carefully. Record leftovers. 4. If child has poor appetite, coax and encourage to finish the feed. If unfinished, reoffer later. Use NG tube if eating ≤80% of the amount offered. 5. If breastfed, encourage continued breastfeeding but also give F75. 6. Transfer to F100 when appetite returns (usually within 1 wk) and edema has been lost or is reduced. 7. Weigh daily and plot weight.

Dehydration status is easily misdiagnosed in severely wasted children, because the usual signs (e.g., slow skin pinch, sunken eyes) may be present even without dehydration. Rehydration must therefore be closely monitored for signs of fluid overload. Serum electrolyte levels can be misleading because of sodium leaking from the blood into cells and potassium leaking out of cells. Keeping the intake of electrolytes and nutrients constant (see Table 62.8) allows systems to stabilize more quickly than adjusting intake in response to laboratory results.

Table 62.11 provides a recipe for the special rehydration solution used in severe malnutrition (ReSoMal). Therapeutic **Combined Mineral Vitamin mix (CMV)** contains electrolytes, minerals, and vitamins and is added to ReSoMal and feeds. If unavailable, potassium, magnesium, zinc, and copper can be added as an electrolyte/mineral stock solution (Table 62.12 provides a recipe), and a multivitamin supplement can be given separately.

Rehabilitation

The signals for entry to the rehabilitation phase are reduced or minimal edema and return of appetite. A controlled transition over 3 days is recommended to prevent refeeding syndrome (see Chapter 63). After the transition, unlimited amounts should be given of a high-energy, high-protein milk formula such as F100 (100 kcal and 3 g protein per 100 mL), or a **ready-to-use therapeutic food**

Table 62.9 Recommended Antibiotics for Malnourished Children*

	GIVE
If no complications	Amoxicillin, 25 mg/kg PO twice daily for 5 days
If complications (shock, hypoglycemia, hypothermia, skin lesions, respiratory or urinary tract infections, or lethargy/sickly)	Gentamicin, 7.5 mg/kg IV or IM once daily for 7 days *and* Ampicillin, 50 mg/kg IV or IM every 6 hr for 2 days, then amoxicillin, 25-40 mg/kg PO every 8 hr for 5 days

If specific infections are identified, add appropriate antibiotics.
For persistent diarrhea or small bowel overgrowth, add metronidazole, 7.5 mg/kg PO every 8 hr for 7 days.
*Local resistance patterns may require these to be adjusted: Ensure that there is gram-negative coverage.
PO, Orally; IM, intramuscularly; IV, intravenously.

Table 62.11 Recipe for Rehydration Solution for Malnutrition (ReSoMal)

INGREDIENT	AMOUNT
Water	2 L
WHO ORS	One 1-L sachet*
Sucrose	50 g
Electrolyte/mineral solution†	40 mL

ReSoMal contains 37.5 mmol sodium and 40 mmol potassium/L.
*Sachet contains 2.6 g sodium chloride, 2.9 g trisodium citrate dihydrate, 1.5 g potassium chloride, and 13.5 g glucose.
†See Table 62.12 for recipe, or use commercially available therapeutic Combined Mineral Vitamin mix (CMV).

Zinc acetate: Zn acetate$\cdot 2H_2O$	8.2	300 µmol
Copper (cupric) sulfate: $CuSO_4 \cdot 5H_2O$	1.4	45 µmol
Water: make up to	2500 mL	

Add 20 mL when preparing 1 L of feed or ReSoMal.
*Make fresh each month. Use cooled boiled water.

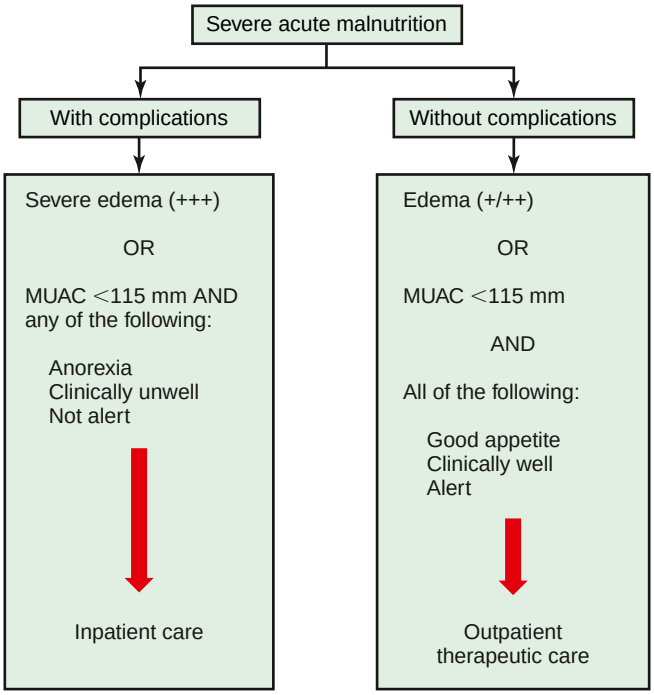

Fig. 62.8 Flow diagram for inpatient care *(left)* and outpatient care *(right)* in the child with severe acute malnutrition. MUAC, Mid-upper arm circumference.

(RUTF), or family foods modified to have comparable energy and protein contents.

To make the transition, for 2 days replace F75 with an equal volume of F100, then increase each successive feed by 10 mL until some feed remains uneaten (usually at about 200 mL/kg/day). After this transition, give 150-220 kcal/kg/day and 4-6 g protein/kg/day and continue to give potassium, magnesium, and micronutrients. Add iron (3 mg/kg/day). If breastfed, encourage continued breastfeeding. Children with severe malnutrition have developmental delays, so loving care, structured play, and sensory stimulation during and after treatment are essential to aid recovery of brain function.

Community-Based Treatment

Many children with severe acute malnutrition can be identified in their communities before medical complications arise. If these children have a good appetite and are clinically well, they can be rehabilitated at home through community-based management of acute malnutrition, which has the added benefit of reducing their exposure to nosocomial infections and providing continuity of care after recovery. It also reduces the time caregivers spend away from home and their opportunity costs and can be cost-effective for health services.

Figure 62.8 shows the criteria for inpatient and outpatient care. To maximize coverage and compliance, community-based therapeutic care has 4 main elements: community mobilization and sensitization, active case finding, therapeutic care, and follow-up after discharge.

Community-based therapeutic care comprises steps 8-10 (see Fig. 62.7), plus a broad-spectrum antibiotic (step 5). RUTF is usually provided, especially in times of food shortage. RUTF is specially designed for rehabilitating children with severe acute malnutrition at home. It is high in energy and protein and has electrolytes and micronutrients added. The most widely used RUTF is a thick paste that contains milk powder, peanuts, vegetable oil, and sugar. Pathogens cannot grow in it because of its low moisture content. Hospitalized children who have completed steps 1-7 can be transferred to community-based care for completion of their rehabilitation, thereby reducing their hospital stay to about 7-10 days.

Chapter 63

Refeeding Syndrome

Jason M. Nagata and Andrea K. Garber

Refeeding syndrome occurs in response to reintroduction of nutrition in the malnourished patient. Rapid electrolyte and fluid shifts in response to the surge of insulin brought on by the presence of nutrients can lead to numerous medical complications shown in Table 63.1 and may progress to life-threatening outcomes, including coma, heart failure, and sudden death. Early accounts of the syndrome were among starved survivors of wartime sieges and concentration camps and among prisoners of war when given sudden access to unlimited food. Refeeding syndrome occurs as a result of oral, enteral, or parenteral (highest risk) feeding of malnourished individuals, especially in the setting of aggressive refeeding. Patient populations at risk for refeeding syndrome include those with anorexia nervosa and other restrictive eating disorders, chronic conditions causing malnutrition (cancer, congenital heart disease), malabsorptive syndromes (inflammatory bowel disease, cystic fibrosis), cerebral palsy, bariatric surgery, and bowel resections (Table 63.2).

In malnourished patients with anorexia nervosa, cases of refeeding syndrome have been documented during refeeding. Risk is greatest within the first 7 days of the start of feeding and is primarily indicated by serum hypophosphatemia (<3.0 ng/dL); hypokalemia (<3.5 mmol/L) and hypomagnesemia (<1.8 mg/dL) are also seen. Studies have identified low weight, but not the caloric load, as the primary risk factor for refeeding syndrome.

An increase in the supply of energy (usually carbohydrates) is accompanied by an increase in sodium pump activity, and too sudden a supply risks causing a rapid release of accumulated sodium from cells, causing expansion of extracellular and plasma volumes. At the same time, there is increased cellular uptake of glucose, potassium, magnesium, and phosphate. Reactivation of metabolic pathways for adenosine triphosphate (ATP) production further depletes serum phosphorus.

For decades, the key to preventing the syndrome was believed to be lower-calorie refeeding with cautious advancement. Diets starting at 1,000-1,200 calories per day were recommended by multiple organizations in the United States. Diets as low as 500 calories per day were recommended in Europe. These cautious approaches are *still recommended* for patients with extreme malnutrition (<60% of median body mass index for age and sex) and children in developing

Table 63.2 Refeeding Syndrome: National Institutes for Clinical Excellence (NICE) Guidelines for Management of Refeeding Syndrome

PATIENTS AT RISK FOR REFEEDING SYNDROME	
ONE OR MORE OF THE FOLLOWING	—OR— TWO OR MORE OF THE FOLLOWING
• BMI <16 kg/m^2	• BMI <18.5 kg/m^2
• Unintentional weight loss of >15% in the previous 3-6 mo	• Unintentional weight loss of >10% in the previous 3-6 mo
• Little or no nutritional intake for >10 days	• Little or no nutritional intake for >5 days
• Low levels of potassium, phosphorus, or magnesium before refeeding	• History of alcohol or drug use, including insulin, chemotherapy, antacids, or diuretics

From Sachs K, Andersen D, Sommer J, Winkelman A, Mehler PS. Avoiding medical complications during the refeeding of patients with anorexia nervosa. *Eat Disord.* 2015;23(5):411–421, Table 1, p. 414.

nations, where the World Health Organization (WHO) guidelines for the treatment of malnutrition are still in place (see Chapter 62). However, the majority of patients hospitalized in the United States are adolescents with acute, moderate malnutrition. In this patient population, studies have demonstrated the feasibility of higher-calorie refeeding beginning >1,400 calories per day. A randomized clinical trial has demonstrated the efficacy and safety of starting with 2,000 calories per day in hospitalized adolescents with moderate malnutrition secondary to anorexia nervosa. In the United States, meal-based refeeding is most common, with food served on bedside trays, whereas higher-calorie refeeding by nasogastric tube is reported in Australia. Electrolyte shifts are much lower than expected using these protocols; serum electrolyte levels can be monitored daily in hospital settings and decreased electrolyte levels may be corrected with supplementation.

The following guidance is a suggestion for possible electrolyte repletion for refeeding syndrome in adolescents with eating disorders. For hypophosphatemia: Phos-Na-K 1 packet (250 mg) tid for phosphorous 2.5-2.9 mg/dL; Phos-Na-K 2 packets (500 mg) tid for phosphorous 2.0-2.4 mg/dL; IV Na-K-Phos 0.24 mmol/kg max 15 mmol/dose, and consider intensive care consultation for phosphorous <2.0 mg/dL. For hypokalemia: extended release KCl 20 mEq PO for potassium 3.1-3.4 mmol/L (recheck in 8-12 hours); extended release KCl 40 mEq PO for potassium 2.5-3.0 mmol/L (recheck in 8-12 hours); extended release KCl 40 mEq PO stat for potassium 2.2-2.4 mmol/L; and IV KCl and consider intensive care consultation for potassium <2.2 mmol/L. For hypomagnesemia: Mag-oxide 1 tablet (133-200 mg elemental Mg each) bid for magnesium 1.3-1.7 mg/dL; Mag-oxide 2 tablets (133-200 mg elemental Mg each) bid for magnesium 1.0-1.2 mg/dL; and IV Mg-SO_4 @50 mg/kg; max 2 g/dose and consider intensive care consultation for magnesium <1.0 mg/dL. Declining electrolytes but within the normal range generally do not need to be treated.

Chapter 64

Malnutrition in High-Resource Settings

Liliane K. Diab, Stephanie P. Gilley, and Nancy F. Krebs

See Chapter 62 for malnutrition in low- and middle-income countries. **Malnutrition** refers to **undernutrition** and is defined as an imbalance between nutrient requirements and intake or delivery that then results in deficits—of energy, protein, or micronutrients—that negatively affect growth and development. Malnutrition may be illness related or nonillness related, or both. Illness-related malnutrition may be caused by one or more diseases, infections, or congenital anomalies and by injury or surgery. Nonillness-related causes include environmental, psychosocial, or behavioral factors. Often, one cause may be primary and exacerbated by another. Patients with malnutrition may present with growth deceleration, or actual weight loss, as measured by anthropometric parameters, including weight, length/height, skinfolds, and mid-upper arm circumference (see Chapter 62). **Wasting** is defined as being too thin for height (weight for length or body mass index [BMI] *z* score less than −2). **Stunting** is defined as being too short for age (height or length *z* score less than −2).

U.S. data suggest 10% of children seen by primary care physicians are diagnosed with growth faltering. Malnutrition is a primary diagnosis in 1–5% of all hospital admissions. The prevalence of malnutrition in hospitalized patients is ~25%; malnutrition in children can contribute to poor outcomes, especially in intensive care units.

Although **failure to thrive (FTT)** has classically been the term used to describe children who are not meeting weight gain targets based on growth curves, the term *malnutrition* more accurately describes this cohort of children and removes perceived accusations or blame from the diagnosis.

CLINICAL MANIFESTATIONS

The degree of malnutrition can be assessed by inadequate weight-for-corrected age, failure to gain adequate weight over time (weight gain velocity), height velocity, weight-for-length or BMI depending on age, and developmental outcomes (see Chapter 62). These growth and anthropometric parameters are measured longitudinally and plotted on growth charts appropriate for the child's sex, age (corrected if premature), and, if known, genetic disorders, such as trisomy 21 or Turner syndrome. The American Academy of Pediatrics (AAP) and the U.S. Centers for Disease Control and Prevention (CDC) recommend the 2006 World Health Organization (WHO) standards for infants up to 2 years of age who are measured supine for length. The CDC 2000 growth references are recommended for children and adolescents (age 2-20 years) when measured with a standing height. The severity of malnutrition (mild, moderate, or severe) may be determined by plotting the *z* score (standard deviation [SD] from the mean) for each of these anthropometric values on the age- and sex-appropriate growth chart (Table 64.1). Most electronic health records are able to calculate and plot the *z* scores for measured anthropometrics. *Z* scores can also be obtained by entering measurements in electronic applications such as peditools.org. In infants less than 6 months old, a slow or slowing weight gain velocity can indicate malnutrition even if weight/length is preserved. The presence of bilateral pitting edema and low albumin triggers concern for **edematous malnutrition** (kwashiorkor) in the absence of an alternative explanation (such as heart, liver, or renal disease). Edema in the setting of malnutrition automatically classifies as **severe malnutrition** (see Table 64.1).

ETIOLOGY AND DIAGNOSIS

The most common mechanisms of pediatric malnutrition are nonillness related and are secondary to insufficient calorie intake, whether the result of low maternal breast milk supply, psychosocial factors such as food insecurity, or feeding difficulties. Picky eating, although common in young children, can occasionally be so restrictive as to result in malnutrition and/or micronutrient deficiencies. **Avoidant restrictive food intake disorder** is one risk factor and is often seen in children with autism, food aversions, or those on elimination diets for fear of food allergies or gluten sensitivity (Fig. 61.3) (Table 64.2). The most important illness-related

Table 64.1 Comprehensive Malnutrition Indicators

INDICATORS*	SEVERE MALNUTRITION	MODERATE MALNUTRITION	MILD MALNUTRITION
Weight-for-length *z* score	≤−3	−2.0 to −2.99	−1.0 to −1.99†
BMI-for-age *z* score	≤−3	−2.0 to −2.99	−1.0 to −1.99†
Length *z* score	≤−3	No data	No data
Mid-upper arm circumference	≤−3	−2.0 to −2.99	−1.0 to −1.99
†Weight gain velocity (<2 years of age)	<75% of the norm for expected weight gain	<50% of the norm for expected weight gain	<25% of the norm for expected weight gain
†Weight loss (2-20 yr of age)	>10% of UBW	>7.5% UBW	>5% UBW
†Deceleration in weight-for-length/height or BMI-for-age	Deceleration across 3 *z* score lines	Deceleration across 2 *z* score lines	Deceleration across 1 *z* score line
†Inadequate nutrient intake	≤25% of estimated energy/protein need	26–50% of estimated energy/protein need	51–75% of estimated energy/protein need
^Edema	Present	Absent	Absent

Use clinical judgment when applying these diagnostic criteria.
*It is recommended that when a child meets more than one malnutrition acuity level, the highest acuity level is used for diagnosis to ensure that appropriate evaluation, monitoring, and treatment are provided.
^The presence of bilateral pitting edema and low albumin is diagnostic for kwashiorkor, which is severe malnutrition regardless of any other indicator(s).
†Needs additional positive diagnostic criteria to make a malnutrition diagnosis.
BMI, Body mass index; UBW, usual body weight.
Adapted with modifications from Becker PJ, Nieman Carney L, Corkins MR, et al. Consensus statement of the Academy of Nutrition and Dietetics/American Society for Parenteral and Enteral Nutrition: indicators recommended for the identification and documentation of pediatric malnutrition (undernutrition). *J Acad Nutr Diet.* 2014;114(12):1988–2000.

cause of insufficient growth is inability to consume sufficient calories or starvation. The differential diagnosis in this case is broad and includes many health conditions such as cardiac and neurologic diseases. Oral aversion can sometimes be a manifestation of eosinophilic esophagitis or dysphagia. Other causes of malnutrition are (1) increased nutrient losses (e.g., protein-losing enteropathy, chronic diarrhea); (2) increased metabolic demands, as seen in extensive burn injuries, congenital heart disease, and thyroid disorders; (3) altered nutrient digestion, absorption, or utilization (e.g., cystic fibrosis, short bowel syndrome, celiac disease); and (4) some chromosome abnormalities that can be associated with poor growth such as Russel Silver syndrome. More than one mechanism can exist simultaneously (Fig. 64.1). *Chronic malnutrition* is defined as malnutrition having a duration of ≥3 months (see Chapter 62).

Table 64.2 DSM-5 Diagnosis of Avoidant/Restrictive Food Intake Disorder

A. An eating or feeding disturbance (e.g., apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate nutritional and/or energy needs associated with one (or more) of the following:
   1. Significant weight loss (or failure to achieve expected weight gain or faltering growth in children).
   2. Significant nutritional deficiency.
   3. Dependence on enteral feeding or oral nutritional supplements.
   4. Marked interference with psychosocial functioning.

B. The disturbance is not better explained by lack of available food or by associated culturally sanctioned practice.

C. The eating disturbance does not occur exclusively during the course of anorexia nervosa or bulimia nervosa, and there is no evidence of a disturbance in the way in which one's body weight or shape is experienced.

D. The eating disturbance is not attributable to a concurrent medical condition or not better explained by another mental disorder. When the eating disturbance occurs in the context of another condition or disorder, the severity of the eating disturbance exceeds that routinely associated with the condition or disorder and warrants additional clinical attention.

From the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. p. 947. Copyright 2013. American Psychiatric Association.

A complete history includes information regarding the onset of the growth faltering, a detailed review of systems, past medical history, and family history including parents' heights and growth patterns. The perinatal history is also important to identify children who are born small for gestational age (SGA). SGA infants who are asymmetric (birthweight is disproportionally more depressed than length or head circumference) have a better prognosis for catch-up growth than do infants who have symmetric intrauterine growth restriction. A detailed nutritional history should include unusual nutritional beliefs and the quantity, quality, and frequency of meals. A comprehensive physical examination can help elucidate possible underlying etiologies and manifestations of micronutrient deficiencies to guide laboratory or imaging evaluation if indicated (Table 64.3 and see Table 62.6). Tanner staging cannot be used as a marker for nutritional status, but it is influenced and often delayed by malnourishment. Puberty will usually resume progression when the malnourished state improves. A reasonable initial screen should include a complete blood count, a comprehensive metabolic panel (CMP), and urinalysis.

Additional measurements that are useful for classifying the severity of malnutrition and following the progress of the acutely malnourished child are mid-upper arm circumference (MUAC) and triceps skin folds (TSF). MUAC can be used as an independent anthropometric tool to screen for and diagnose malnutrition (depletion of subcutaneous fat stores) when obtaining an accurate length or height is difficult. The MUAC is used as a predictor of malnutrition-related mortality by the WHO (increased risk of death from malnutrition if less than 11.5 cm in infants and children 6-64

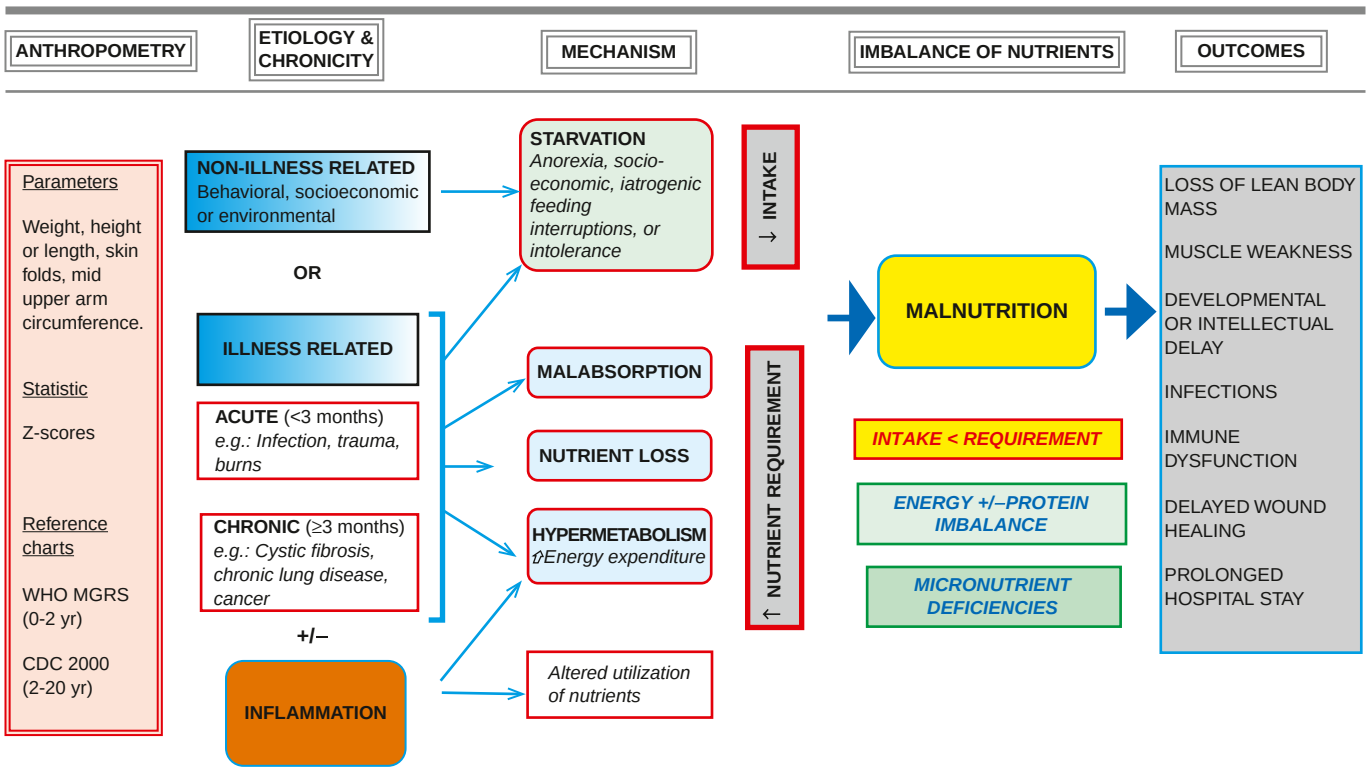

Fig. 64.1 Defining malnutrition in hospitalized children (ASPEN). CDC, Centers for Disease Control and Prevention; MGRS, Multicenter Growth Reference Study; WHO, World Health Organization. *(From Mehta NM, Corkins MR, Lyman B, et al. Defining pediatric malnutrition: A paradigm shift toward etiology-related definitions.* J Parenter Enteral Nutr. 2013;37[4]:460-481.*)*

Table 64.3 Approach to Malnutrition Based on Review of Systems

CAUSE	HISTORY AND PHYSICAL EXAMINATION	DIAGNOSTIC CONSIDERATION	WORKUP
Psychosocial	Lack of structure, poor sleep, permissive or intrusive feeding, feeding difficulties and food refusal starting in infancy	Low caloric intake secondary to home feeding environment; in extreme cases need to consider child neglect or abuse Avoidant restrictive food intake disorder (ARFID)	May need blood tests to check for certain micronutrient deficiencies based on diet history
CNS	Developmental delay, poor feeding, vomiting, large head circumference, abnormal neurologic exam	Brain tumor, intracranial bleeding (consider child abuse)	Referral to developmental pediatrics or neurology, MRI, EEG, specific test for neuromuscular function
Gastrointestinal	Chronic vomiting or diarrhea, fatty stool, crying with feedings, nocturnal cough, snoring, history of travel to/from developing countries	Malabsorption, intestinal parasites, milk protein intolerance, pancreatic insufficiency, cystic fibrosis, celiac disease, immunodeficiency, inflammatory bowel disease, small bowel bacterial overgrowth	May need referral to gastroenterology; stool studies (reducing substance, occult blood, fat stain), upper GI with small bowel follow-through; may need endoscopic evaluation
Cardiac	Slow feeding, dyspnea, diaphoresis with feeding, restless sleep, heat murmur	Congenital heart disease, heart failure	Referral to cardiology, ECG, echocardiogram
Genetic	May have a positive family history of developmental delay; often facies typical of a syndrome, skeletal abnormalities, heart murmur; consider in symmetric IUGR.	Noonan syndrome, William syndrome, Turner syndrome, Russel Silver syndrome	Specific genetic testing
Pulmonary	Dyspnea, tachypnea, recurrent wheezing, pulmonary infections	Asthma, aspiration, food allergies, cystic fibrosis, immunodeficiency, neuroendocrine hyperplasia of infancy	Chest x-ray, sweat chloride test; specialty referral
Renal	History of recurrent UTI, abnormal urinalysis, elevated BUN and creatinine	UTI, renal tubular acidosis	General chemistry with BUN and creatinine, urinalysis, urine and serum osmolality
Endocrine	Hypothyroidism is associated with decreased activity level; diabetes is associated with polyuria and polydipsia; growth hormone deficiency is associated with decreased linear growth velocity	Hypothyroidism, type 1 diabetes, growth hormone deficiency	Thyroid function tests, blood glucose and urinalysis, pituitary function tests

BUN, Blood urea nitrogen; CNS, central nervous system; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalogram; IUGR, intrauterine growth restriction; UTI, urinary tract infection.

Adapted from Carrasco MM, Wolford JE. Child abuse and neglect. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of Pediatric Physical Diagnosis*, 7th ed. Philadelphia: Elsevier; 2018, Table 6.6.

months of age). TSF is a measure of subcutaneous fat and is a sensitive indicator of total body fat. Both MUAC and TSF are especially useful tools for nutrition status assessment in children with altered body composition such as low muscle mass due to cerebral palsy. However, TSF needs to be done by experienced providers to minimize errors. MUAC and TSF charts are available on the WHO website.

TREATMENT

While an illness-related etiology of malnutrition is being investigated, caloric supplementation can occur simultaneously. Both the medical workup and the initiation of supplemental oral feeds can occur in the outpatient setting with close follow-up. Consider including a speech or occupational therapist for a suck-and-swallow evaluation if the history suggests difficulty with oral feeds. Hospitalization may be indicated for cases of severe malnutrition because of the potential for refeeding syndrome (see Chapter 63), or if a child with mild to moderate malnutrition has not responded after 2-3 months of outpatient management. Hospitalization may include initiation of nasogastric tube feeds, further diagnostic and laboratory evaluation, assessment and observed implementation of adequate nutrition, and evaluation of the parent-child feeding interaction. The type of caloric supplementation is based on the age of the child, the severity of malnutrition, and the underlying medical condition. Every effort to maximize the breastfeeding relationship in breastfed infants should be made, ideally involving lactation support, expressing breast milk to increase supply if low, and fortification of maternal milk if indicated.

Feeding style is equally important to caloric intake. Parents should be encouraged to respond to the child's cues of hunger and satiety and to have a structured schedule for meals and snacks (every 2-3 hours). A responsive feeding style that respects the toddler's autonomy but retains parental control over food choices helps establish healthy feeding habits (see Chapter 61). Grazing behaviors with frequent small snacks interfere with eating at mealtimes. Commonly used spill-proof and squeezable packaging foster eating "on the go" and has been associated with poor self-regulation of energy intake.

Use of liquid **oral nutritional supplements** resulted in significantly better catch-up growth in children with moderate to severe malnutrition (Tables 64.4 and 64.5). Oral nutritional supplements are most helpful when monitored and balanced with food intake. Start with 30-40 kcal per kg per day and serve them in small amounts simultaneously with meals to allow intake of age-appropriate food. However, children with oral motor difficulties may need to consume a larger proportion of calories in a liquid form.

Table 64.4 Nutritional Supplements

CATEGORY	BRAND EXAMPLES	FEATURES AND COMMENTS
ORAL SUPPLEMENTS		
Standard, cow's milk protein	Boost Kid Essentials 1.0 or 1.5 (with or without fiber) PediaSure 1.0 or 1.5 (with or without fiber) Nutren Jr 1.0 (with or without fiber) Kate Farms Pediatric Standard 1.2 *EnfaGrow *Nido *Scandishake	May or may not contain lactose.
Semi-elemental	Kate Farms Pediatric Peptide 1.5 PediaSure Peptide 1.0 or 1.5 Peptamen Jr	Used for malabsorption. Contains MCT.
Elemental	EleCare Junior Neocate Splash Neocate Jr Puramino Peptamen Jr	Used for malabsorption or severe protein allergy. Contains MCT.
Soy protein	Bright Beginnings Soy Pediasmart Soy	Cow-milk protein free.
Clear liquid	*Boost Breeze *Ensure Clear	Clear liquid, fruit flavored, fat free; cow's milk protein source. For supplemental nutrition *only;* none are a complete nutrition supplement.
Wound healing supplement	Juven Arginaid	Arginaid: L-Arginine only. Juven: Arginine glutamine, and betahydroxy-betamethylbutyrate.
TUBE FEEDING		
Standard, cow's milk protein	Boost Kid Essentials 1.0, 1.5 Nutren Junior PediaSure 1.0	Isotonic, most available with or without additional fiber.
High calorie	Boost Kid Essentials 1.5 *(1.5 kcal/mL)* PediaSure 1.5 *(1.5 kcal/mL)* Kate Farms Pediatric Peptide 1.5 *(1.5 kcal/mL)*	For increased caloric needs or fluid restriction.
Food-based formulas	Compleat Pediatric *(1.0 kcal/mL)* Compleat Pediatric Reduced Calorie *(0.6 kcal/mL)* Compleat Pediatric Organic Blends *(1.2 kcal/mL)* PediaSure Harvest *(1.0 kcal/mL)* Kate Farms Pediatric Standard *(1.2 kcal/mL)* Nourish *(1.13 kcal/mL)*	

List of products is not exhaustive and does not imply endorsement. Pediatric formulas are appropriate for children ages 1-11 years and are not appropriate for use in infants. After 11 years, adult formulations (not listed) may be used.
*Does not provide complete sole source of nutrition.
Adapted from Pediatric Nutrition Handbook/internal guide at Children's Hospital Colorado.

The response to feeding depends on the specific diagnosis, medical treatment, and severity of malnutrition. The same anthropometric measures used to diagnose malnutrition can be used to measure progress and recovery from the malnourished state. Target recovery growth is 150% of the normal rate of weight gain for age (Table 64.6). Many children with malnutrition require empiric micronutrient supplementation with zinc (and thiamine, if concerns about refeeding). Iron deficiency is also common in young children, but supplementation is most effective if initiated after resolution of any acute inflammatory processes (such as infection) and is typically not initiated until after 1-2 weeks of successful weight restoration. Additional supplementation for other micronutrients such as vitamin D and vitamin A can be considered based on symptoms and laboratory evaluation.

Interventions for contributing psychosocial factors are ideally targeted to the underlying issue, such as maternal depression or insufficient funds for food. Some children who develop feeding aversion behaviors will require treatment by a specialized feeding team. If abuse or purposeful neglect is a concern, the family should be referred to the child protective services team.

Kwashiorkor has a specific set of treatment guidelines from the WHO, including empiric antibiotics and avoidance of intravenous fluids and rapid repletion, as this can precipitate heart failure. Treatment of kwashiorkor in a low-resource setting is discussed in more detail in Chapter 62. In a high-resource setting, treatment may involve continuous feeds of a semi-elemental formula through a nasogastric tube to stabilize blood sugars in conjunction with close monitoring of electrolytes.

Table 64.5 Calorie Boosters for Oral and Enteral Feeding

	Kcal/g	Kcal/Tbsp	FEATURES AND COMMENTS
CARBOHYDRATE (CHO)			
Cornstarch	3.8	33	Can add to formula or water to treat hypoglycemia in glycogen storage disease or other disorders; dose per weight, age, and glucose levels; suggested starting dose of 0.5 g per kg per feed.
Infant rice cereal	—	15	Thickens formula, not human milk; start with 1 teaspoon rice cereal/oz formula (adds 5 kcal/oz, dilutes other nutrients). Not recommended to administer through feeding tube.
FAT			
MCT oil	8.3	116	7.7 kcal/mL; does not mix well, can administer as small bolus.
Heavy whipping cream		50	3.3 kcal/mL can be added to milk or nutritional supplements.
Butter		100	Easy to mix and use in a variety of foods.
PROTEIN			
Beneprotein	3.6	16.7	100% whey protein; 1 packet = 1 scoop = 7 g weight, 6 g protein, 25 kcal; can add to formula, human milk, food, or beverages.
COMBINATION			
Duocal	4.9	42	Hydrolyzed corn starch and fat (35% MCT); can add to formula, human milk, food, or beverages.
MCT Procal	6.6	—	1 packet (16 g) = 105 kcal, 10 g MCT, 2 g protein. For altered fat absorption or metabolism. Contains MCT and milk protein; can add to formula, food, and beverages.
Carnation Instant Breakfast			1 packet (36 g) = 140 kcal

Table 64.6 Weight Gain Velocity (0-2 Years of Age, g/day)

AGE (MONTHS)	EXPECTED GROWTH (g/DAY)	CATCH-UP GROWTH (g/DAY)
Preterm infant	30-40	
0-3	20-30	30-45
3-6	15-20	20-30
6-9	10-15	15-20
9-12	10	15
12-24	6	10

PROGNOSIS

Malnutrition, regardless of cause, can potentially have a detrimental effect on physical and intellectual growth and development, especially in infants younger than 2 years old. Early diagnosis and treatment of acute malnutrition may avoid long-term consequences. Multiple studies point to a negative impact of chronic malnutrition and stunting on intelligence quotient (IQ) later in life. Pediatric medical providers are encouraged to approach nutritional status in children as a controllable factor that can have a profound influence on brain function throughout life.

Chapter 65

Overweight and Obesity

Sheila Gahagan

EPIDEMIOLOGY

Obesity is an important pediatric public health problem associated with risk of complications in childhood and increased morbidity and mortality throughout adult life. Obesity is linked to more deaths than underweight. In 2016, according to the World Health Organization (WHO), 39% of adults aged 18 years and older were overweight and 13% were obese.

In the United States, child and adolescent obesity prevalence has increased by 300% over the past 40 years. In 2017–2018, the U.S. prevalence of pediatric obesity was 19.3%, affecting about 14.4 million children and adolescents. Obesity prevalence increases by age-group, with 13.4% of 2- to 5-year-olds, 20.3% of 6- to 11-year-olds, and 21.2% of 12- to 19-year-olds affected. Some U.S. populations have higher rates of childhood obesity than others do. Prevalence of obesity in children was 25.6% among Hispanic children, 24.2% among non-Hispanic Black children, 16.1% in non-Hispanic White children, and 8.7% in non-Hispanic Asian children. Higher maternal education confers protection against childhood obesity across all ethnic groups.

The first 1,000 days, the period from conception to age 2 years, are a modifiable period related to risk for childhood obesity. Recommendations for the first 1,000 days include (1) a healthy and nutritious diet during pregnancy; (2) good care for all mothers during pregnancy; (3) exclusive breastfeeding for 6 months; (4) nurturing and responsive care for infants and toddlers; (5) the right foods introduced to babies at the right time; (6) water and other healthy beverages with no added sugars for toddlers; (7) a healthy and nutritious diet for babies and toddlers; (8) the right knowledge and skills for parents and caregivers to properly nourish young children; (9) consistent access to enough nutritious food for families of young children; and (10) societal investments in the well-being of every baby and toddler (for further information see https://thousanddays.org/resource/nourishing-americas-future/).

Parental obesity correlates with a higher risk for obesity in the children. Prenatal factors, including high preconceptual weight, gestational weight gain, high birthweight, and maternal smoking, are associated with increased risk for later obesity. Paradoxically, intrauterine growth restriction with early infant catch-up growth is associated with the development of central adiposity and adult-onset cardiovascular (CV) risk. Breastfeeding is modestly protective for obesity based on dose and duration. Infants with high levels of negative reactivity (temperament) are more at risk for obesity than those with better self-regulation. The incidence of obesity in children was noted to increase during the COVID-19 pandemic.

BODY MASS INDEX

Obesity, or increased adiposity, is defined using the **body mass index (BMI)**, an excellent proxy for more direct measurement of body fat. BMI = weight in kg/(height in meters)^2. Adults with a BMI ≥30 meet the criterion for obesity, and those with a BMI 25-30 fall in the overweight range. During childhood, levels of body fat change beginning with high adiposity during infancy. Body fat levels decrease for approximately 5.5 years until the period called *adiposity rebound,* when body fat is typically at the lowest level. Adiposity then increases until early adulthood (Fig. 65.1). Consequently, obesity and overweight are defined using BMI percentiles for children ≥2 years old and weight/length percentiles for infants <2 years old. The criterion for **obesity** is BMI ≥95th percentile, and for **overweight** is BMI between 85th and 95th percentiles.

ETIOLOGY

Humans have the capacity to store energy in adipose tissue, allowing improved survival in times of famine. Simplistically, obesity results from an imbalance of caloric intake and energy expenditure. Even incremental but sustained caloric excess results in excess adiposity. Individual adiposity is the result of a complex interplay among genetically determined body habitus, appetite, nutritional intake, **physical activity (PA)**, and energy expenditure. Environmental factors determine levels of available food, preferences for types of foods, levels of PA, and preferences for types of activities. Food preferences play a role in the consumption of energy-dense foods. Humans innately prefer sweet and salty foods and tend initially to reject bitter flavors, common to many vegetables. Repeated exposure to healthy foods promotes their acceptance and liking, especially in early life. This human characteristic to adapt to novel foods can be used to promote healthy food selection.

Environmental Changes

Over more than 4 decades, the food environment changed dramatically related to urbanization and the food industry as fewer families routinely prepare meals. Foods prepared by a food industry have higher levels of calories, simple carbohydrates, and fat. The price of many foods has declined relative to the family budget. These changes, in combination with marketing pressure, have resulted in larger portion sizes and increased snacking between meals. The increased consumption of high-carbohydrate beverages, including sodas, sport drinks, fruit punch, and juice, adds to these factors.

According to the National Center for Health Statistics, fast food is consumed by 36.3% of 2- to 19-year-old U.S. children each day and by two thirds of children every week. A typical fast-food meal can contain 2,000 kcal and 84 g of fat. Many children consume four servings of high-carbohydrate beverages per day, resulting in an additional 560 kcal of low nutritional value. Sweetened beverages have been linked to increased risk for obesity. The dramatic increase in the use of high-fructose corn syrup to sweeten beverages and prepared foods is another important environmental change, leading to availability of inexpensive calories.

Since World War II, levels of PA in children and adults have declined. According to the 2017 National Health and Nutrition Examination Survey (NHANES) survey, 26.1% of adolescents met PA guidelines of 60 minutes of PA per day. Only 20% met guidelines for aerobic PA and muscle strengthening. The persistence of low levels of PA is related to many factors, including changes in the built environment, more reliance on cars, lower levels of active transportation, safety issues, and increasingly sedentary lifestyles. Many sectors of society do not engage in PA during leisure time. For children, budgetary constraints and pressure for academic performance have led to less time devoted to physical education in schools. Perception of poor neighborhood safety also leads to lower levels of PA. Furthermore, screens (televisions, tablets, smartphones, computers) offer compelling sedentary activities that do not burn calories.

Sleep plays a role in the risk for obesity. Over the past 4 decades, children and adults have decreased the amount of time spent sleeping. Reasons for these changes may relate to increased time at work, increased time watching television, and a generally faster pace of life. Chronic partial sleep loss can increase risk for weight gain and obesity, with the impact possibly greater in children than in adults. In studies of young, healthy, lean men, short sleep duration was associated with decreased leptin levels and increased ghrelin levels, along with increased hunger and appetite. *Sleep debt* also results in decreased glucose tolerance and insulin sensitivity related to alterations in glucocorticoids and sympathetic activity. Some effects of sleep debt might relate to *orexins,* peptides synthesized in the lateral hypothalamus that can increase feeding, arousal, sympathetic activity, and neuropeptide Y activity.

Genetics

Genetic determinants also have a role in individual susceptibility to obesity (Table 65.1). Findings from genome-wide association studies explain a very small portion of interindividual variability in obesity.

Table 65.1 Endocrine and Genetic Causes of Obesity

DISEASE	SYMPTOMS	LABORATORY
ENDOCRINE		
Cushing syndrome	Central obesity, hirsutism, moon face, hypertension	Dexamethasone suppression test
GH deficiency	Short stature, slow linear growth	Evoked GH response, IGF-1
Hyperinsulinism	Nesidioblastosis, pancreatic adenoma, hypoglycemia, Mauriac syndrome	Insulin level
Hypothyroidism	Short stature, weight gain, fatigue, constipation, cold intolerance, myxedema	TSH, FT_4
Pseudohypoparathyroidism	Short metacarpals, subcutaneous calcifications, dysmorphic facies, intellectual disability, short stature, hypocalcemia, hyperphosphatemia	Urine cAMP after synthetic PTH infusion
GENETIC/SYNDROMIC		
Albright hereditary osteodystrophy	Short stature, skeletal defects, PTH resistance	*GNAS* gene, in syndromic but also in isolated nonsyndromic obesity
Alström syndrome	Cognitive impairment, retinitis pigmentosa, insulin-resistant diabetes mellitus, hearing loss, hypogonadism, cardiomyopathy	*ALMS1* gene
Bardet-Biedl syndrome	Retinitis pigmentosa, renal abnormalities, polydactyly, syndactyly, hypogonadism	~21 different genes
BDNF/TrkB deficiency	Hyperactivity, impaired concentration, limited attention span, impaired short-term memory and pain sensation	*BDNF/TrkB* gene
Biemond syndrome	Cognitive impairment, iris coloboma, hypogonadism, polydactyly	
Carpenter syndrome	Polydactyly, syndactyly, cranial synostosis, intellectual disability	*RAB23* gene, located on chromosome 6 in humans
Cohen syndrome	Mid-childhood-onset obesity, short stature, prominent maxillary incisors, hypotonia, intellectual disability, microcephaly, decreased visual activity, neutropenia, joint laxity	*VPS13B* gene (often called *COH1*) at locus 8q22
Deletion 9q34	Early-onset obesity, intellectual disability, brachycephaly, synophrys, prognathism, behavior and sleep disturbances	Deletion 9q34
Down syndrome	Short stature, dysmorphic facies, intellectual disability	Trisomy 21
ENPP1 gene	Insulin resistance, childhood obesity	Gene on chromosome 6q
Fragile X	Long facies, large, prominent ears, macroorchidism, autism	*FMR1*; CGG repeat expansion >200
Fröhlich syndrome	Hypothalamic tumor	
FTO gene polymorphism, plus upstream regulatory and downstream activation genes	Dysregulation of orexigenic hormone acyl-ghrelin, poor postprandial appetite suppression	Homozygous for *FTO* AA allele
Kabuki syndrome	Characteristic facies, intellectual disability, visceral and skeletal malformations	*KMT2D, MLL2, ALR, KABUK1*
Kleefstra syndrome	Intellectual disability, autism-like behavior, hypotonia, cardiac defects	*EHMT1*
KSR2 deficiency	Mild hyperphagia and reduced basal metabolic rate, insulin resistance often with acanthosis nigricans, irregular menses, early development of type 2 diabetes mellitus	*KSR2* gene
Leptin or leptin receptor gene deficiency	Early-onset severe obesity, infertility (hypogonadotropic hypogonadism), hyperphagia, infections	Leptin
Leptin variant (antagonistic)	Hyperphagia, obesity; treatment with high dose recombinant leptin	High leptin levels
Melanocortin 4 receptor gene mutation	Early-onset severe obesity, increased linear growth, hyperphagia, hyperinsulinemia; **most common known genetic cause of obesity;** homozygous worse than heterozygous	*MC4R* variant
MEHMO	Intellectual disability, epilepsy, hypogonadism, microcephaly, obesity	Xp22.13-p21.1
MORM	Intellectual disability, obesity, retinal dystrophy, micropenis	*INPP5E*
PCSK1 deficiency	Small bowel enteropathy, hypoglycemia, hypothyroidism, ACTH deficiency, diabetes insipidus	*PCSK1* gene
Prader-Willi syndrome	Neonatal hypotonia, slow infant growth, small hands and feet, intellectual disability, hypogonadism, hyperphagia leading to severe obesity, paradoxically elevated ghrelin	Partial deletion of chromosome 15 or loss of paternally expressed genes: *MKRN3, ZNF127, MAGEL2, SNRPN*
Proopiomelanocortin (POMC) deficiency	Obesity, red hair, pale skin, adrenal insufficiency due to ACTH deficiency, hyperproinsulinemia, hyperphagia, cholestatic jaundice	Loss-of-function of *POMC* gene
Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD); ROHHADNET (with neuroendocrine tumor)	Often confused with congenital central hypoventilation syndrome (CCHS); presentation ≥1.5 yr with weight gain, hyperphagia, hypoventilation, cardiac arrest, central diabetes insipidus, hypothyroidism, GH deficiency, pain insensitivity, hypothermia, precocious puberty, and neural crest tumors	Unknown genes May be a paraneoplastic disorder
Rubinstein-Taylor syndrome	Short stature, visual impairment, scoliosis, dysmorphic facies	*CREBBP, EP300*
SH2B1 deficiency	Hyperphagia, disproportionate hyperinsulinemia, early speech and language delay that often resolves, behavioral problems including aggression	*SH2B1* gene
SIM1 deficiency (Prader-Willi–like)	Hyperphagia with autonomic dysfunction (characterized by low systolic blood pressure), speech and language delay, neurobehavioral abnormalities including autistic-type behaviors	*SIM1*gene
Smith-Magenis syndrome	Intellectual disability, delayed speech, facial dysmorphology	*RAI1*
TUB deficiency	Retinal dystrophy, deafness	*TUB* gene
Turner syndrome	Ovarian dysgenesis, lymphedema, web neck, short stature, cognitive impairment	XO chromosome
WAGRO	Wilms tumor, aniridia, genitourinary anomalies, mental retardation, obesity	*BDNF*

ACTH, Adrenocorticotropic hormone; cAMP, cyclic adenosine monophosphate; FT_4, free thyroxine; GH, growth hormone; IGF, insulin-like growth factor; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

One important example, the *FTO* gene at 16q12, is associated with adiposity in childhood, probably explained by increased energy intake. Monogenic forms of obesity have also been identified, including **melanocortin-4 receptor (**MC4R**)** deficiency, associated with early-onset obesity and food-seeking behavior. Pathogenic variants in *MC4R* are a common cause of **monogenetic** obesity but a rare (0.1%) cause of obesity in general. Deficient activation of *MC4R* is also seen in patients with **proopiomelanocortin (POMC)** deficiency, a prohormone precursor of adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone (MSH), resulting in adrenal insufficiency, light skin, red hair, hyperphagia, and obesity. Leptin releases MSH, which can then activate MC4R, affecting appetite.

In addition, evidence suggests that appetitive traits are moderately heritable. Some genes associated with appetite also relate to weight, and vice-versa. In addition, there are genetic conditions associated with obesity, such as **Prader-Willi syndrome**, which results from absence of paternally expressed imprinted genes in the 15q11.2-q13 region. Prader-Willi syndrome is characterized by insatiable appetite and food seeking. In the era of genomic medicine, it will be increasingly possible to identify risks according to specific genes and consider gene-environment interactions. Epigenetic environmental modification of genes may have a role in the development of obesity, especially during fetal and early life.

Endocrine and Neural Physiology

Monitoring of "stored fuels" and short-term control of food intake (appetite and satiety) occurs through neuroendocrine feedback loops linking adipose tissue, the GI tract, and the CNS (Figs. 65.2 and 65.3). GI hormones, including cholecystokinin, glucagon-like peptide 1, peptide YY (PYY), and vagal neuronal feedback, promote satiety. *Ghrelin* stimulates appetite. Adipose tissue provides feedback regarding energy storage levels to the brain through hormonal release of adiponectin and leptin. These hormones act on the arcuate nucleus in the hypothalamus and on the solitary tract nucleus in the brainstem and in turn activate distinct neuronal networks. Adipocytes secrete *adiponectin* into the blood, with reduced levels in response to obesity and increased levels in response to fasting. Reduced adiponectin levels are associated with lower insulin sensitivity and adverse CV outcomes. *Leptin* is directly involved in satiety; low leptin levels stimulate food intake, and high leptin levels inhibit hunger in animal models and in healthy human volunteers. However, the negative feedback loop from leptin to appetite may be more adapted to preventing starvation than excess intake.

Numerous neuropeptides in the brain, including PYY agouti-related peptide, and orexin, appear to affect appetite stimulation, whereas melanocortins and α-melanocortin–stimulating hormone are involved in satiety (see Fig. 65.3). The neuroendocrine control of appetite and weight involves a negative feedback system, balanced between short-term control of appetite and long-term control of adiposity (including leptin). PYY reduces food intake via the vagal-brainstem-hypothalamic pathway. Developmental changes in PYY are evident, as infants have higher PYY levels than school-aged children and adults. Obese children have lower fasting levels of PYY than adults. Weight loss may restore PYY levels in children, even though this does not happen in adults. In addition, patients homozygous for the *FTO* obesity-risk allele demonstrate poor regulation of the orexigenic hormone acyl-ghrelin and have poor postprandial appetite suppression.

COMORBIDITIES

Complications of pediatric obesity occur during childhood and adolescence and persist into adulthood. An important reason to prevent and treat pediatric obesity is the increased risk for morbidity and mortality later in life. Males who are overweight during adolescence are twice as likely to die from CV disease as those who have normal weight. More immediate comorbidities include type 2 diabetes, hypertension, hyperlipidemia, and **nonalcoholic fatty liver disease** (NAFLD) (Table 65.2). Insulin resistance increases with increasing adiposity and independently affects lipid metabolism and CV health. **Metabolic syndrome** (central obesity, hypertension, glucose intolerance, and hyperlipidemia) increases the risk for CV morbidity and mortality. NAFLD has been reported in 34% of patients treated in a pediatric obesity clinic. NAFLD is the most common chronic liver disease in U.S. children and adolescents. It can present with advanced fibrosis or nonalcoholic steatohepatitis and may result in cirrhosis and hepatocellular carcinoma. Insulin resistance is often associated. NAFLD is also independently associated with increased risk of CV disease.

Obesity may also be associated with chronic inflammation. Adiponectin, a peptide with antiinflammatory properties, occurs in reduced levels in obese patients compared with insulin-sensitive, lean persons. Low adiponectin levels correlate with elevated levels of free fatty acids and plasma triglycerides in addition to a high BMI, and high adiponectin levels correlate with peripheral insulin sensitivity. Adipocytes secrete peptides and cytokines into the circulation, and proinflammatory peptides such interleukin (IL)-6 and tumor necrosis factor (TNF)-α occur in higher levels in obese patients. Specifically, IL-6 stimulates production of CRP in the liver. CRP is a marker of inflammation and might link obesity, coronary disease, and subclinical inflammation.

Some complications of obesity are mechanical, including obstructive sleep apnea and orthopedic complications. Orthopedic complications include Blount disease and slipped femoral capital epiphysis (see Chapters 718 and 719.4).

Mental health problems can coexist with obesity, with the possibility of bidirectional effects. These associations are modified by gender, ethnicity, and socioeconomic status. Self-esteem may be lower in obese adolescent females than in nonobese peers. Some studies have found an association between obesity and adolescent depression. There is considerable interest in the co-occurrence of eating disorders and obesity. Obese youth are also at risk for bullying.

IDENTIFICATION

Overweight and obese children are often identified as part of routine medical care. The child and family may be unaware that the child has increased adiposity. They may be unhappy with the medical provider for raising this issue and may respond with denial or apparent lack of concern. It is often necessary to begin by helping the family understand the importance of healthy weight for current and future health. Forging a good therapeutic relationship is important because obesity intervention requires a chronic disease management approach. Intervention and successful resolution of this problem require considerable effort by the family and the child over an extended period in order to change eating and activity behaviors.

EVALUATION

The evaluation of the overweight or obese child begins with examination of the growth chart for weight, height, and BMI trajectories; consideration of possible medical causes of obesity; and detailed exploration of family eating, nutritional, and activity patterns. A complete pediatric history is used to uncover comorbid disorders. The family history focuses on the adiposity of other family members and the family history of obesity-associated disorders. The physical examination adds data that can lead to important diagnoses. Laboratory testing is guided by the need to identify comorbidities.

Examination of the **growth chart** reveals the severity, duration, and timing of obesity onset. Children who are overweight (BMI in 85th-95th percentile) are less likely to have developed comorbid conditions than those who are obese (BMI ≥95th percentile). Those with a BMI ≥99th percentile are most likely to have coexisting medical problems. Once obesity severity is determined, the BMI trajectory is examined to elucidate when the child became obese. Several periods during childhood are considered *sensitive* periods, or times of increased risk for developing obesity, including infancy, adiposity rebound (when body fat is lowest at approximately age 5.5 years), and adolescence. An abrupt change in BMI might signal the onset of a medical problem or a period of family or personal stress for the child. Examination of the weight trajectory can further reveal how the problem developed. A young child might exhibit high weight and high height because linear growth can increase early in childhood if a child consumes excess energy. At some point the weight percentile exceeds the height percentile, and the child's BMI climbs into the obese range. Another example

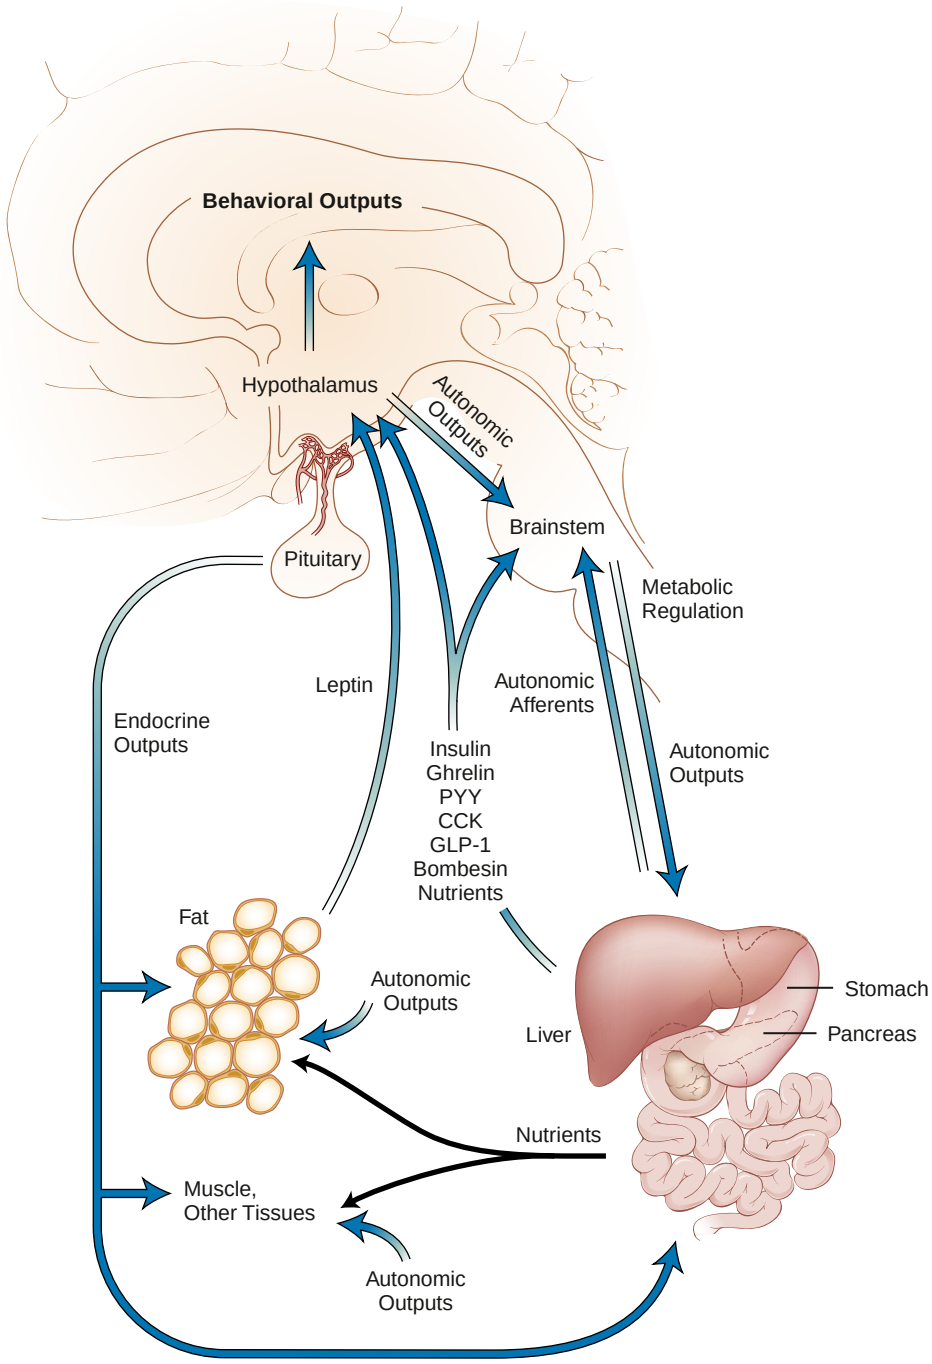

Fig. 65.2 Regulation of energy homeostasis by the brain-gut-adipose axis. CCK, Cholecystokinin; GLP-1, glucagon-like peptide 1; PYY, peptide YY. *(From Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. Williams Textbook of Endocrinology, 13th ed. Philadelphia: Elsevier; 2016, p. 1610.)*

is a child whose weight rapidly increases when they reduce their activity level and consume more meals away from home. Examination of the height trajectory can reveal endocrine problems, which often occur with slowing of linear growth.

Consideration of possible medical causes of obesity is essential, even though endocrine, syndromic, and monogenetic causes are rare (see Table 65.1). Growth hormone deficiency, hypothyroidism, and Cushing syndrome are examples of endocrine disorders that can lead to obesity. In general, these disorders manifest with slow linear growth. Because children who consume excessive amounts of calories tend to experience accelerated linear growth, short stature warrants further evaluation. Genetic disorders associated with obesity may manifest extreme hyperphagia, or they can have coexisting dysmorphic features, cognitive impairment, vision and hearing abnormalities, or short stature. In some children with congenital disorders such as myelodysplasia or muscular dystrophy, lower levels of PA can lead to secondary obesity. Some medications, such as atypical antipsychotics, can cause excessive appetite and hyperphagia, resulting in obesity (Table 65.3). Rapid weight gain in a child or adolescent taking one of these medications might require its discontinuation. Poor linear growth and rapid changes in weight gain are indications for evaluation of possible medical causes.

Exploration of family eating, nutritional, and activity patterns begins with a description of regular meal and snack times and family habits for walking, bicycle riding, active recreation, and **screen time** (TV, computer, video games). It is useful to request a 24-hour dietary recall with special attention to intake of fruits, vegetables, and water, as well as high-calorie foods and high-carbohydrate beverages. When possible, evaluation by a nutritionist is extremely helpful. This information will form the basis for incremental changes in eating behavior, caloric intake, and PA during the intervention.

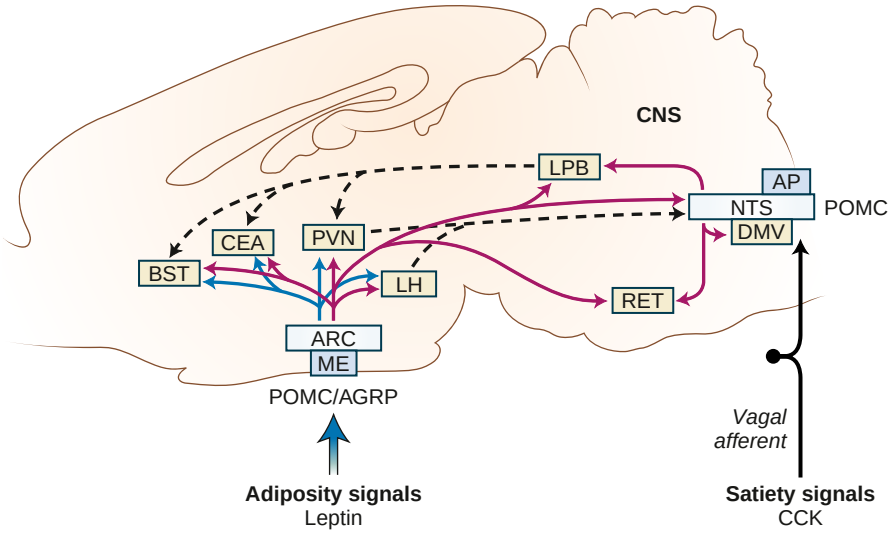

Fig. 65.3 Brain structures involved in energy homeostasis. Receipt of long-term adipostatic signals and acute satiety signals by neurons in arcuate nucleus and brainstem, respectively. Pale-blue boxes indicate nuclei containing proopiomelanocortin (POMC) neurons; tan boxes indicate nuclei containing melanocortin-4 receptor (MC4R) neurons that may serve to integrate adipostatic and satiety signals; and darker-blue boxes show some circumventricular organs involved in energy homeostasis. Magenta arrows designate a subset of projections of POMC neurons; blue arrows show a subset of projections of agouti-related peptide (AGRP) neurons. AP, Area postrema; ARC, arcuate nucleus; BST, bed nucleus of stria terminalis; CCK, cholecystokinin; CEA, central nucleus of amygdala; CNS, central nervous system; DMV, dorsal motor nucleus of vagus; LH, lateral hypothalamic area; LPB, lateral parabrachial nucleus; ME, median eminence; NTS, nucleus tractus solitarius; PVN, paraventricular nucleus of hypothalamus; RET, reticular formation. *(Modified from Fan W, Ellacott KL, Halatchev IG, Takahashi K, Yu P, Cone RD. Cholecystokinin-mediated suppression of feeding involves the brainstem melanocortin system. Nat Neurosci. 2004;7[4]:335–336.)*

Table 65.2 Obesity-Associated Comorbidities

DISEASE	POSSIBLE SYMPTOMS	LABORATORY CRITERIA
CARDIOVASCULAR		
Dyslipidemia	HDL <40, LDL >130, total cholesterol >200 mg/dL	Fasting total cholesterol, HDL, LDL, triglycerides
Hypertension	SBP >95% for sex, age, height	Serial testing, urinalysis, electrolytes, blood urea nitrogen, creatinine
ENDOCRINE		
Type 2 diabetes mellitus	Acanthosis nigricans, polyuria, polydipsia	Fasting blood glucose >110, hemoglobin A_{1c}, insulin level, C-peptide, oral glucose tolerance test
Metabolic syndrome	Central adiposity, insulin resistance, dyslipidemia, hypertension, glucose intolerance	Fasting glucose, LDL and HDL cholesterol
Polycystic ovary syndrome	Irregular menses, hirsutism, acne, insulin resistance, hyperandrogenemia	Pelvic ultrasound, free testosterone, LH, FSH
GASTROINTESTINAL		
Gallbladder disease	Abdominal pain, vomiting, jaundice	Ultrasound
Nonalcoholic fatty liver disease (NAFLD)	Hepatomegaly, abdominal pain, dependent edema, ↑ transaminases Can progress to fibrosis, cirrhosis	AST, ALT, ultrasound, CT, or MRI
NEUROLOGIC		
Pseudotumor cerebri	Headaches, vision changes, papilledema	Cerebrospinal fluid opening pressure, CT, MRI
Migraines	Hemicrania, headaches	None
ORTHOPEDIC		
Blount disease (tibia vara)	Severe bowing of tibia, knee pain, limp	Knee radiographs
Musculoskeletal problems	Back pain, joint pain, frequent strains or sprains, limp, hip pain, groin pain, leg bowing	Radiographs
Slipped capital femoral epiphysis	Hip pain, knee pain, limp, decreased mobility of hip	Hip radiographs
PSYCHOLOGIC		
Behavioral complications	Anxiety, depression, low self-esteem, disordered eating, signs of depression, worsening school performance, social isolation, problems with bullying or being bullied	Child Behavior Checklist, Children's Depression Inventory, Peds QL, Eating Disorder Inventory 2, subjective ratings of stress and depression, Behavior Assessment System for Children, Pediatric Symptom Checklist
PULMONARY		
Asthma	Shortness of breath, wheezing, coughing, exercise intolerance	Pulmonary function tests, peak flow
Obstructive sleep apnea	Snoring, apnea, restless sleep, behavioral problems	Polysomnography, hypoxia, electrolytes (respiratory acidosis with metabolic alkalosis)

ALT, Alanine transaminase; AST, aspartate transaminase; CT, computed tomography; FSH, follicle-stimulating hormone; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; MRI, magnetic resonance imaging; Peds QL, Pediatric Quality of Life Inventory; SBP, systolic blood pressure.

Table 65.4 Normal Laboratory Values for Recommended Tests

LABORATORY TEST	NORMAL VALUE
Glucose	<110 mg/dL
Insulin	<15 mU/L
Hemoglobin A_{1c}	<5.7%
AST (age 2-8 yr)	<58 U/L
AST (age 9-15 yr)	<46 U/L
AST (age 15-18 yr)	<35 U/L
ALT	<35 U/L
Total cholesterol	<170 mg/dL
LDL	<110 mg/dL
HDL	>45 mg/dL
Triglycerides (age 0-9 yr)	<75 mg/dL
Triglycerides (age 10-19 yr)	<90 mg/dL

AST, Aspartate transaminase; ALT, alanine transaminase; LDL, low-density lipoprotein; HDL, high-density lipoprotein.
From Children's Hospital of Wisconsin. *The NEW (nutrition, exercise and weight management) kids program.* http://www.chw.org/display/displayFile.asp?docid=33672&filename=/Groups/NEWKids/NewKidsReferral.PDF.

Initial assessment of the overweight or obese child includes a complete review of bodily systems, focusing on the possibility of comorbid conditions (see Table 65.2). Developmental delay and visual and hearing impairment can be associated with genetic disorders. Difficulty sleeping, snoring, or daytime sleepiness suggests sleep apnea. Abdominal pain might suggest NAFLD. Symptoms of polyuria, nocturia, or polydipsia may be the result of type 2 diabetes. Hip or knee pain can be caused by secondary orthopedic problems, including Blount disease and slipped capital femoral epiphysis. Irregular menses may be associated with polycystic ovary syndrome. Acanthosis nigricans can suggest insulin resistance and type 2 diabetes (Fig. 65.4).

The family history begins with identifying other obese family members. Parental obesity is an important risk for child obesity. If all family members are obese, focusing the intervention on the entire family is reasonable. The child may be at increased risk for developing type 2 diabetes if a family history exists. Identification of a family history of hypertension, CV disease, or metabolic syndrome indicates increased risk for developing these obesity-associated conditions. If the clinician helps the family to understand that childhood obesity increases the risk for developing these chronic diseases, this educational intervention might serve as motivation to improve their nutrition and PA.

Physical examination should be thorough, focusing on possible comorbidities (see Table 65.2). Careful screening for hypertension using an appropriately sized blood pressure cuff is important. Systematic examination of the skin can reveal acanthosis nigricans, suggesting insulin resistance, or hirsutism, suggesting polycystic ovary syndrome. Tanner staging can reveal premature adrenarche secondary to advanced sexual maturation in overweight and obese females.

Laboratory testing for fasting plasma glucose, triglycerides, low-density lipoprotein and high-density lipoprotein cholesterol, and liver function tests are recommended as part of the initial evaluation for newly identified pediatric obesity (Table 65.4). Overweight children (BMI 85th-95th percentile) who have a family history of diabetes mellitus or signs of insulin resistance should also be evaluated with a fasting plasma glucose test. Other laboratory testing should be guided by history or physical examination findings. Figure 65.5 provides a recommended approach to categorization, evaluation, and treatment.

INTERVENTION

Evidence shows that some interventions result in modest but significant and sustained improvement in body mass. Based on behavior change theories (see Chapter 18), treatment includes specifying target behaviors, self-monitoring, goal setting, stimulus control, and promotion of self-efficacy and self-management skills. **Behavior changes** associated with improving BMI include drinking lower quantities of sugar-sweetened beverages, consuming higher-quality diets, increasing exercise, decreasing screen time, and self-weighing. Most successful interventions have been *family based* and consider the child's developmental age. "Parent-only" treatment may be as effective as "parent–child" treatment. Because obesity is multifactorial, not all children and adolescents will respond to the same approach. For example, *loss-of-control eating,* associated with weight gain and obesity, predicts poor outcome in response to family-based treatment. Furthermore, clinical treatment programs are expensive and not widely available. Therefore interest has grown in novel approaches such as internet-based treatments and guided self-help.

It is important to begin with clear recommendations about **appropriate caloric intake** for the obese child (Table 65.5). Working with a dietitian is essential. Meals should be based on fruits, vegetables, whole grains, lean meat, fish, and poultry. Prepared foods should be chosen for their nutritional value, with attention to calories and fat. Foods that provide excessive calories and low nutritional value should be reserved for infrequent treats. The World Health Organization recommends avoiding artificial sweeteners (aspartame, sucralose, stevia).

Weight reduction diets in adults generally do not lead to sustained weight loss. Therefore the focus should be on changes that can be maintained for life. Attention to eating patterns is helpful. Families should be encouraged to plan *family meals,* including breakfast. It is almost impossible for a child to make changes in nutritional intake and eating patterns if other family members do not make the same changes.

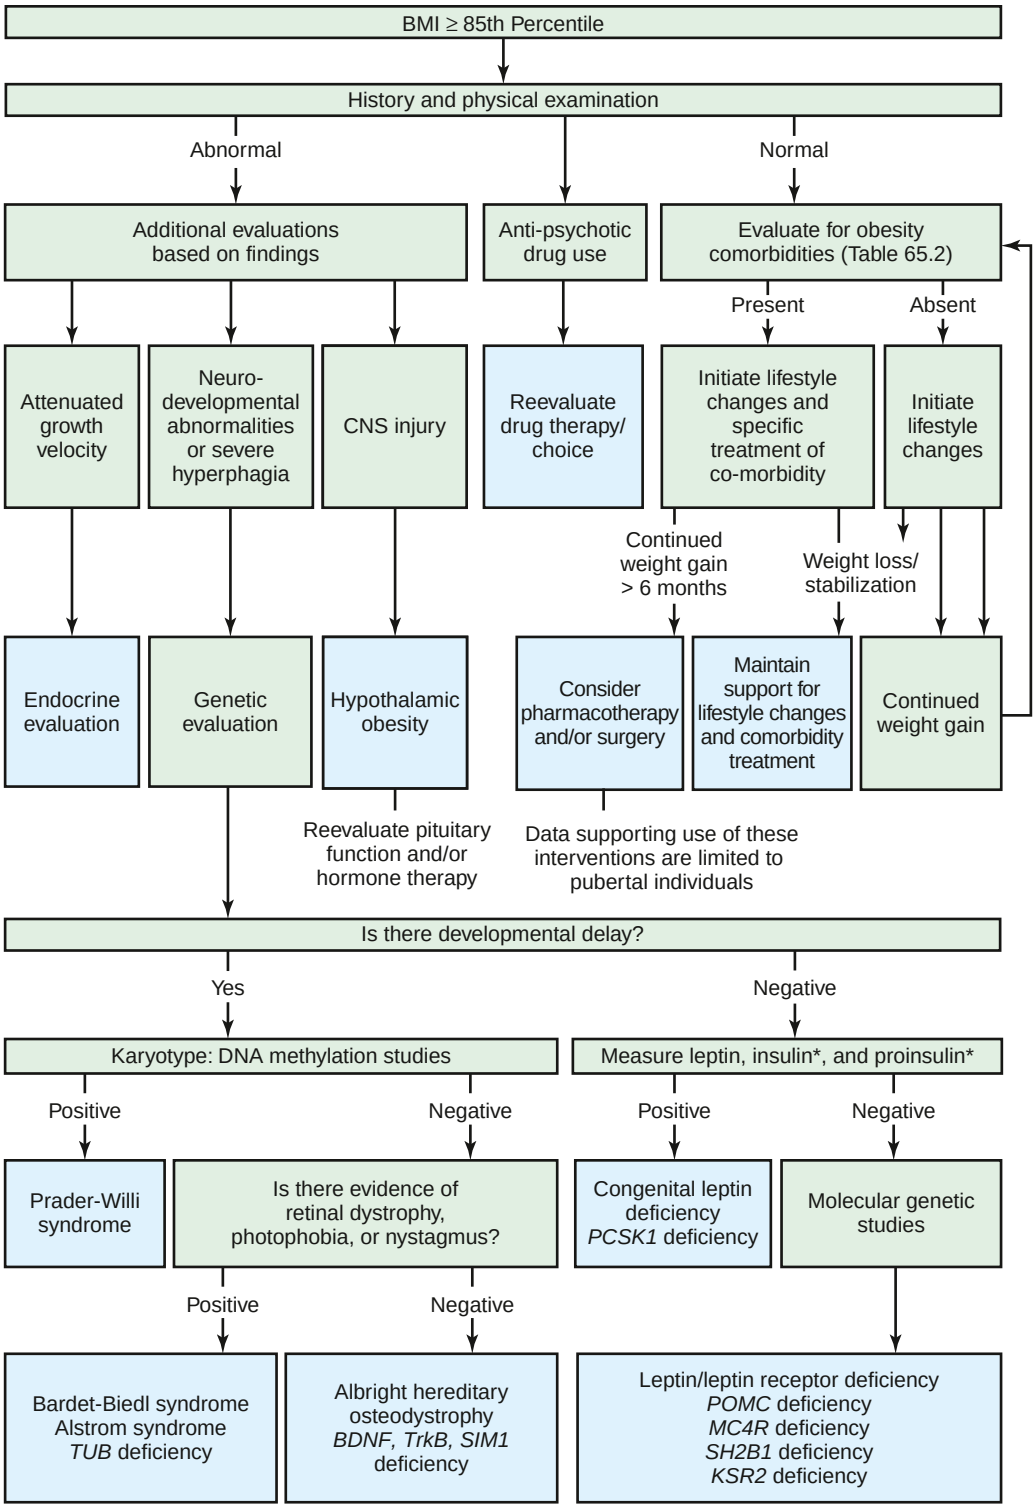

Fig. 65.5 Diagnostic and treatment algorithm for the evaluation of the overweight or obese child. *Measure insulin and proinsulin in patients with clinical features of PCSK1 deficiency. BMI, Body mass index; CNS, central nervous system. *(From Farooqi SOR, O'Rahilly S. Genetic obesity syndromes. In Grant S, ed. The Genetics of Obesity. New York: Springer; 2014, pp. 23–32; originally adapted from August GP, Caprio S, Fennoy I, et al. Prevention and treatment of pediatric obesity: An Endocrine Society clinical practice guideline based on expert opinion. J Clin Endocrinol Metab. 2008;93:4576–4599.)*

Dietary needs also change developmentally; adolescents require greatly increased calories during their growth spurts, and adults who lead inactive lives need fewer calories than active, growing children.

Psychologic strategies are helpful. The **"traffic light" diet** groups foods into those that can be consumed without any limitations (green), in moderation (yellow), or reserved for infrequent treats (red) (Table 65.6). The concrete categories are very helpful to children and families. This approach can be adapted to any ethnic group or regional cuisine. **Motivational interviewing** begins with assessing how ready the patient is to make important behavioral changes. The professional then engages the patient in developing a strategy to take the next step toward the ultimate goal of healthy nutritional intake.

Table 65.5 Recommended Caloric Intake Designated by Age and Gender

LIFE-STAGE GROUP	AGE (YR)	RELATIVELY SEDENTARY LEVEL OF ACTIVITY (KCAL)	MODERATE LEVEL OF ACTIVITY (KCAL)	ACTIVE (KCAL)
Child	2-3	1,000	1,000-1,400	1,000-1,400
Female	4-8	1,200	1,400-1,600	1,400-1,800
	9-13	1,600	1,600-2,000	1,800-2,200
	14-18	1,800	2,000	2,400
Male	4-8	1,400	1,400-1,600	1,600-2,000
	9-13	1,800	1,800-2,200	2,000-2,600
	14-18	2,200	2,400-2,800	2,800-3,200

Adapted from U.S. Department of Agriculture. Dietary guidelines for Americans, 2005. http://www.health.gov/DIETARYGUIDELINES/dga2005/document/html/chapter2.htm.

Table 65.6 "Traffic Light" Diet Plan

FEATURE	GREEN LIGHT FOODS	YELLOW LIGHT FOODS	RED LIGHT FOODS
Quality	Low-calorie, high-fiber, low-fat, nutrient-dense	Nutrient-dense, but higher in calories and fat	High in calories, sugar, and fat
Types of food	Fruits, vegetables	Lean meats, dairy, starches, grains	Fatty meats, sugar, sugar-sweetened beverages, fried foods
Quantity	Unlimited	Limited	Infrequent or avoided

This method allows the professional to take the role of a coach, helping the child and family reach their goals. Other behavioral approaches include family rules about where food may be consumed (e.g., "not in the bedroom").

Increasing PA without decreasing caloric intake is unlikely to result in weight loss. However, **aerobic exercise** training improves metabolic profiles in obese children and adolescents. Furthermore, it can increase aerobic fitness and decrease percent body fat even without weight loss. Therefore increasing PA can decrease risk for CV disease, improve well-being, and contribute to weight loss. Increased PA can be accomplished by walking to school, engaging in PA during leisure time with family and friends, or enrolling in organized sports. Children are more likely to be active if their parents are active; family PA is recommended. When adults lose significant weight, they may regain that weight despite eating fewer calories. The body may adapt to weight loss by reducing the basal metabolic rate (BMR), thus requiring fewer calories. One approach to this phenomenon is to increase PA.

Active pursuits can replace more sedentary activities. The American Academy of Pediatrics recommends that screen time be restricted to no more than 2 hours/day for children >2 years old and that children <2 years old not watch television. Screen time in general, and TV watching in particular, is often associated with eating and poorer-quality diets, as many highly caloric food products are marketed directly to children during child-oriented television programs.

Pediatric healthcare providers should assist families to develop goals to change nutritional intake and PA. They can also provide the child and family with needed information. The family should not expect immediate lowering of BMI percentile related to behavioral changes, but can instead count on a gradual decrease in the rate of BMI percentile increase until it stabilizes, followed by a gradual decrease. Referral to multidisciplinary, comprehensive pediatric weight management programs is ideal for obese children whenever possible.

Pharmacotherapy for weight loss in the pediatric population is understudied. Randomized controlled trials (RCTs) have evaluated many medications, including metformin, orlistat, sibutramine, and exenatide (Table 65.7). Available medications result in modest weight loss or BMI improvement, even when combined with behavioral interventions. Various classes of drugs are of interest, including those that decrease energy intake or act centrally as **anorexiants**, those that affect the availability of nutrients through intestinal or renal tubular reabsorption, and those that affect metabolism. One U.S. Food and Drug Administration (FDA)–approved medication for obesity in children <16 years old is *orlistat,* which decreases absorption of fat, resulting in modest weight loss. Complications include flatulence, oily stools, and spotting. This agent offers little benefit to severely obese adolescents.

Saxenda *(liraglutide)* and semaglutide are also FDA approved for chronic weight management among pediatric patients aged 12 and older who are obese. Both drugs are glucagon-like peptide-1 receptor agonists, are approved for children ≥12 years old, and have been effective in reducing weight. In addition, semaglutide improves adverse cardiometabolic features associated with obesity. Adverse reactions include headache, abdominal pain, emesis, and diarrhea. Long-term therapy may increase the risk of medullary thyroid carcinoma and pancreatitis. This class of medication has produced the most significant weight loss of drug-treated obesity.

Because multiple redundant neural mechanisms act to protect body weight, promoting weight loss is extremely difficult. Thus there is considerable interest in combining therapies that simultaneously target multiple weight-regulating pathways. One promising example is the combination of *amylin analogs* (decreases food intake and slows gastric emptying) with *leptin,* which has no anorexigenic effects when given alone. This combination requires injection and is in clinical trials in adults. Another FDA-approved drug for adults is *lorcaserin,* a selective serotonin 2α receptor agonist. Some medications approved for the treatment of type 2 diabetes, such as other glucagon-like peptide-1 (GLP-1) agonists and sodium-glucose cotransporter-2 (SGLT-2) inhibitors, are being evaluated for treatment of obesity in adults. Establishing long-term safety and tolerability

Table 65.7 Medications for Weight Management with Mechanism of Action, Availability, and Dosing

MEDICATION	MECHANISM OF ACTION	AVAILABLE FOR CHRONIC USE		MEAN PERCENTAGE WEIGHT LOSS		ADVANTAGES	DISADVANTAGES
		USA	EU	PLACEBO	DRUG		
Phentermine, 15-30 mg PO	Sympathomimetic	For short-term use	No	Not stated in label	Not stated in label	Inexpensive	Side effect profile; no long-term data*
Orlistat, 120 mg PO tid before meals	Pancreatic lipase inhibitor	Yes	Yes	−2.6%†	−6.1%†	Not absorbed; long-term data*	Modest weight loss; side effect profile
Lorcaserin, 10 mg PO bid	5-HT_{2c} serotonin agonist with little affinity for other serotonergic receptors	Yes	No	−2.5%	−5.8%	Mild side effects; long-term data*	Expensive; modest weight loss
Phentermine/topiramate ER, 7.5 mg/46 mg or 15 mg/92 mg PO indicated as rescue (requires titration)	Sympathomimetic anticonvulsant (GABA receptor modulation, carbonic anhydrase inhibition, glutamate antagonism)	Yes	No	−1.2%	−7.8% (mid-dose) −9.8% (full dose)	Robust weight loss; long-term data*	Expensive; teratogen
Naltrexone SR/bupropion SR, 32 mg/360 mg PO (requires titration)	Opioid receptor antagonist; dopamine and noradrenaline reuptake inhibitor	Yes	Yes	−1.3%	−5.4%	Reduces food craving; long-term data*	Moderately expensive; side effect profile
Liraglutide, 3.0 mg injection (requires titration)	GLP-1 receptor agonist	Yes	Yes	−3%	−7.4% (full dose)	Side effect profile; long-term data*	Expensive; injectable
Semaglutide, 2.4 mg once weekly injection	GLP-1 receptor agonist	Yes	Yes	−1%	−10 to −15%	As above	As above

Information is from US product labels, except where noted. The data supporting these tables are derived from the prescribing information labeling approved by the US Food and Drug Administration.
*Data from randomized controlled trials lasting >52 wk.
†Assuming the average patient in the orlistat and placebo groups weighed 100 kg at baseline.
ER, Extended release; GLP-1, glucagon-like peptide-1; SR, sustained release; PO, orally; bid, twice daily; tid, 3 times daily.
Adapted from Bray GA, Frühbeck G, Ryan DH, Wilding JPH. Management of obesity. *Lancet*. 2016;387:1947–1965, p. 1950.

in children is a challenge because medications of interest have CNS effects or interfere with absorption of nutrients. Teratologic effects must be considered for use in adolescent females. *Setmelanotide*, which binds to and activates *MC4R*, is approved to treat proopiomelanocortin deficiency, leptic receptor deficiency, and proprotein subtilisin/kexin type 1 disorder. **Hormone replacement therapy** is available for patients with leptin deficiency and may become available for patients with POMC deficiency.

In some cases, it is reasonable to refer adolescents for **bariatric surgery** evaluation. The American Pediatric Surgical Association guidelines recommend that surgery be considered only in children with complete or near-complete skeletal maturity, a BMI ≥40, and a medical complication resulting from obesity, *after* they have failed 6 months of a multidisciplinary weight management program. Surgical approaches include the Roux-en-Y and the adjustable gastric band (Fig. 65.6). Endoscopically placed space-occupying fluid or air-filled gastric balloons(s) is approved for adults and may be a nonsurgical intervention. In obese adults, bariatric surgery reduces the risk of developing type 2 diabetes mellitus. In obese adult patients with existing type 2 diabetes, bariatric surgery improves diabetic control. Nutritional complications of bariatric surgery include malabsorption and vitamin (A, B_1, B_2, B_6, B_{12}, D, E, K) and mineral (copper, iron) deficiencies that require supplementation.

PREVENTION

Prevention of child and adolescent obesity is essential for public health in the United States and most other countries (Tables 65.8 and 65.9). Efforts by pediatric providers can supplement national and community public health programs. The National Institutes of Health (NIH) and U.S. Centers for Disease Control and Prevention (CDC) recommend a variety of initiatives to combat the current obesogenic environment, including promotion of breastfeeding, access to fruits and vegetables, walkable communities, and 60 minutes/day of activity for children. The U.S. Department of Agriculture (USDA) sponsors programs promoting 5.5 cups of fruits and vegetables per day. Incentives for the food industry to promote consumption of healthier foods should be considered. Marketing of unhealthy foods to children is now being regulated. Changes in federal food programs are expected, including commodity foods, the Women, Infant, and Children Supplemental Food Program (WIC), and school lunch programs, to meet the needs of today's children.

Pediatric prevention efforts begin with careful monitoring of weight and BMI percentiles at healthcare maintenance visits. Attention to changes in BMI percentiles can alert the pediatric provider to increasing adiposity before the child becomes overweight or obese. All families should be counseled about healthy nutrition for their children, because the current prevalence of overweight and obesity in adults is 65%. Therefore approximately two thirds of all children can be considered at risk for becoming overweight or obese at some time in their lives. Those who have an obese parent are at increased risk. Prevention efforts begin with promotion of *exclusive breastfeeding for 6 months* and total breastfeeding for 12 months. Introduction of infant foods at 6 months should focus on cereals, fruits, and vegetables. Lean meats, poultry, and fish may be introduced later in the first year of life. Parents should be specifically counseled to *avoid introducing highly sugared beverages and foods in the first*

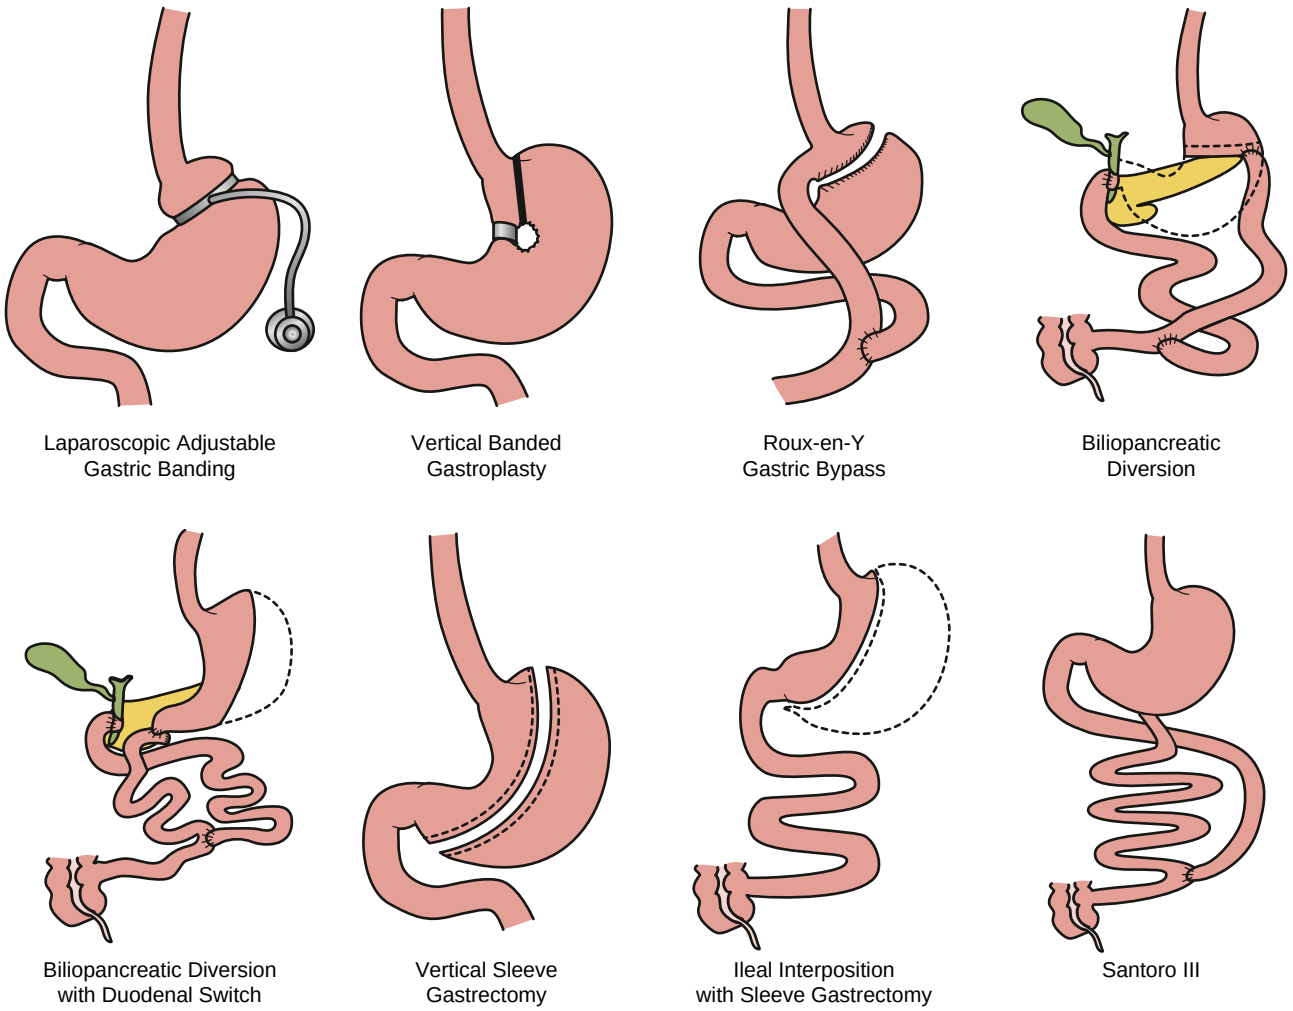

Fig. 65.6 Bariatric surgical procedures, including laparoscopic adjustable gastric banding, Roux-en-Y gastric bypass, and vertical sleeve gastrectomy techniques.

year of life. Instead, they should expose their infants and young children to a rich variety of fruits, vegetables, grains, lean meats, poultry, and fish to facilitate acceptance of a diverse and healthy diet. Parenting matters, and authoritative parents are more likely to have children with a healthy weight than those who are authoritarian or permissive. Families who eat regularly scheduled meals together are less likely to have overweight or obese children. Child health professionals can address a child's nutritional status and provide expertise in child growth and development.

Child health professionals can also *promote PA* during regular healthcare maintenance visits. Parents who spend some of their leisure time in PA promote healthy weight in their children. Beginning in infancy, parents should be cognizant of their child's developmental capability and need for PA. Because TV, computer, and video game time can replace health-promoting PA, physicians should counsel parents to limit screen time for their children. Snacking during TV watching should be discouraged. Parents can help their children to understand that television commercials intend to sell a product. Children can learn that their parents will help them by responsibly choosing healthy foods.

Because obesity is determined by complex multifactorial conditions, prevention will take efforts at multiple levels of social organization. Successful programs include **EPODE** (Ensemble Prévenons l'Obésité Des Enfants), a multilevel prevention strategy that began in France and has been adopted by more than 500 communities in 6 countries. **Shape Up Somerville** is a citywide campaign to increase daily PA and healthy eating in Somerville, Massachusetts, since 2002. The **"Let's Move"** campaign was championed by former First Lady Michelle Obama. Because community and environmental factors are related to pediatric obesity risk, changes in local environments, daycare centers, schools, and recreational settings can have a public health impact. Programs can empower families to adopt practices that promote healthy lifestyles for children and adolescents. The most successful programs are comprehensive and rely on four strategies: political commitment to change, resources to support social

Table 65.8 Proposed Suggestions for Preventing Obesity

PREGNANCY
- Normalize body mass index (BMI) before pregnancy.
- Do not smoke.
- Maintain moderate exercise as tolerated.
- In women with gestational diabetes, provide meticulous glucose control.
- Monitor gestational weight gain within Institute of Medicine (IOM) recommendations.

POSTPARTUM AND INFANCY
- Breastfeeding: exclusive for 4-6 mo; continue with other foods for 12 mo.
- Postpone introduction of baby foods to 4-6 mo and juices to 12 mo.

FAMILIES
- Eat meals as a family in a fixed place and time.
- Do not skip meals, especially breakfast.
- Do not allow television during meals.
- Use small plates and keep serving dishes away from the table.
- Avoid unnecessary sweet or fatty foods and sugar-sweetened drinks.
- Remove televisions from children's bedrooms; restrict times for TV viewing and video games.
- Do not use food as a reward.

SCHOOLS
- Eliminate candy and cookie sales as fundraisers.
- Review the contents of vending machines and replace with healthier choices; eliminate sodas.
- Avoid financial support for sports teams from beverage and food industries.
- Install water fountains and hydration stations.
- Educate teachers, especially physical education and science faculty, about basic nutrition and the benefits of physical activity (PA).
- Educate children from preschool through high school on appropriate diet and lifestyle.
- Mandate minimum standards for physical education, including 60 min of strenuous exercise 5 times weekly.
- Encourage "the walking school bus": groups of children walking to school with adult supervision.

COMMUNITIES
- Increase family-friendly exercise and safe play facilities for children of all ages.
- Develop more mixed residential-commercial developments for walkable and bicyclable communities.
- Discourage the use of elevators and moving walkways.
- Provide information on how to shop and prepare healthier versions of culture-specific foods.

HEALTHCARE PROVIDERS
- Explain the biologic and genetic contributions to obesity.
- Give age-appropriate expectations for body weight in children.
- Work toward classifying obesity as a disease to promote recognition, reimbursement for care, and willingness and ability to provide treatment.

INDUSTRY
- Mandate age-appropriate nutrition labeling for products aimed at children (e.g., "red light/green light" foods, with portion sizes).
- Encourage marketing of interactive video games in which children must exercise to play.
- Use celebrity advertising directed at children for healthful foods to promote breakfast and regular meals.
- Reduce portion size (drinks and meals).

GOVERNMENT AND REGULATORY AGENCIES
- Classify childhood obesity as a legitimate disease.
- Find novel ways to fund healthy lifestyle programs (e.g., with revenues from food and drink taxes).
- Subsidize government-sponsored programs to promote the consumption of fresh fruits and vegetables.
- Provide financial incentives to the industry to develop more healthful products and to educate the consumer on product content.
- Provide financial incentives to schools that initiate innovative PA and nutrition programs.
- Allow tax deductions for the cost of weight loss and exercise programs.
- Provide urban planners with funding to establish bicycle, jogging, and walking paths.
- Ban advertising of fast foods, non-nutritious foods, and sugar-sweetened beverages directed at preschool children, and restrict advertising to school-aged children.
- Ban toys as gifts to children for purchasing fast foods.

Adapted from Speiser PW, Rudolf MCJ, Anhalt H, et al. Consensus statement: Childhood obesity. *J Clin Endocrinol Metab*. 2005;90:1871–1887.

Table 65.9 Anticipatory Guidance: Establishing Healthy Eating Habits in Children

- Do not punish a child during mealtimes with regard to eating. The emotional atmosphere of a meal is very important. Interactions during meals should be pleasant and happy.
- Do not use foods as rewards.
- Parents, siblings, and peers should model healthy eating, tasting new foods, and eating a well-balanced meal.
- Children should be exposed to a wide range of foods, tastes, and textures.
- New foods should be offered multiple times. Repeated exposure leads to acceptance and liking.
- Forcing a child to eat a certain food will decrease the child's preference for that food. Children's wariness of new foods is normal and should be expected. Offering a variety of foods with low-energy density helps children balance energy intake.
- Parents should control what foods are in the home. Restricting access to foods in the home will increase rather than decrease a child's desire for that food.
- Children tend to be more aware of satiety than adults, so allow children to respond to satiety and stop eating. Do not force children to "clean their plate."

Adapted from Benton D. Role of parents in the determination of food preferences of children and the development of obesity. *Int J Obes Relat Metab Disord*. 2004;28:858–869.

marketing and changes, support services, and evidence-based practices. Community-wide programs are important because neighborhood environmental factors (e.g., poverty) have been associated with obesity in its residents. There is considerable interest in focusing these efforts early in the life cycle. Beginning obesity prevention during pregnancy and engaging health systems, early childhood programs, and community systems to support healthier life cycles is an approach with great promise.

Chapter 66

Vitamin A Deficiencies and Excess

Libo Tan and A. Catharine Ross

OVERVIEW OF VITAMIN A

Vitamin A is a fat-soluble micronutrient that cannot be synthesized de novo by mammals; thus it is an obligatory dietary factor. The term **vitamin A** is generally used to refer to a group of compounds that possess the biologic activity of all-*trans* retinol (Fig. 66.1). Vitamin A is recognized as being essential for all vertebrates for normal vision, reproduction, cell and tissue differentiation, and immune system functions. Vitamin A plays critical roles in neonatal development. It is required for normal embryonic development, hematopoiesis, and growth and differentiation of many types of cells.

Vitamin A can be obtained from the diet from preformed vitamin A (retinyl esters, such as retinyl palmitate) primarily in foods of animal origin. Organ meats (especially liver and kidney) are very rich in vitamin A, whereas other meats, milk, and cheese contain moderate levels. Other sources of vitamin A include several provitamin A carotenoids, which are found naturally in many fruits and vegetables, especially yellow-orange vegetables (pumpkin, squash, sweet potato) and leafy green vegetables (chard, spinach, broccoli). One of the most abundant carotenoids is β-carotene. Several *cultivars,* or biofortified forms, of sweet potatoes have been introduced to elevate carotene intake in areas of the world where vitamin A deficiency still is prevalent. α-carotene and oxygenated carotenoids, such as β-cryptoxanthin, found in oranges, also possess vitamin A activity, but at a lower bioactivity. In the body, these precursors are used for the synthesis of two essential metabolites of vitamin A. **All-*trans* retinoic acid** is the form required for cell differentiation and regulation of gene transcription and is the most bioactive form of vitamin A; **11-*cis* retinal** is the form required for vision as the light-absorbing chromophore of the visual pigments rhodopsin and iodopsin.

METABOLISM OF VITAMIN A

Vitamin A compounds in foods must first be released through normal digestive processes. Retinyl esters must first be hydrolyzed in the intestinal lumen to liberate unesterified retinol for absorption across the mucosal barrier. Once in the enterocyte, most of the retinol is reesterified, forming new retinyl esters for inclusion in chylomicrons. Approximately 70–90% of dietary preformed vitamin A is absorbed provided there is approximately 10 g of fat in the meal; otherwise, the absorption efficiency is lower. Chronic intestinal disorders or lipid malabsorption can result in vitamin A deficiency. Provitamin-A carotenoids are transported from the intestinal lumen into the enterocytes by specific transporters and then either incorporated intact into chylomicrons or cleaved to form *retinal,* a precursor for retinol; β-carotene becomes retinol through this process. The estimated efficiency of absorption of carotenoids is 20–50%, lower than for preformed vitamin A. Moreover, the efficiency is reduced when the body's vitamin A status is high, and because vitamin A status may vary, there is significant interindividual variability in absorption efficiency. The carotene cleavage enzyme β-carotene monooxygenase, present in the enterocyte and in other tissues at lower levels, exhibits certain single nucleotide polymorphisms (SNPs) that, at least in vitro, reduce the efficiency of conversion of β-carotene to retinol. Clinical studies suggest a similar effect in vivo.

Once retinol is esterified in the enterocyte, retinyl ester is then packaged into nascent chylomicrons, which are secreted into the lymphatic vessels, enter the systemic circulation, and are then transported to and taken up by various tissues. When vitamin A status is adequate, in most mammals, including humans, the liver

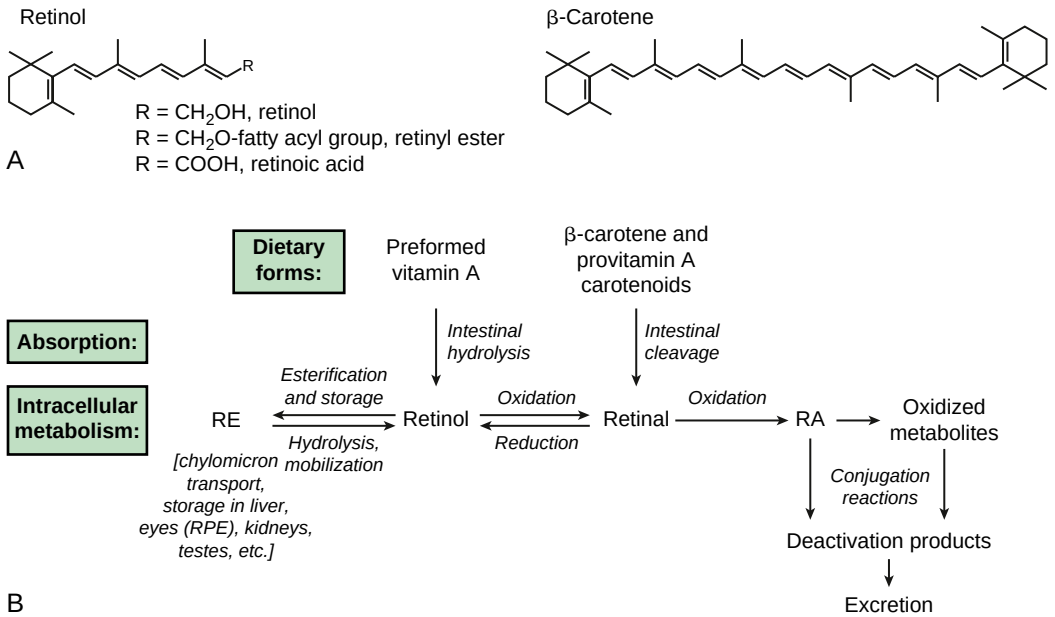

Fig. 66.1 A, Vitamin A structures. B, Overview of vitamin A metabolism. RA, All-*trans* retinoic acid; RE, retinyl ester; RPE, retinal pigment epithelium.

is the major site of chylomicron vitamin A uptake and storage, with potentially high levels of retinyl esters within hepatic stellate cells (HSCs). As vitamin A status deteriorates into the deficient range, vitamin A stores are mobilized from the HSCs, such that the released retinol can be taken up and used by extrahepatic tissues. Circulating retinol is bound to a specific transport protein, retinol-binding protein (RBP), which in turn binds to the thyroid hormone transport protein, transthyretin (TTR); this complex delivers plasma retinol (and the thyroid hormone) to a large number of vitamin A target tissues. The major physiologic mediator of retinol uptake by cells in many tissues is Stra6, a widely expressed multitransmembrane domain protein that functions as a cell surface receptor for retinol bound to RBP. Stra6 is not significantly expressed in the liver, but a homologous receptor may perform the similar function. Within target tissues, retinol is either esterified into retinyl esters for storage or oxidized into retinoic acid for function. In the eye, 11-*cis*-retinal is formed and bound to the protein rhodopsin (rods) or iodopsin (cones), where it functions as a light-sensing receptor.

Inflammation Causing Low Plasma Retinol

Inflammation is a cause of reduced levels of plasma retinol as a result of reduced synthesis of RBP and TTR. This condition may mimic a lack of vitamin A, but will not be corrected by supplementation. In U.S. adults, those with moderately elevated levels of CRP, indicative of mild inflammation, had lower average plasma retinol levels. The extent to which inflammation is a factor in low plasma retinol in children is uncertain but likely significant in acute infectious diseases such as measles, and possibly in chronic inflammatory conditions such as cystic fibrosis.

FUNCTIONS OF VITAMIN A AND MECHANISMS OF ACTION

Except for its role in vision, the pleiotropic actions of this micronutrient are mediated by all-*trans*-retinoic acid (RA), which is a ligand for specific nuclear transcription factors, **retinoic acid receptor (RAR)** and **retinoid X receptor (RXR)**, that regulate the expression of several hundred genes. When an RAR is activated by RA, an RAR-RXR complex is formed, which binds to and activates specific DNA sequences present in retinoid-responsive genes, RAREs and RXREs. Genes can be either induced or repressed, depending on additional co-activators or co-repressors recruited to the RAR-RXR complex. Retinoid-regulated genes are involved in several fundamental biologic activities, including regulation of cell division, death, and differentiation. The term *retinoids* is now applied to both natural and synthetic compounds with vitamin A activity, although it is most often used in the context of vitamin A and RA acting at the gene level. Numerous synthetic retinoids have gained clinical acceptance in the treatment of skin disorders and certain cancers.

During embryonic development, RA is among the most important signaling molecules that determine body patterning (morphogenesis). Many physiologic processes are sensitive to a deficiency or excess of vitamin A or RA, including reproduction, growth, bone development, and the functions of the respiratory, gastrointestinal, hematopoietic, and immune systems. Vitamin A supplementation may be particularly important in developing countries, where it reduces morbidity and mortality, presumably by enhancing immune function and host defense, from various infectious diseases, including measles (see Chapter 293).

Vitamin A plays a critical role in vision, mediated by 11-*cis* retinal. The human retina contains two distinct photoreceptor systems: the *rods,* in which rhodopsin senses light of low-intensity, and the *cones,* in which iodopsins detect different colors; 11-*cis*-retinal is the prosthetic group on both these visual proteins. The mechanism of vitamin A action is similar for rods and cones, based on *photoisomerization* of 11-*cis* to all-*trans* retinal (change shape when exposed to light), which initiates signal transduction via the optic nerve to the brain, resulting in visual sensation. After isomerization (also known as *photobleaching*), a series of reactions serves to regenerate the 11-*cis* retinal for resynthesis of rhodopsin and iodopsin, as is necessary for an efficient visual process. Accessory cells, including retinal pigment epithelium (RPE) cells and Müller cells, are involved in this recycling process.

VITAMIN A DEFICIENCY

If the growing child has a well-balanced diet and obtains vitamin A from foods rich in vitamin A or provitamin A (Table 66.1), the risk of vitamin A deficiency is small. However, even subclinical vitamin A deficiency can have serious consequences.

Deficiency states in developed countries are rare, except in some impoverished populations (see Chapter 62) or after mistakes in food preparation or with fad diets or restrictive/elimination diets, but are common in many developing countries and often associated with global malnutrition. In the clinical setting, vitamin deficiencies can also occur as complications in children with various chronic disorders or diseases. Information obtained in the medical history related to dietary habits can be important in identifying the risk of such nutritional problems. Except for vitamin A, toxicity from excess intake of vitamins is rare. Table 66.1 summarizes the food sources, functions, and deficiency and excess symptoms of the vitamin.

Vitamin A Status in Neonates

Neonates begin life with low levels of vitamin A in plasma, liver, and extrahepatic tissues compared with those in adults. Normal plasma levels of retinol are 20-50 μg/dL in infants and increase gradually as children become older. Median serum retinol values are 1.19 μmol/L in both males and females ages 4-8 years; 1.4 and 1.33 μmol/L in males and females, respectively, ages 9-13; and 1.71 and 1.57 μmol/L in males and females, ages 14-18 (for conversion, 1 μmol/L = 28.6 μg/dL). Values of 1.96 and 1.85 μmol/L are found in 19- to 30-year-old adult men and women, respectively. Figure 66.2 shows the distribution of serum retinol concentrations in U.S. children. Few healthy children are severely vitamin A deficient, but the 5th percentile of children 4-8 years and 9-13 years of age, respectively, in the National Health and Examination Survey (NHANES) fell below 1.05 μmol/L, which is interpreted as mild vitamin A deficiency.

Retinol levels are even lower in neonates in developing countries, where vitamin A intakes may be low and vitamin A deficiency is a common nutritional problem. Lower vitamin A stores and plasma retinol concentrations are also seen in low birthweight infants and in preterm newborns, and poor vitamin A status (plasma retinol concentrations <0.35 μmol/L) may contribute to the development of chronic lung disease, such as bronchopulmonary dysplasia (BPD; see Chapter 127).

Clinical Manifestations of Vitamin A Deficiency

The most obvious symptoms of vitamin A deficiency are associated with changes in epithelial cell morphology and functions. In the intestines, mucus-secreting goblet cells are affected, and loss of an effective barrier against pathogens can cause diarrhea or impairment of epithelial barrier function. Similarly, mucus secretion by the epithelium is essential in the respiratory tract for the disposal of inhaled pathogens and toxicants. Characteristic epithelial changes result from vitamin A deficiency, including proliferation of basal cells, hyperkeratosis, and formation of stratified cornified squamous epithelium. Squamous metaplasia of the renal pelvis, ureters, vaginal epithelium, and the pancreatic and salivary ducts can lead to increased infections in these areas. In the urinary bladder,

Table 66.1 Vitamin A Characteristics

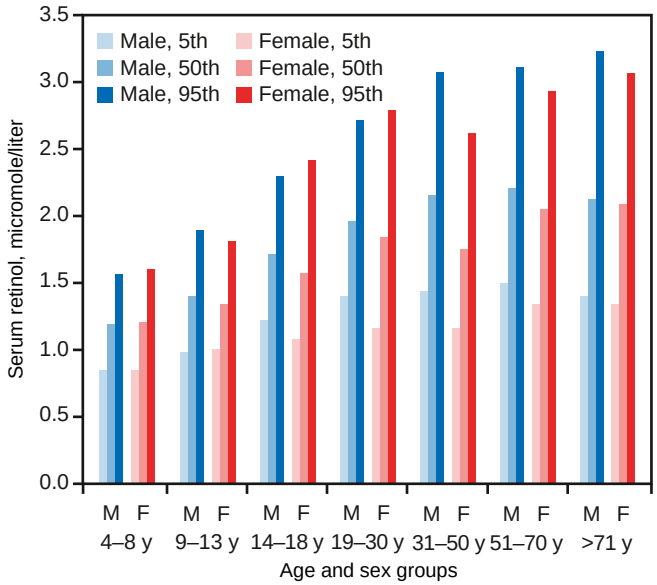

Fig. 66.2 Distribution of serum retinol concentrations in U.S. children and adults by age and sex in the National Health and Nutrition Examination Survey (NHANES).

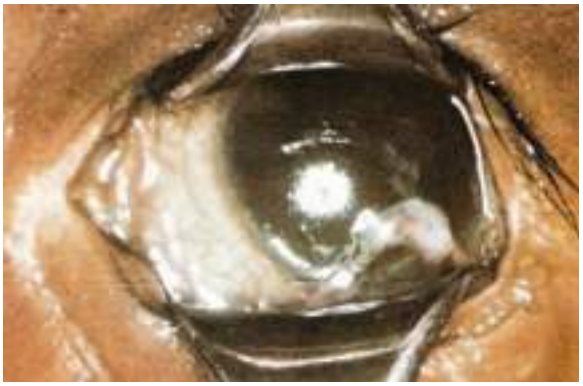

Fig. 66.3 Advanced xerophthalmia with an opaque, dull cornea and some damage to the iris in a 1-yr-old boy. *(From Oomen HAPC. Vitamin A deficiency, xerophthalmia and blindness. Nutr Rev. 1974;6:161–166.)*

loss of epithelial integrity can result in pyuria and hematuria. In the skin, vitamin A deficiency manifests as dry, scaly, hyperkeratotic patches, typically on the arms, legs, shoulders, and buttocks. The combination of defective epithelial barriers to infection, low immune response, and lowered response to inflammatory stress, all from insufficient vitamin A, can cause poor growth and serious health problems in children.

The most characteristic and specific signs of vitamin A deficiency are *eye lesions,* but these may manifest rather late in the progression of vitamin A deficiency, develop insidiously, and rarely occur before age 2 years. An earlier symptom of vitamin A deficiency is delayed dark adaptation as a result of reduced resynthesis of rhodopsin; this may progress to **night blindness**. Photophobia is a common symptom. The RPE, one of the structural elements of the retina, undergoes keratinization. When the RPE degenerates, the rods and cones have no support and eventually break down, resulting in blindness.

As vitamin A deficiency progresses, the corneal and conjunctival epithelial tissues of the eye become severely altered because of a lack of sufficient RA for normal epithelial cell differentiation. The cornea protects the eye from the environment and is also important in light refraction. Stages in vitamin A deficiency include corneal keratinization and opacity, susceptibility to infection, and formation of dry, scaly layers of cells (**xerophthalmia**) (Figs. 66.3 and 66.4). The conjunctival membrane undergoes keratinization and may develop foamy-appearing plaques (**Bitôt spots**; Fig. 66.5). When lymphocytes infiltrate the cornea in later stages of infection, it degenerates irreversibly (**keratomalacia** and **corneal ulceration**), resulting in irreversible blindness. These eye lesions are primarily diseases of

the young and are a major cause of blindness in developing countries. Although rates of xerophthalmia have fallen, the number of affected children is still too high. Treatment with vitamin A, up to the stage of keratomalacia, is effective in rapidly repleting the individual and saving vision.

Other clinical signs of vitamin A deficiency include poor overall growth, diarrhea, susceptibility to infections, anemia, apathy, intellectual impairment, and increased intracranial pressure, with wide separation of the cranial bones at the sutures. There may be vision problems as a consequence of bone overgrowth causing pressure on the optic nerve.

Malnutrition, particularly protein deficiency, can cause vitamin A deficiency through impaired synthesis of retinol transport protein. In developing countries, subclinical or clinical zinc deficiency can increase the risk of vitamin A deficiency. There is also some evidence of marginal zinc intakes in U.S. children.

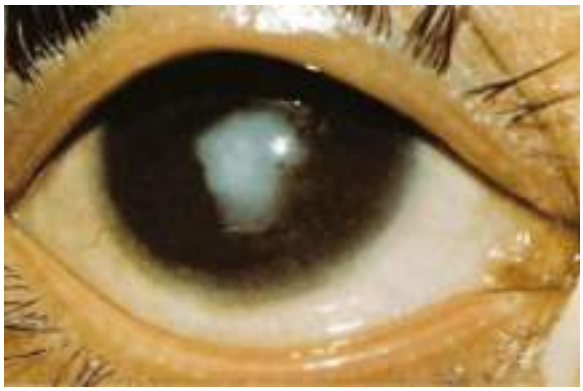

Fig. 66.4 Recovery from xerophthalmia, showing a permanent eye lesion. *(From Bloch CE. Blindness and other disease arising from deficient nutrition [lack of fat soluble A factor]. Am J Dis Child. 1924;27:139.)*

Fig. 66.5 Bitôt spots with hyperpigmentation seen in a 10-mo-old Indonesian boy. *(From Oomen HAPC. Vitamin A deficiency, xerophthalmia and blindness. Nutr Rev 1974;6:161–166.)*

Diagnosis

Dark adaptation tests can be used to assess early-stage vitamin A deficiency. Although Bitôt spots develop relatively early, those related to active vitamin A deficiency are usually confined to preschool-age children. Xerophthalmia is a very characteristic lesion of vitamin A deficiency. For detection of less severe deficiency (marginal vitamin A status), methods include conjunctival impression cytology, relative dose response, and modified relative dose response tests. A diet history is useful in suggesting or ruling out low intake as a cause of symptoms. Marginal vitamin A status is relatively prevalent among pregnant and lactating women in low-resource (and therefore poor dietary intake) areas of the world. Although plasma retinol level is not a completely accurate indicator of vitamin A status, various guidelines have been proposed for categorizing vitamin A status based on serum retinol. In children, plasma retinol <0.35 μmol/L is considered *very deficient,* 0.35-0.7 μmol/L *deficient,* 0.7-1.05 μmol/L *marginal,* and >1.05 μmol/L *adequate.* It has long been thought that a liver vitamin A concentration >20 μg/g is needed to support a normal rate of secretion of retinol-RBP into plasma, and therefore normal delivery of retinol to peripheral tissues.

Epidemiology and Public Health Issues

Vitamin A deficiency and xerophthalmia still occur throughout much of the developing, income-poor world and are linked to undernourishment and complicated by illness. Various public health programs to provide large doses of vitamin A periodically have been instituted. Vitamin A supplementation is considered part of the strategy of the World Health Organization (WHO) Millennium Development Goals to reduce <5 year mortality. Neonatal supplementation may be most effective in populations with a high incidence of maternal vitamin A deficiency. Other strategies being tested include improving the content of β-carotene in staple foods through plant breeding (biofortification).

Dietary Reference Intakes for the Healthy Population

Table 66.2 summarizes the dietary reference intakes for infants and children. Dietary reference intake values include the estimated average requirement (EAR), which is the mean biologic requirement for the nutrient for the age/sex-group of interest; the recommended dietary allowance (RDA), which is set to cover the physiologic needs of >97% of the population (thus the needs of many people are more than met by consuming the RDA); and the upper level

Table 66.2 Dietary Reference Intakes for Vitamin A in Children

AGE RANGE	RECOMMENDED DIETARY ALLOWANCE (RDA)*	UPPER LEVEL (UL)*	COMMENTS
0-6 mo	400	600	The recommended intake for infants is an adequate intake, based on the amount of vitamin A normally present in breast milk.
7-12 mo	500	600	
1-3 yr	300	600	The UL applies only to preformed vitamin A (retinol).
4-8 yr	400	900	
9-13 yr	600	1,700	
14-18 yr	900, male; 700, female	2,800	

*μg retinol equivalents per day.

of normal (UL), an intake level above which risk of adverse effects may increase; the UL pertains only to chronic consumption of preformed vitamin A. The RDA is expressed as retinol activity equivalents (RAEs; 1 RAE = 1 μg all-*trans* retinol; equivalents for provitamin-A in foods = 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin). From infancy to age 18 years, the RDA increases as a result of increased body size, becoming higher for males than for females during adolescence. During pregnancy the RDA is 750-770 μg, and during lactation it increases to 1,200-1,300 μg to ensure sufficient vitamin A content during breastfeeding.

It is noteworthy that, especially for young children, the UL is only about two times higher than the RDA. This suggests that for children whose diet is good, care should be taken not to overuse dietary supplements (vitamin-mineral supplements) containing preformed vitamin A and/or to avoid excessive consumption of foods that are very rich in vitamin A, such as liver.

Vitamin A for Treatment of Deficiency

A daily supplement of 1,500 μg of vitamin A is sufficient for treating latent vitamin A deficiency, after which intake at the RDA level should be the goal. In children without overt signs of vitamin A deficiency but suspected low reserves of vitamin A, rates of morbidity and mortality, as from viral infections such as measles, have been reduced by a weekly dose of vitamin A at the RDA level. More often, higher doses of 30-60 mg of retinol (100,000-200,000 IU/child) are given once or twice, under careful monitoring to avoid toxicity associated with excess vitamin A. Xerophthalmia is treated by giving 1,500 μg/kg body weight orally for 5 days, followed by intramuscular injection of 7,500 μg of vitamin A in oil, until recovery.

HYPERVITAMINOSIS A

Chronic hypervitaminosis A results from excessive ingestion of preformed vitamin A (retinol or retinyl ester), generally for several weeks or months. Hypervitaminosis A is most often caused by vitamin A–containing supplements or food faddism, including high intakes of organ meats. Chronic daily intakes of 15,000 μg and 6,000 μg can be toxic in adults and children, respectively. Because there is no antidote for hypervitaminosis A, and vitamin A is readily stored in liver and other tissues, it is most important to prevent toxicity. Symptoms may subside rapidly on withdrawal of the vitamin, but the rate of improvement depends on the amount of vitamin A stored in tissues. Extreme hypervitaminosis A is fatal. Signs of subacute or chronic toxicity can include headache; vomiting (early signs); anorexia; dry, itchy, desquamating skin; and seborrheic cutaneous lesions. With chronic hypervitaminosis A, one may observe fissuring at the corners of the mouth; alopecia and coarsening of the hair; bone abnormalities, including swelling and resorption; enlargement of the liver and spleen; diplopia; increased intracranial pressure; dryness of the mucous membranes; and desquamation of the palms and the soles of the feet. Radiographs may show *hyperostosis* affecting several long bones, especially in the middle of the shafts (Fig. 66.6). Manifestations of hypervitaminosis A may also include nonspecific changes in affect, including severe headache, irritability, stupor, and limited motion. Serum levels of vitamin A are elevated, mostly in the form of retinyl esters carried in lipoproteins, which may result in tissue damage and release of liver enzymes into plasma. Hypercalcemia and/or liver cirrhosis may be present. Hypervitaminosis A is distinct from cortical hyperostosis (see Chapter 741).

In young children, signs of vitamin A toxicity include vomiting and bulging fontanels, neither of which is specific. Combined with anorexia, pruritus, and a lack of weight gain, vitamin A toxicity should be considered. Less common symptoms include diplopia, papilledema, cranial nerve palsies, and other symptoms suggesting **pseudotumor cerebri**.

Fig. 66.6 Hyperostosis of the ulna and tibia in 21-mo-old infant, resulting from vitamin A positioning. **A,** Long, wavy cortical hyperostosis of the ulna *(arrow)*. **B,** Long, wavy cortical hyperostosis of the right tibia *(arrow)*, with a striking absence of metaphyseal changes. *(From Caffey J. Pediatric X-Ray Diagnosis, 5th ed. Chicago: Year Book;1967: 994.)*

If high levels of vitamin A or synthetic retinoids are taken early in pregnancy, **severe congenital malformations** may occur in the fetus. **Teratogenicity** has been associated with therapeutic doses (0.5-1.5 mg/kg) of oral 13-*cis*-retinoic acid (e.g., Accutane), generally taken for the treatment of acne or cancer, during the first trimester of pregnancy. A high incidence (>20%) of spontaneous abortions and birth defects, including characteristic craniofacial abnormalities, has prompted the U.S. Food and Drug Administration (FDA) to enact more stringent prescription regulations for such drugs in women of childbearing age to attempt to reduce these birth defects.

Carotenoids, even in high doses, *are not* associated with toxicity but can cause yellowing of the skin (**carotenodermia**), including palms of the hands, and high levels in serum (carotenemia); this relatively benign state disappears slowly when carotene intake is reduced. Children with liver disease, diabetes mellitus, or hypothyroidism are more susceptible. Food faddism, such as excessive consumption of carotene-rich foods and juices, may be a cause of carotenodermia.

Chapter 67

Vitamin B Complex Deficiencies and Excess

H.P.S. Sachdev and Dheeraj Shah

Vitamin B complex includes a number of water-soluble nutrients, including thiamine (vitamin B1), riboflavin (B2), niacin (B3), pyridoxine (B6), folate (B9), cobalamin (B12), biotin (B7), and pantothenic acid (B5). *Choline* and *inositol* are also considered parts of the B complex and are important for normal body functions, but specific deficiency syndromes have not been attributed to a lack of these factors in the diet (Table 67.1).

B-complex vitamins serve as coenzymes in many metabolic pathways that are functionally closely related. Consequently, a lack of one of the vitamins has the potential to interrupt a chain of chemical processes, including reactions that are dependent on other vitamins, and ultimately can produce diverse clinical manifestations. Because diets deficient in any one of the B-complex vitamins are often poor sources of other B vitamins, manifestations of several vitamin B deficiencies usually can be observed in the same person. *It is therefore a general practice in a patient who has evidence of deficiency of a specific B vitamin to treat with the entire B-complex group of vitamins.*

Table 67.1 Water-Soluble Vitamins

NAMES AND SYNONYMS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	TREATMENT OF DEFICIENCY	CAUSES OF DEFICIENCY	DIETARY SOURCES	DIETARY REFERENCE INTAKES BY AGE	
						RDA*	EAR**
Thiamine (vitamin B1)	Coenzyme in carbohydrate metabolism Nucleic acid synthesis Neurotransmitter synthesis	Neurologic (dry beriberi): irritability, peripheral neuritis, muscle tenderness, ataxia Cardiac (wet beriberi): tachycardia, edema, cardiomegaly, cardiac failure	3-5 mg/day PO thiamine for 6 wk	Polished rice–based diets Malabsorptive states Severe malnutrition Malignancies Alcoholism	Meat, especially pork; fish; liver Rice (unmilled), wheat germ; enriched cereals; legumes	0-6 mo: 0.2 mg/day 7-12 mo: 0.3 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 0.9 mg/day 14-18 yr: Females: 1.0 mg/day Males: 1.2 mg/day	1-3 yr: 0.4 mg/day 4-8 yr: 0.5 mg/day 9-13 yr: 0.7 mg/day 14-18 yr: Females: 0.9 mg/day Males: 1.0 mg/day
Riboflavin (vitamin B2)	Constituent of flavoprotein enzymes important in redox reactions: amino acid, fatty acid, and carbohydrate metabolism and cellular respiration	Glossitis, photophobia, lacrimation, corneal vascularization, poor growth, cheilosis	3-10 mg/day PO riboflavin	Severe malnutrition Malabsorptive states Prolonged treatment with phenothiazines, probenecid, or OCPs	Milk, milk products, eggs, fortified cereals, green vegetables	0-6 mo: 0.3 mg/day 7-12 mo: 0.4 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 0.9 mg/day 14-18 yr: Females: 1.0 mg/day Males: 1.3 mg/day	1-3 yr: 0.4 mg/day 4-8 yr: 0.5 mg/day 9-13 yr: 0.8 mg/day 14-18 yr: Females: 0.9 mg/day Males: 1.1 mg/day
Niacin (vitamin B3)	Constituent of NAD and NADP, important in respiratory chain, fatty acid synthesis, cell differentiation, and DNA processing	Pellagra manifesting as diarrhea, symmetric scaly dermatitis in sun-exposed areas, and neurologic symptoms of disorientation and delirium	50-300 mg/day PO niacin	Predominantly maize-based diets Anorexia nervosa Carcinoid syndrome	Meat, fish, poultry Cereals, legumes, green vegetables	0-6 mo: 2 mg/day 7-12 mo: 4 mg/day 1-3 yr: 6 mg/day 4-8 yr: 8 mg/day 9-13 yr: 12 mg/day 14-18 yr: Females: 14 mg/day Males: 16 mg/day	1-3 yr: 5 mg/day 4-8 yr: 6 mg/day 9-13 yr: 9 mg/day 14-18 yr: Females: 11 mg/day Males: 12 mg/day
Pyridoxine (vitamin B6)	Constituent of coenzymes for amino acid and glycogen metabolism, heme synthesis, steroid action, neurotransmitter synthesis	Irritability, convulsions, hypochromic anemia Failure to thrive Oxaluria	5-25 mg/day PO for deficiency states 100 mg IM or IV for pyridoxine-dependent seizures	Prolonged treatment with INH, penicillamine, OCPs	Fortified ready-to-eat cereals, meat, fish, poultry, liver, bananas, rice, potatoes	0-6 mo: 0.1 mg/day 7-12 mo: 0.3 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 1.0 mg/day 14-18 yr: Females: 1.2 mg/day Males: 1.3 mg/day	1-3 yr: 0.4 mg/day 4-8 yr: 0.5 mg/day 9-13 yr: 0.8 mg/day 14-18 yr: Females: 1.0 mg/day Males: 1.1 mg/day

Table 67.1 Water-Soluble Vitamins—cont'd

NAMES AND SYNONYMS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	TREATMENT OF DEFICIENCY	CAUSES OF DEFICIENCY	DIETARY SOURCES	DIETARY REFERENCE INTAKES BY AGE	
						RDA*	EAR**
Biotin (vitamin B7)	Cofactor for carboxylases, important in gluconeogenesis, fatty acid and amino acid metabolism	Scaly periorificial dermatitis, conjunctivitis, alopecia, lethargy, hypotonia, and withdrawn behavior	1-10 mg/day PO biotin	Consumption of raw eggs for prolonged periods Parenteral nutrition with infusates lacking biotin Valproate therapy	Liver, organ meats, fruits	0-6 mo: 5 µg/day 7-12 mo: 6 µg/day 1-3 yr: 8 µg/day 4-8 yr: 12 µg/day 9-13 yr: 20 µg/day 14-18 yr: 25 µg/day	Not established
Pantothenic acid (vitamin B5)	Component of coenzyme A and acyl carrier protein involved in fatty acid metabolism	Experimentally produced deficiency in humans: irritability, fatigue, numbness, paresthesias (burning feet syndrome), muscle cramps		Isolated deficiency extremely rare in humans	Beef, organ meats, poultry, seafood, egg yolk Yeast, soybeans, mushrooms	0-6 mo: 1.7 mg/day 7-12 mo: 1.8 mg/day 1-3 yr: 2 mg/day 4-8 yr: 3 mg/day 9-13 yr: 4 mg/day 14-18 yr: 5 mg/day	Not established
Folic acid (vitamin B9)	Coenzymes in amino acid and nucleotide metabolism as an acceptor and donor of 1-carbon units	Megaloblastic anemia Growth stunting, glossitis Neural tube defects in progeny	0.5-1 mg/day PO folic acid	Malnutrition Malabsorptive states Malignancies Hemolytic anemias Anticonvulsant therapy	Enriched cereals, beans, leafy vegetables, citrus fruits, papaya	0-6 mo: 65 µg/day 7-12 mo: 80 µg/day 1-3 yr: 150 µg/day 4-8 yr: 200 µg/day 9-13 yr: 300 µg/day 14-18 yr: 400 µg/day	1-3 yr: 120 µg/day 4-8 yr: 160 µg/day 9-13 yr: 250 µg/day 14-18 yr: 330 µg/day
Cobalamin (vitamin B12)	As deoxyadenosylcobalamin, acts as cofactor for lipid and carbohydrate metabolism As methylcobalamin, important for conversion of homocysteine to methionine and folic acid metabolism	Megaloblastic anemia, irritability, developmental delay, developmental regression, involuntary movements, hyperpigmentation	500-1,000 µg IM or oral vitamin B12	Vegan diets Malabsorptive states Crohn disease Intrinsic factor deficiency (pernicious anemia)	Organ meats, seafood, poultry, egg yolk, milk, fortified ready-to-eat cereals	0-6 mo: 0.4 µg/day 7-12 mo: 0.5 µg/day 1-3 yr: 0.9 µg/day 4-8 yr: 1.2 µg/day 9-13 yr: 1.8 µg/day 14-18 yr: 2.4 µg/day	1-3 yr: 0.7 µg/day 4-8 yr: 1.0 µg/day 9-13 yr: 1.5 µg/day 14-18 yr: 2.0 µg/day
Ascorbic acid (vitamin C)	Important for collagen synthesis, metabolism of cholesterol and neurotransmitters Antioxidant functions and nonheme iron absorption	Scurvy manifesting as irritability, tenderness and swelling of legs, bleeding gums, petechiae, ecchymoses, follicular hyperkeratosis, and poor wound healing	100-200 mg/day PO ascorbic acid for up to 3 mo	Predominantly milk-based (non–human milk) diets Severe malnutrition	Citrus fruits and fruit juices, peppers, berries, melons, tomatoes, cauliflower, leafy green vegetables	0-6 mo: 40 mg/day 7-12 mo: 50 mg/day 1-3 yr: 15 mg/day 4-8 yr: 25 mg/day 9-13 yr: 45 mg/day 14-18 yr: Females: 65 mg/day Males: 75 mg/day	1-3 yr: 13 mg/day 4-8 yr: 22 mg/day 9-13 yr: 39 mg/day 14-18 yr: Females: 56 mg/day Males: 63 mg/day

*For healthy breastfed infants, the values represent adequate intakes (AI), that is, the mean intake of apparently "normal" infants. For biotin and pantothenic acid also, the values represent AI, as the RDA has not been established.

**Values have not been established for infants (0-12 mo).

PO, Orally; IM, intramuscularly; IV, intravenously; INH, isoniazid; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; OCP, oral contraceptive pill; RDA, recommended dietary allowance (average daily nutrient intake level estimated to meet the requirements of nearly all the healthy individuals); EAR, estimated average requirement (average daily nutrient intake level estimated to meet the requirements of 50% of the healthy individuals).

67.1 Thiamine (Vitamin B1)

H.P.S. Sachdev and Dheeraj Shah

Thiamine diphosphate, the active form of thiamine, serves as a cofactor for several enzymes involved in carbohydrate catabolism such as pyruvate dehydrogenase, transketolase, and α-ketoglutarate. These enzymes also play a role in the hexose monophosphate shunt that generates nicotinamide adenine dinucleotide phosphate (NADP) and pentose for nucleic acid synthesis. Thiamine is also required for the synthesis of acetylcholine (ACh) and γ-aminobutyric acid (GABA), which have important roles in nerve conduction. Thiamine is absorbed efficiently in the gastrointestinal (GI) tract and

Table 67.2 Genetic Pathogenic Variants Affecting Thiamine Metabolism

DISEASE	VARIANT	PROTEIN	AGE AT ONSET	CLINICAL SYMPTOMS	MANAGEMENT (DOSE)
TRMA/Rogers syndrome	*SLC19A2*	THTR1	Birth to adolescence	Megaloblastic anemia, diabetes mellitus, sensorineural deafness, optic atrophy, congenital heart defects, short stature	Thiamine (50-200 mg/day)
Biotin–thiamine-responsive basal ganglia disease	*SLC19A3*	THTR2	Birth to adolescence	*Episodic* encephalopathy associated with febrile illness, seizures, external ophthalmoplegia, dysphagia, gait ataxia, bilateral lesions of the basal ganglia	Biotin (5-10 mg/kg/day), thiamine (up to 40 mg/kg/day)
Amish lethal microcephaly/ THMD3	*SLC25A19*	Mitochondrial TPP carrier	Birth	*Episodic* encephalopathy associated with lactic acidosis and alpha-ketoglutaric aciduria, microcephaly, delayed psychomotor development, seizures, increased urinary lactate	Phenobarbital (for seizures) and physical therapy High-fat diet
Thiamine metabolism dysfunction syndrome 4/THMD4 (progressive polyneuropathy type)	*SLC25A19*	MTPC	Adolescence	*Episodic* encephalopathy associated with febrile illness, transient neurologic dysfunction, residual weakness, progressive axonal polyneuropathy, bilateral striatal degeneration	High-dose (600 mg/day) thiamine may prevent acute episodes
Thiamine metabolism dysfunction syndrome 5 (episodic encephalopathy type) THMD5	*TPK1*	Thiamine phosphokinase 1	Early childhood	*Episodic* encephalopathy (Leigh-like) associated with high serum and CSF lactate with progressive neurologic and motor dysfunctions (gait disturbances, ataxia, dystonia, and spasticity, which, in some cases, may result in loss of ability to walk) triggered by infections Cognitive function usually preserved; some developmental delay; some patients may recover from some neurologic deficits; in others, the outcome is fatal.	Oral thiamine (100-200 mg/day)

Modified from Dhir S, Tarasenko M, Napoli E, Giulivi C. Neurological, psychiatric, and biochemical aspects of thiamine deficiency in children and adults. *Front Psychiatry*. 2019;10:207, Table 1.

may be deficient in persons with GI or liver disease. The requirement of thiamine is increased when carbohydrates are taken in large amounts and during periods of increased metabolism, such as fever, muscular activity, hyperthyroidism, pregnancy, and lactation. Alcohol affects various aspects of thiamine transport and uptake, contributing to the deficiency in alcoholics.

Pork (especially lean), fish, and poultry are good **dietary sources** of thiamine. Main sources of thiamine for vegetarians are rice, oat, wheat, and legumes. Most ready-to-eat breakfast cereals are enriched with thiamine. Thiamine is water soluble and heat labile; most of the vitamin is lost when the rice is repeatedly washed and the cooking water is discarded. The breast milk of a well-nourished mother provides adequate thiamine; breastfed infants of thiamine-deficient mothers are at risk for deficiency. Thiamine antagonists (coffee, tea, carbonated caffeinated beverages) and thiaminases (fermented fish) may contribute to thiamine deficiency. Most infants and older children consuming a balanced diet obtain an adequate intake of thiamine from food and do not require supplements.

THIAMINE DEFICIENCY

Deficiency of thiamine is associated with severely malnourished states, including malignancy and after surgery. The disorder (or spectrum of disorders) is classically associated with a diet consisting largely of polished rice (**oriental beriberi**); it can also arise if highly refined wheat flour forms a major part of the diet, in persons with alcoholic use disorder, and in food faddists (occidental beriberi). Thiamine deficiency has often been reported from inhabitants of refugee camps consuming the polished rice–based monotonous diets and in breastfed infants of mothers on a predominantly polished rice–based diet. Low thiamine concentrations are also noted during critical illnesses.

Thiamine-responsive megaloblastic anemia (TRMA) syndrome is a rare autosomal recessive disorder characterized by megaloblastic anemia, diabetes mellitus, and sensorineural hearing loss, responding in varying degrees to thiamine treatment. The syndrome occurs because of pathologic variants of the *SLC19A2* gene, encoding a thiamine transporter protein, leading to abnormal thiamine transportation and cellular vitamin deficiency (Table 67.2). Another dependency state, **biotin-thiamine–responsive basal ganglia disease (BTBGD)**, results from pathologic variants of the *SLC19A3* gene (see Table 67.2). It classically presents in children with recurrent episodes of subacute encephalopathy manifesting as lethargy, dystonia, rigidity, dysphagia, and convulsions and responds to combined treatment with biotin (5-10 mg/kg/day) and thiamine (up to 40 mg/kg/day). An infantile form manifesting with acidosis, lethargy, poor feeding, and infantile spasms is also described. Other genetic disorders are noted in Table 67.2. Thiamine and related vitamins may improve the outcome in children with Leigh encephalomyelopathy.

Clinical Manifestations

Thiamine deficiency can develop within 2-3 months of a deficient intake. Early symptoms of thiamine deficiency are nonspecific, such as fatigue, apathy, irritability, depression, drowsiness, poor mental concentration, anorexia, nausea, and abdominal discomfort. As the condition progresses, more specific manifestations of **beriberi** develop, such as peripheral neuritis (manifesting as tingling, burning, and paresthesias of the toes and feet), decreased deep tendon reflexes, loss of vibration sense, tenderness and cramping of the leg muscles, heart failure, and psychologic disturbances. Patients can have ptosis of the eyelids and atrophy of the optic nerve. Hoarseness or aphonia caused by paralysis of the laryngeal nerve is a characteristic sign. Muscle atrophy and tenderness of the nerve trunks are followed by ataxia, loss of coordination, and loss of deep sensation. Later signs include increased intracranial pressure, meningismus, and coma. The clinical picture of nutritional thiamine deficiency is usually divided into a dry (**neuritic**) type and a wet (**cardiac**) type. The disease is wet or dry depending on the amount of fluid that accumulates in the body because of cardiac and renal dysfunction, even though the exact cause for this edema is unknown. Many cases of thiamine deficiency show a mixture of both features and are more properly termed **thiamine deficiency with cardiopathy and peripheral neuropathy**. A fulminant form of beriberi (**Shoshin beriberi**) manifesting acutely with severe metabolic acidosis, hypotension, and cardiogenic shock has also been described.

The classic clinical triad of **Wernicke encephalopathy**—mental status changes, ocular signs, and ataxia—is rarely reported in infants and young children with severe deficiency secondary to malignancies or feeding of defective formula. An epidemic of life-threatening thiamine deficiency was seen in infants fed a defective soy-based formula that had undetectable thiamine levels. Manifestations included emesis, lethargy, restlessness, ophthalmoplegia, abdominal distention, developmental delay, failure to thrive (malnutrition), lactic acidosis, nystagmus, diarrhea, apnea, seizures, and auditory neuropathy. An acute presentation with tachycardia, aphonia/hoarse cry, pulmonary hypertension, and severe metabolic acidosis responding to parenteral thiamine has been reported in infants of mothers consuming polished and frequently washed rice.

Death from nutritional thiamine deficiency usually is secondary to cardiac involvement. The initial signs are cyanosis and dyspnea, but tachycardia, enlargement of the liver, loss of consciousness, and convulsions can develop rapidly. The heart, especially the right side, is enlarged. The electrocardiogram (ECG) shows an increased QT interval, inverted T waves, and low voltage. These changes, as well as the cardiomegaly, rapidly revert to normal with treatment, but without prompt treatment, cardiac failure can develop rapidly and result in death. In fatal cases of beriberi, lesions are principally located in the heart, peripheral nerves, subcutaneous tissue, and serous cavities. The heart is dilated, and fatty degeneration of the myocardium is common. Generalized edema or edema of the legs, serous effusions, and venous engorgement are often present. Degeneration of myelin and axon cylinders of the peripheral nerves, with Wallerian degeneration beginning in the distal locations, is also common, particularly in the lower extremities. Lesions in the brain include vascular dilation and hemorrhage.

Diagnosis

The diagnosis is often suspected based on clinical setting and compatible symptoms. A high index of suspicion in children presenting with unexplained cardiac failure may sometimes be lifesaving. Objective biochemical tests of thiamine status include measurement of erythrocyte transketolase activity and the thiamine pyrophosphate effect. The biochemical diagnostic criteria of thiamine deficiency consist of low erythrocyte transketolase activity and high thiamine pyrophosphate effect (normal range: 0–14%). Urinary excretion of thiamine or its metabolites (thiazole or pyrimidine) after an oral loading dose of thiamine may also be measured to help identify the deficiency state. A diagnostic approach to genetic thiamine deficiencies is noted in Table 67.3. MRI changes of nutritional and genetic thiamine deficiency in infants are characterized by bilateral symmetric hyperintensities of the basal ganglia and frontal lobe, in addition to the lesions in the mammillary bodies, periaqueductal region, and thalami described in adults (Fig. 67.1).

Table 67.3 Suggested Criteria for the Diagnosis of Inherited Thiamine Defects with Prominent Neurologic Involvement

REQUIRED

1. Clinical criteria
   a. *SLCI9A3*: Acute or recurrent episodes of encephalopathy (decreased consciousness, irritability) with two or more of the following: (a) dystonia, (b) hypotonia, (c) bulbar dysfunction, (d) ataxia, and (e) seizures. Of note, 16% of patients may have an insidious onset of symptoms (psychomotor regression, clumsy or abnormal gait, and stiff limbs).
   b. *SLC25AI9*: Acute or recurrent episodes of encephalopathy with (a) progressive peripheral neuropathy or (b) severe congenital microcephaly with brain malformations.
   c. *TPK1*: Acute or recurrent episodes of encephalopathy, with two or more of the following: (a) dystonia, (b) hypotonia, (c) ataxia, (d) seizures, and (e) developmental delay. Of note, some patients may have a nonepisodic early-onset global developmental delay.
2. Biochemical criteria
   a. Normal total thiamine blood levels
   b. Low free-thiamine in CSF and/or fibroblasts (SLC19A3)
   c. Low TPP in blood, muscle, and/or fibroblasts (TPK1)
   d. High excretion of alpha-ketoglutaric acid in urine (common in TPK1 and SLC25A19, rare in SLC19A3)
3. Radiologic criteria
   a. MRI pattern compatible with Leigh syndrome (SLC19A3, SLC25A19, TPK1) or Wernicke encephalopathy (SLC19A3)
      i. *SLC19A3*: Symmetric T2W hyperintensity of caudate, putamen, cortico/subcortical areas, and/or ventromedial thalamus. No involvement of mammillary bodies. Diffuse T2W hyperintensity of brain white matter (single adult patient reported).
      ii. *SLC25A19*: Symmetric T2W hyperintensity in the caudate and putamen.
      iii. TPK1: Symmetric T2W hyperintensity in basal ganglia and cerebellum (dentate nuclei).
4. Therapeutic criteria
   a. Clinical improvement after thiamine supplementation

SUPPORTIVE

1. Consanguinity
2. Trigger event (e.g., infection, vaccination, trauma, intense physical activity)
3. Absence of predisposing factors of beriberi or Wernicke encephalopathy
4. Absence of systemic features of mitochondrial disease (cardiomyopathy, arrhythmia/conduction defects, renal tubulopathy, or dysmorphic features)
5. Increased lactate in blood and/or CSF or presence of a lactate peak on MRS
6. Normal OXPHOS and PDHc activity in muscle and fibroblast

CSF, Cerebrospinal fluid; MRI, magnetic resonance imaging; OXPHOS, oxidative phosphorylation: PDHc, pyruvate dehydrogenase complex; MRS, magnetic resonance spectroscopy; TPP, thiamine pyrophosphate; T2W, T2-weighted.

From Marcé-Grau A, Martí-Sánchez L, Baide-Mairena H, Ortigoza-Escobar JD, Pérez-Dueñas B. Genetic defects of thiamine transport and metabolism: A review of clinical phenotypes, genetics, and functional studies. *J Inherit Metab Dis.* 2019;42(4):581–597, Table 3, p. 586.

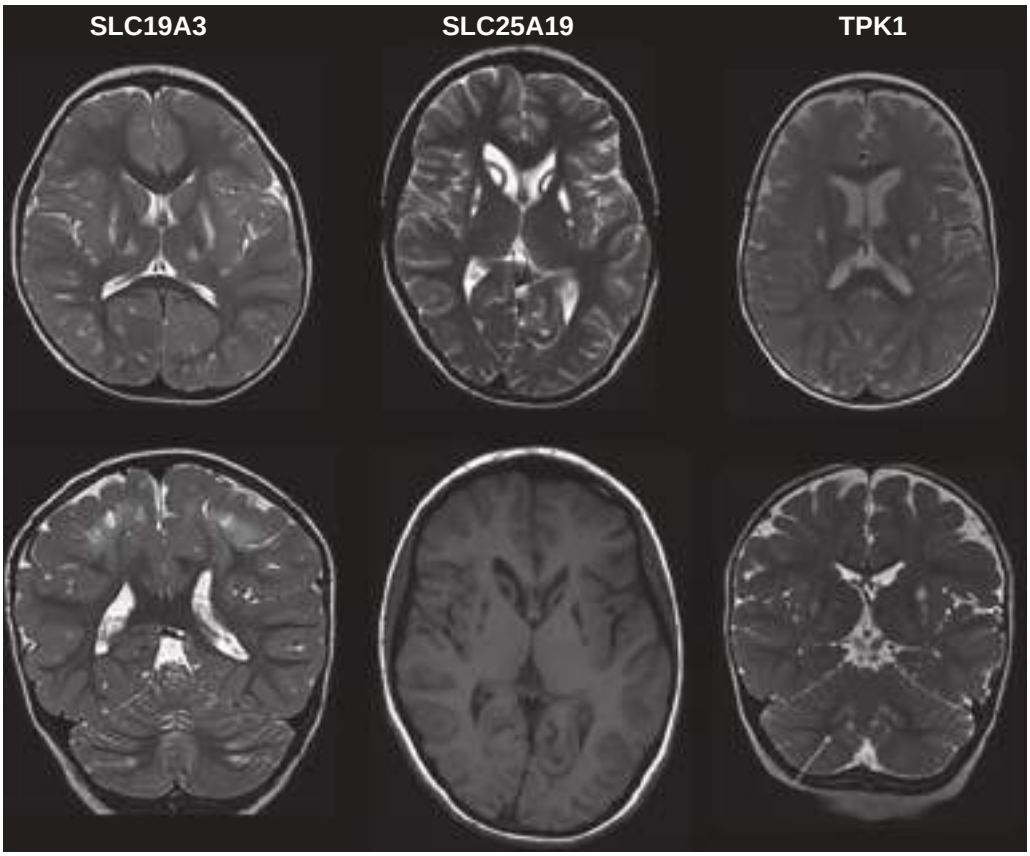

Fig. 67.1 MRI patterns in patients with inherited thiamine defects. *SLC19A3*, Axial and coronal T2-weighted images show bilateral symmetric involvement of the putamen and thalamus along with patchy cortical and subcortical hyperintensities. *SLC25A19*, Axial T2-weighted and T1-weighted images show cystic necrosis of the caudate and putamen. *TPK1*, Axial and coronal T2-weighted spin-echo images show involvement of the posterior putamen and dentate nuclei *(gray arrow). (Modified from Ortigoza-Escobar JD, Alfadhel M, Molero-Luis M, et al. Thiamine deficiency in childhood with attention to genetic causes: Survival and outcome predictors. Ann Neurol. 2017;82[3]:317-330, Fig. 3, p. 322.)*

Prevention

A maternal diet containing sufficient amounts of thiamine prevents thiamine deficiency in breastfed infants, and infant formulas marketed in all developed countries provide recommended levels of intake. During complementary feeding, adequate thiamine intake can be achieved with a varied diet that includes meat and enriched or whole-grain cereals. When the staple cereal is polished rice, special efforts need to be made to include legumes and/or nuts in the ration. Thiamine and other vitamins can be retained in rice by **parboiling**, a process of steaming the rice in the husk before milling. Improvement in cooking techniques, such as not discarding the water used for cooking, minimal washing of grains, and reduction of cooking time, helps to minimize the thiamine losses during the preparation of food. Thiamine supplementation should be ensured during total parenteral nutrition (TPN).

Treatment

In the absence of GI disturbances, oral administration of thiamine is effective. Children with cardiac failure, convulsions, or coma should be given 10-50 mg of thiamine intramuscularly (IM) or intravenously (IV) daily for the first week. This treatment should then be followed by 3-5 mg/day of thiamine orally (PO) for at least 6 weeks. The response is dramatic in infants and in those having predominantly cardiovascular manifestations, whereas the neurologic response is slow and often incomplete. Epilepsy, mental disability, and language and auditory problems of varying degrees have been reported in survivors of severe infantile thiamine deficiency.

Patients with beriberi often have other B-complex vitamin deficiencies; therefore all other B-complex vitamins should also be administered. **Treatment of TRMA syndrome and other genetic pathogenic variants of thiamine metabolism require higher dosages (Table 67.2).** The anemia responds well to thiamine administration, and insulin for associated diabetes mellitus can also be discontinued in many patients with TRMA syndrome. Patients with BTBGD need lifelong supplementation.

THIAMINE TOXICITY

There are no reports of adverse effects from consumption of excess thiamine by ingestion of food or supplements. A few isolated cases of pruritus and anaphylaxis have been reported in patients after parenteral administration of vitamin B1.

67.2 Riboflavin (Vitamin B2)

H.P.S. Sachdev and Dheeraj Shah

Riboflavin is part of the structure of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide, which participate in oxidation-reduction (redox) reactions in numerous metabolic pathways and in energy production via the mitochondrial respiratory chain. Specific transporter proteins direct riboflavin intracellularly for these functions. Riboflavin is stable to heat but is destroyed by light. Milk and dairy products, eggs, organ meats, legumes, and mushrooms are rich dietary sources of riboflavin. Most commercial cereals, flours, and breads are enriched with riboflavin.

RIBOFLAVIN DEFICIENCY

The causes of riboflavin deficiency (**ariboflavinosis**) are mainly related to malnourished and malabsorptive states, including GI infections. Treatment with some drugs, such as probenecid, phenothiazine, doxorubicin, or oral contraceptives (OCs), can also cause the deficiency. Phototherapy for hyperbilirubinemia can contribute to deficiency as the side chain of the vitamin is photochemically destroyed because it is involved in the photosensitized oxidation of bilirubin to more polar excretable compounds.

Brown-Vialetto-Van Laere syndrome (BVVLS) and Fazio-Londe syndrome are clinically overlapping conditions related to **riboflavin transporter deficiency (RTD)**. Pathologic variants (autosomal recessive) of the *SLC52A1* (type 1), *SLC52A2* (type 2), and *SLC52A3* (type 3) genes, which encode intestinal human riboflavin transporter proteins, have been demonstrated in these disorders characterized by *progressive* neurologic deterioration, peripheral neuropathy, hypotonia, ataxia, sensorineural hearing loss (usually the first symptom), optic atrophy, pontobulbar palsy, and respiratory insufficiency. Age of onset is variable; the later the onset, the milder the symptoms. Treatment with high doses (10-80 mg/kg/day) of riboflavin lead to clinical improvement in the majority of cases, especially if treated early in the disease course. Prophylaxis with riboflavin has been demonstrated to be effective in the reduction of frequency of headache in adult migraine; the evidence is insufficient in children and adolescents.

Clinical Manifestations

Clinical features of nutritional riboflavin deficiency include cheilosis, glossitis, keratitis, conjunctivitis, photophobia, lacrimation, corneal vascularization, and seborrheic dermatitis. Cheilosis begins with pallor at the angles of the mouth and progresses to thinning and maceration of the epithelium, leading to fissures extending radially into the skin (Fig. 67.2). In glossitis the tongue becomes smooth, with loss of papillary structure (Fig. 67.3). Normochromic, normocytic anemia may also be seen because of the impaired erythropoiesis. A low riboflavin content of the maternal diet has been linked to congenital heart defects, but the evidence is weak.

Diagnosis

Most often, the diagnosis is based on the clinical features of angular cheilosis in a malnourished child, who responds promptly to riboflavin supplementation. A functional test of riboflavin status is done by measuring the activity of erythrocyte glutathione reductase (EGR), with and without the addition of FAD. An EGR activity coefficient (ratio of EGR activity with added FAD to EGR activity without FAD) of >1.4 is used as an indicator of deficiency. Urinary excretion of riboflavin <30 μg/24 hr also suggests low intake.

Riboflavin transporter deficiency may be detected by genetic testing.

Prevention

Table 67.1 lists the recommended daily allowance of riboflavin for infants, children, and adolescents. Adequate consumption of milk, milk products, and eggs prevents riboflavin deficiency. Fortification of cereal products is helpful for those who follow vegan diets or who are consuming inadequate amounts of milk products for other reasons.

Treatment

Treatment includes oral administration of 3-10 mg/day of riboflavin, often as an ingredient of a vitamin B–complex mix. The child should also be given a well-balanced diet, including milk and milk products.

RIBOFLAVIN TOXICITY

No adverse effects associated with riboflavin intake from food or supplements have been reported, and the upper safe limit for consumption has not been established. Although the photosensitizing property of vitamin B2 suggests some potential risks, limited absorption in high-intake situations precludes such concerns.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

67.3 Niacin (Vitamin B3)

H.P.S. Sachdev and Dheeraj Shah

Niacin (nicotinamide or nicotinic acid) forms part of two cofactors, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are important in several biologic reactions, including the respiratory chain, fatty acid and steroid synthesis, cell differentiation, and DNA processing. Niacin is rapidly absorbed from the stomach and the intestines and can also be synthesized from tryptophan in the diet.

Major dietary sources of niacin are meat, fish, and poultry for nonvegetarians and cereals, legumes, and green leafy vegetables for vegetarians. Enriched and fortified cereal products and legumes also are major contributors to niacin intake. Milk and eggs contain little niacin but are good sources of tryptophan, which can be converted to NAD (60 mg tryptophan = 1 mg niacin).

NIACIN DEFICIENCY

Pellagra, the classic niacin deficiency disease, occurs chiefly in populations where corn (maize), a poor source of tryptophan, is the major foodstuff. A severe dietary imbalance, such as in anorexia nervosa and in war or famine conditions, also can cause pellagra. Pellagra is rare outside the African subcontinent; however, consumption of a highly restrictive diet, such as in autism, has led to some resurgence in high-income countries. Pellagra can also develop in conditions associated with disturbed tryptophan metabolism, such as carcinoid syndrome and Hartnup disease.

Fig. 67.4 A, Symmetric, well-demarcated, erythematous, eroded plaques with desquamation over hands and forearms. B, Brownish plaques with desquamation in the distribution of neck collar (Casal necklace) because of pellagra in a child with autism on highly restrictive diet. *(From Zaenglein A, Martin A, Carlson L, Williams KE. Pellagra secondary to selective eating in a child with autism. Pediatr Dermatol. 2020;37:698–700.)*

Clinical Manifestations

The early symptoms of pellagra are vague: anorexia, lassitude, weakness, burning sensation, numbness, and dizziness. After a long period of deficiency, the classic triad of dermatitis, diarrhea, and dementia appears. **Dermatitis**, the most characteristic manifestation of pellagra, can develop suddenly or insidiously and may be initiated by irritants, including intense sunlight. The lesions first appear as symmetric areas of erythema on exposed surfaces, resembling sunburn, and might go unrecognized. The lesions are usually sharply demarcated from the surrounding healthy skin, and their distribution can change frequently. The lesions on the hands and feet often have the appearance of a glove or stocking (Fig. 67.4A). Similar demarcations can also occur around the neck (**Casal necklace**) (see Fig. 67.4B). In some cases, vesicles and bullae develop (wet type). In others there may be suppuration beneath the scaly, crusted epidermis; in still others the swelling can disappear after a short time, followed by desquamation (Fig. 67.5). The healed parts of the skin might remain pigmented. The cutaneous lesions may be preceded by or accompanied by stomatitis, glossitis, vomiting, and diarrhea. Swelling and redness of the tip of the tongue and its lateral margins is often followed by intense redness, even ulceration, of the entire tongue and the papillae. Central nervous system symptoms include depression, disorientation, insomnia, and delirium.

The classic symptoms of pellagra usually are not well developed in infants and young children, but anorexia, irritability, anxiety, and apathy are common. Young patients might also have sore tongues and lips and usually have dry scaly skin. Diarrhea and constipation can alternate, and anemia can occur. Children who have pellagra often have evidence of other nutritional deficiency diseases.

Diagnosis

Because of lack of a good functional test to evaluate niacin status, the diagnosis of deficiency is usually made from the physical signs of glossitis, GI symptoms, and a symmetric dermatitis. Rapid clinical response to niacin is an important confirmatory test. A decrease in the concentration and/or a change in the proportion of the niacin metabolites N^1-methylnicotinamide and 2-pyridone in the urine provide biochemical evidence of deficiency and can be seen before the appearance of overt signs of deficiency. Histopathologic changes from the affected skin include dilated blood vessels without significant inflammatory infiltrates, ballooning of the keratinocytes, hyperkeratosis, and epidermal necrosis.

Fig. 67.5 Clinical manifestations of niacin deficiency before (A) and after (B) therapy. *(From Weinsier RL, Morgan SL. Fundamentals of Clinical Nutrition. St Louis: Mosby; 1993:99.)*

Prevention

Adequate intake of niacin is easily met by consumption of a diet that consists of a variety of foods and includes meat, eggs, milk, and enriched or fortified cereal products. The dietary reference intake (DRI) is expressed in milligram niacin equivalents (NE) in which 1 mg NE = 1 mg niacin or 60 mg tryptophan. The DRI is summarized in Table 67.1.

Treatment

Children usually respond rapidly to treatment. A liberal and varied diet should be supplemented with 50-300 mg/day of niacin; in severe cases or in patients with poor intestinal absorption, 100 mg may be given IV. The diet should also be supplemented with other vitamins, especially other B-complex vitamins. Sun exposure should be avoided during the active phase of pellagra, and the skin lesions may be covered with soothing applications. Other coexisting nutrient deficiencies such as iron-deficiency anemia should be treated. Even after successful treatment, the diet should continue to be monitored to prevent recurrence.

NIACIN TOXICITY

No toxic effects are associated with the intake of naturally occurring niacin in foods. Shortly after the ingestion of large doses of nicotinic acid taken as a supplement or a pharmacologic agent, a person often experiences a burning, tingling, and itching sensation, as well as flushing on the face, arms, and chest. Large doses of niacin also can have nonspecific GI effects and can cause cholestatic jaundice or hepatotoxicity. Tolerable upper intake levels for children are 10 mg/day for 1-3 years, 15 mg/day for 4-8 years, 20 mg/day for 9-13 years, and 30 mg/day for 14-18 years.

67.4 Vitamin B6 (Pyridoxine)

H.P.S. Sachdev and Dheeraj Shah

Vitamin B6 includes a group of closely related compounds: pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivatives. **Pyridoxal 5′-phosphate (PLP)** and, to a lesser extent, pyridoxamine phosphate function as coenzymes for many enzymes involved in amino acid metabolism, neurotransmitter synthesis, glycogen metabolism, and steroid action. If vitamin B6 is lacking, glycine metabolism can lead to oxaluria. The major excretory product in the urine is 4-pyridoxic acid.

The vitamin B6 content of human milk and infant formulas is adequate. Good food sources of the vitamin include fortified ready-to-eat cereals, meat, fish, poultry, liver, bananas, rice, and certain vegetables. Large losses of the vitamin can occur during high-temperature processing of foods or milling of cereals, whereas parboiling of rice prevents its loss.

VITAMIN B6 DEFICIENCY

Because of the importance of vitamin B6 in amino acid metabolism, high protein intake can increase the requirement for the vitamin; the recommended daily allowances are sufficient to cover the expected range of protein intake in the population. The risk of deficiency is increased in persons taking medications that inhibit the activity of vitamin B6 (e.g., isoniazid, penicillamine, corticosteroids, phenytoin, carbamazepine), in young women taking oral progesterone-estrogen contraceptives, and in patients receiving maintenance dialysis.

Clinical Manifestations

The vitamin B6 deficiency symptoms seen in infants are listlessness, irritability, seizures, vomiting, and failure to thrive. Peripheral neuritis is a feature of deficiency in adults but is not usually seen in children. EEG abnormalities have been reported in infants and in young adults in controlled depletion studies. Skin lesions include cheilosis, glossitis, and seborrheic dermatitis around the eyes, nose, and mouth. Microcytic anemia can occur in infants but is not common. Oxaluria, oxalic acid bladder stones, hyperglycinemia, lymphopenia, decreased antibody formation, and infections also are associated with vitamin B6 deficiency.

Several types of vitamin B6 **dependence syndromes**, presumably resulting from errors in metabolism or transport of PLP or pyridoxine, respond to large doses of pyridoxine. These syndromes include pyridoxine-dependent epilepsy, a vitamin B6–responsive anemia, xanthurenic aciduria, cystathioninuria, and homocystinuria. Pyridoxine-dependent epilepsy involves pathologic variants in the *ALDH7A1* gene causing deficiency of antiquitin, an enzyme involved in dehydrogenation of α-aminoadipic semialdehyde. Pathologic variants of the genes *PROSC*, which encodes a PLP binding protein, and *PNPO* encoding for the pyridoxamine 5-phosphate oxidase enzyme also cause epilepsy responsive to PLP or high doses of pyridoxine. Neonatal epileptic encephalopathy and hypophosphatasia are associated with impaired import of PLP into the neuronal cells, and seizures occurring in these conditions also respond to pyridoxine therapy.

Diagnosis

The activity of aspartate (glutamic-oxaloacetic) transaminase (AST) and alanine (glutamic-pyruvic) transaminase (ALT) is low in vitamin B6 deficiency; tests measuring the activity of these enzymes before and after the addition of PLP may be useful as indicators of vitamin B6 status. Abnormally high xanthurenic acid excretion after tryptophan ingestion also provides evidence of deficiency. Plasma PLP assays are being used more often, but factors such as inflammation, renal function, and hypoalbuminemia can influence the results. Ratios between substrate-product pairs (e.g., PAr index, 3-hydroxykynurenine/xanthurenic acid ratio, oxoglutarate/glutamate ratio) may attenuate such influence. Quantification of a large number of metabolites, using mass spectrometry–based metabolomics, are being evaluated as functional biomarkers of pyridoxine status.

Vitamin B6 deficiency or dependence should be suspected in all infants with **seizures**. If more common causes of infantile seizures have been eliminated, 100 mg of pyridoxine can be injected, with EEG monitoring if possible. If the seizure stops, vitamin B6 deficiency should be suspected. In older children, 100 mg of pyridoxine may be injected IM while the EEG is being recorded; a favorable response of the EEG suggests pyridoxine deficiency.

Prevention

Deficiency is unlikely in children consuming diets that meet their energy needs and contain a variety of foods. Parboiling of rice prevents the loss of vitamin B6 from the grains. The dietary reference intake for vitamin B6 is shown in Table 67.1. Infants whose mothers have received large doses of pyridoxine during pregnancy are at increased risk for seizures from pyridoxine dependence, and supplements during the first few weeks of life should be considered. Any child receiving a pyridoxine antagonist, such as isoniazid, should be carefully observed for neurologic manifestations; if these develop, vitamin B6 should be administered or the dose of the antagonist should be decreased.

Treatment

Intramuscular or intravenous administration of 100 mg of pyridoxine is used to treat convulsions caused by vitamin B6 deficiency. One dose should be sufficient if adequate dietary intake follows. For pyridoxine-dependent children, daily doses of 2-10 mg IM or 10-100 mg PO may be necessary.

VITAMIN B6 TOXICITY

Adverse effects have not been associated with high intakes of vitamin B6 from food sources. However, ataxia and sensory neuropathy have been reported with dosages above 200 mg/day in adults taking vitamin B6 supplements for several months. Tolerable upper intake levels for children are 30 mg/day for 1-3 years, 40 mg/day for 4-8 years, 60 mg/day for 9-13 years, and 80 mg/day for 14-18 years.

67.5 Biotin

H.P.S. Sachdev and Dheeraj Shah

Biotin (vitamin B7 or vitamin H) functions as a cofactor for enzymes involved in carboxylation reactions within and outside mitochondria. These biotin-dependent carboxylases catalyze key reactions in gluconeogenesis, fatty acid metabolism, and amino acid catabolism.

There is limited information on the biotin content of foods; biotin is believed to be widely distributed, making a deficiency unlikely. *Avidin* found in raw egg whites acts as a biotin antagonist. Signs of biotin deficiency have been demonstrated in persons who consume large amounts of raw egg whites over long periods. Deficiency also has been described in infants and children receiving enteral and parenteral nutrition formula that lacks biotin. Treatment with valproic acid may result in a low biotinidase activity and/or biotin deficiency.

The clinical findings of biotin deficiency include scaly periorificial dermatitis, conjunctivitis, thinning of hair, and alopecia (Fig. 67.6). Central nervous system (CNS) abnormalities seen with biotin deficiency are lethargy, hypotonia, seizures, ataxia, and withdrawn behavior. Biotin deficiency can be successfully treated using 1-10 mg of biotin orally daily. The dietary reference intake for biotin is shown in Table 67.1. No toxic effects have been reported with very high doses.

Biotin-responsive basal ganglia disease or **biotin and thiamine–responsive basal ganglia disease** is a rare childhood neurologic disorder characterized by encephalopathy, seizures, extrapyramidal manifestations, altered signals in basal ganglia (bilateral involvement of caudate nuclei and putamen with sparing of globus pallidus) on MRI, and homozygous pathologic variation in the *SLC19A3* gene (see Table 67.2). Chapter 105 describes conditions involving deficiencies in the enzymes holocarboxylase synthetase and biotinidase that respond to treatment with biotin.

67.6 Folate

H.P.S. Sachdev and Dheeraj Shah

Folate exists in different chemical forms (Fig. 67.7). **Folic acid** (pteroylglutamic acid) is the synthetic form used in fortified foods and supplements. Naturally occurring folates in foods retain the core chemical structure of pteroylglutamic acid but vary in their state of reduction, the single-carbon moiety they bear, or the length of the glutamate chain. These polyglutamates are broken down and reduced in the small intestine to dihydrofolates and tetrahydrofolates, which are involved as coenzymes in amino acid and nucleotide metabolism as acceptors and donors of 1-carbon units. Folate is important for CNS development during embryogenesis.

Rice and cereals are rich dietary sources of folate, especially if enriched. Beans, leafy vegetables, and fruits such as oranges and papaya are good sources as well. The vitamin is readily absorbed from the small intestine and is broken down to monoglutamate derivatives by mucosal polyglutamate hydrolases. A high-affinity proton-coupled folate transporter (PCFT) seems to be essential for absorption of folate in the intestine and in various cell types at low pH. The vitamin is also synthesized by colonic bacteria, and its half-life is prolonged by enterohepatic recirculation.

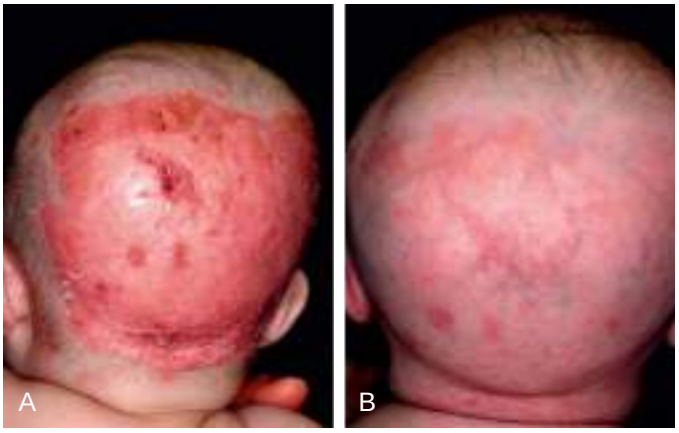

Fig. 67.6 A, Scalp rash in an infant with biotin deficiency before treatment with biotin. B, After 3 weeks of biotin treatment. *(From Ito T, Nishie W, Fujita Y, et al. Infantile eczema caused by formula milk. Lancet. 2013;381:1958.)*

FOLATE DEFICIENCY

Because of folate's role in protein, DNA, and RNA synthesis, the risk of deficiency is increased during periods of rapid growth or increased cellular metabolism. Folate deficiency can result from poor nutrient content in the diet, inadequate absorption (celiac disease, inflammatory bowel disease), increased requirement (sickle cell anemia, psoriasis, malignancies, periods of rapid growth as in infancy and adolescence), or inadequate use (long-term treatment with high-dose nonsteroidal antiinflammatory drugs; anticonvulsants such as phenytoin and phenobarbital; methotrexate). Rare causes of deficiency are hereditary folate malabsorption, inborn errors of folate metabolism (methylene tetrahydrofolate reductase, methionine synthase reductase, and glutamate formiminotransferase deficiencies), and cerebral folate deficiency. A loss-of-function pathologic variant in the gene coding for PCFT is the molecular basis for hereditary folate malabsorption. A high-affinity blocking autoantibody against the membrane-bound folate receptor in the choroid plexus preventing its transport across the blood-brain barrier is the likely cause of **infantile cerebral folate deficiency**.

Clinical Manifestations

Folic acid deficiency results in megaloblastic anemia and hypersegmentation of neutrophils. Nonhematologic manifestations include glossitis, listlessness, and growth retardation not related to anemia. An association exists between low maternal folic acid status and neural tube defects, primarily spina bifida and anencephaly, and the role of periconceptional folic acid in their prevention is well established (see Chapter 503.1).

Hereditary folate malabsorption manifests at 1-3 months of age with recurrent or chronic diarrhea, failure to thrive (malnutrition), oral ulcerations, neurologic deterioration, megaloblastic anemia, and opportunistic infections. **Cerebral folate deficiency** manifests at 4-6 months of age with irritability, microcephaly, developmental delay, cerebellar ataxia, pyramidal tract signs, choreoathetosis, ballismus, seizures, and blindness as a result of optic atrophy. 5-Methyltetrahydrofolate levels are normal in serum and red blood cells (RBCs) but greatly depressed in the cerebrospinal fluid (CSF).

Diagnosis

The diagnosis of folic acid deficiency anemia is made in the presence of macrocytosis along with low folate levels in serum or RBCs. Normal serum folic acid levels are 5-20 ng/mL; with deficiency, levels are <3 ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150-600 ng/mL of packed cells. The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation also are seen.

Cerebral folate deficiency is associated with low levels of 5-methyltetrahydrofolate in CSF and normal folate levels in the plasma

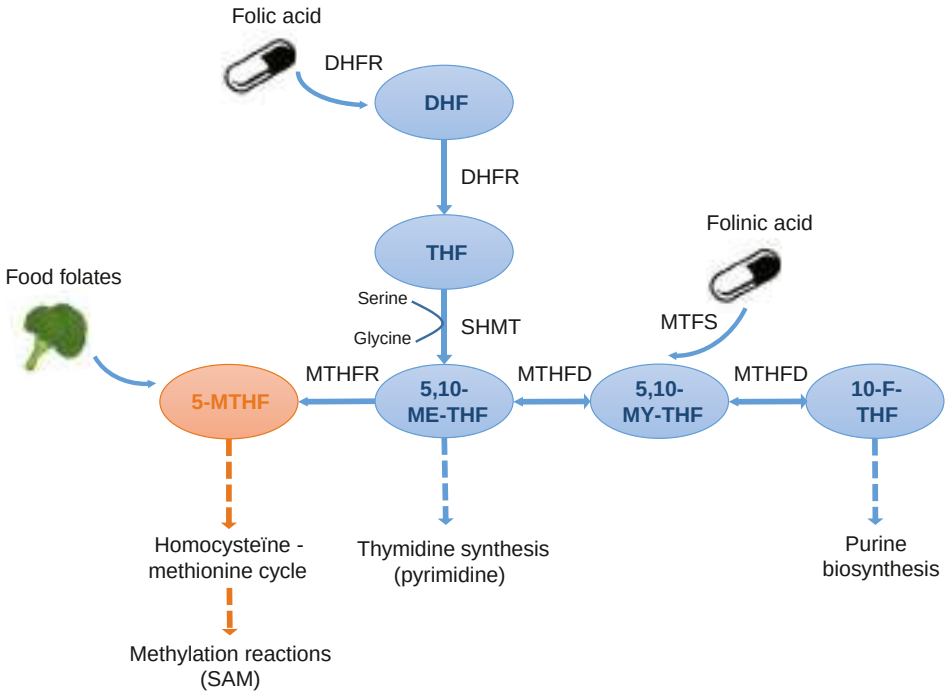

Fig. 67.7 Simplified scheme of folate metabolism; 5-MTHF is the predominant form in which dietary folate enters the circulation. Synthetic folic acid first has to be metabolized in two steps to the biologically active form THF, whereas the biologically derived folinic acid is already reduced and easily converted to 5,10-methenyl-THF. Serine is an important one carbon donor and allows entry of THF into the active one-carbon pool of intermediates by way of 5,10-methylene-THF, which functions as a cofactor for the synthesis of thymidine. 5,10-Methylene-THF can be metabolized to 5-MTHF for the remethylation of homocysteine to methionine, or it can be converted to 10-formyl-THF for use in purine synthesis.1 DHF, dihydrofolate; DHFR, dihydrofolate reductase; THF, tetrahydrofolate; 5-MTHF, 5-methyltetrahydrofolate; SAM, S-adenosylmethionine; 5,10-ME-THF, 5,10-methylene-THF; 5,10-MYTHF, 5,10-methenyl-THF; 10-F-THF, 10-formyl-THF; MTFS, 5,10-methenyltetrahydrofolate synthetase. *(From Lubout CMA, Goorden SMI, van den Hurk K, et al. Successful treatment of hereditary folate malabsorption with intramuscular folinic acid. Pediatr Neurol. 2020;102:62-66, Fig. 2, p. 64.)*

and RBCs. Pathologic variants of the *PCFT* gene are demonstrated in hereditary folate malabsorption.

Prevention

Breastfed infants have better folate nutrition than nonbreastfed infants throughout infancy. Consumption of folate-rich foods and food fortification programs are important to ensure adequate intake in children and in women of childbearing age. The dietary reference intakes (DRIs) for folate are 65 µg of dietary folate equivalents (DFE) for infants 0-6 months of age and 80 µg of DFE for infants 6-12 months. (1 DFE = 1 µg food folate = 0.6 µg of folate from fortified food or as a supplement consumed with food = 0.5 µg of a supplement taken on an empty stomach.) For the DRIs in older children, see Table 67.1. All women desirous of becoming pregnant should consume 400-800 µg folic acid daily; the dose is 4 mg/day in those having delivered a child with a neural tube defect. To be effective, supplementation should be started at least 1 month before conception and continued through the first 2-3 months of pregnancy. The benefit of periconceptional folate supplementation in prevention of congenital heart defects, orofacial clefts, childhood cancers, and autism spectrum disorders are unclear. Preconceptional folate supplementation continued throughout pregnancy may marginally reduce the risk of delivering a preterm or small-for-gestational-age infant. Providing iron and folic acid tablets for prevention of anemia in children and pregnant women is a routine strategy in at-risk populations. Mandatory fortification of cereal flours with folic acid coupled with health education programs has been associated with a substantial reduction in incidence of neural tube defects in many countries.

Treatment

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. Folic acid therapy should be continued for 3-4 weeks or until a definite hematologic response has occurred. Maintenance therapy with 0.2 mg/day of folate is adequate. Prolonged treatment with oral or parenteral folinic acid is required in cerebral folate deficiency, and the response may be incomplete. High-dose intravenous folinic acid may help in refractory cases. Treatment of hereditary folate malabsorption may be possible with intramuscular folinic acid; some patients may respond to high-dose oral folinic acid therapy.

FOLATE TOXICITY

No adverse effects have been associated with consumption of the amounts of folate normally found in fortified foods. Tolerable upper intake levels for children are 300 µg/day for 1-3 years, 400 µg/day for 4-8 years, 600 µg/day for 9-13 years, and 800 µg/day for 14-18 years. Excessive intake of folate supplements might obscure and potentially delay the diagnosis of vitamin B12 deficiency. Massive doses given by injection have the potential to cause neurotoxicity.

67.7 Vitamin B12 (Cobalamin)

H.P.S. Sachdev and Dheeraj Shah

Vitamin B12, in the form of deoxyadenosylcobalamin, functions as a cofactor for isomerization of methylmalonyl-CoA to succinyl-CoA, an essential reaction in lipid and carbohydrate metabolism. Methylcobalamin is another circulating form of vitamin B12 and is essential for methyl group transfer during the conversion of homocysteine to methionine. This reaction also requires a folic acid cofactor and is important for protein and nucleic acid biosynthesis. Vitamin B12 is important for hematopoiesis, CNS myelination, and mental and psychomotor development (Fig. 67.8).

Dietary sources of vitamin B12 are almost exclusively from animal foods. Organ meats, muscle meats, seafood (mollusks, oysters, fish), poultry, and egg yolk are rich sources. Fortified ready-to-eat cereals and milk and their products are the important sources of the vitamin for vegetarians. Human milk is an adequate source for breastfeeding infants if the maternal serum B12 levels are adequate. Vitamin B12 is absorbed from ileum at alkaline pH after binding with intrinsic factor. Enterohepatic circulation, direct absorption, and synthesis by intestinal bacteria are additional mechanisms helping to maintain the vitamin B12 nutriture.

VITAMIN B12 DEFICIENCY

Deficiency of vitamin B12 caused by inadequate dietary intake occurs primarily in persons consuming strict vegetarian or vegan diets. Prevalence of vitamin B12 deficiency is high in predominantly vegetarian or lactovegetarian populations. Breastfeeding infants of B12-deficient mothers are also at risk for significant deficiency. Malabsorption of B_{12} occurs in celiac disease, ileal resections, Crohn disease, *Helicobacter pylori* infection, and autoimmune atrophic gastritis (pernicious anemia). Obesity, type 1 diabetes, and use of metformin and proton pump inhibitors histamine (H_2) receptor antagonists and misuse of nitrous oxide—usually in the form of inhaling aerosol whipped cream (whippits)—may increase the risk of deficiency. **Hereditary intrinsic factor deficiency** and **Imerslund-Gräsbeck disease** are inborn errors of metabolism leading to vitamin B12 malabsorption. Pathologic variants of the hereditary intrinsic factor gene cause hereditary intrinsic factor deficiency, whereas pathologic variation in any of the two subunits (cubilin and amnionless) of the intrinsic factor receptor cause Imerslund-Gräsbeck disease. Maternal vitamin B12 deficiency may produce neonatal B12 deficiency, which may be detected by elevated levels of homocysteine and methylmalonic acid on the newborn screen.

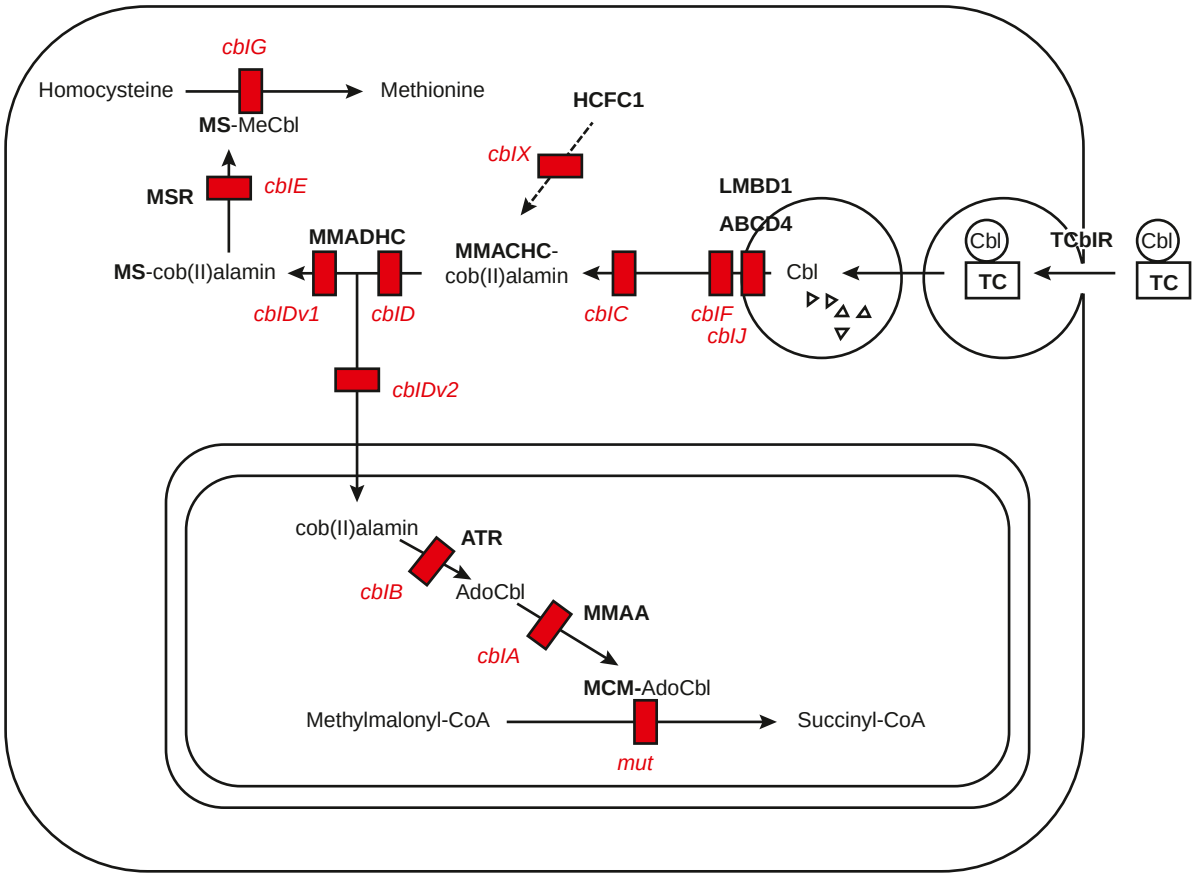

Fig. 67.8 Scheme of cobalamin (Cbl) metabolism. The sites affected by methylmalonyl-CoA mutase deficiency *(mut)* and inborn errors of cobalamin metabolism (*cblA-cblG, cblJ,* and *cblX*) are shown in *red.* The cblA disorder is caused by defects in the MMAA protein; the cblB disorder by defects in the cob(I)alamin adenosyltransferase (MMAB) protein; the cblC disorder by defects in the MMACHC protein; the cblD, cblD variant 1 *(cblDv1),* and cblD variant 2 *(cblDv2)* disorders are caused by defects in the MMADHC protein; cblE disorder is caused by defects in the methionine synthase reductase (MSR) protein; cblG disorder by defects in the methionine synthase (MS) protein; cblJ disorder by pathologic variants in the ABCD4 protein; cblX disorder by pathologic variation in the HCFC1 protein, and the mut disorder by defects in methylmalonyl-CoA mutase (MCM). The protein affected in the cblF disorder is unknown. MCM-AdoCbl, Holomethylmalonyl-CoA mutase (mutase with bound adenosylcobalamin); MS-cob(II)alamin, methionine synthase with bound cob(II)alamin; MS-MeCbl, holomethionine synthase (synthase with bound methylcobalamin); TC, transcobalamin. *(From Orkin SH, Fisher DE, Ginsburg D, et al., eds. Nathan and Oski's Hematology and Oncology of Infancy and Childhood, 8th ed. Philadelphia: Elsevier; 2015:318.)*

Fig. 67.9 MRI of the cervical spine illustrating a long segment of T2 hyperintensity involving the dorsal column of virtually the entire cervical spinal cord consistent with a diagnosis of subacute combined degeneration from vitamin B12 deficiency. *(From Stockton L, Simonsen C, Seago S. Nitrous oxide-induced vitamin B12 deficiency. Proc [Bayl Univ Med Cent]. 2017;30[2]:171–172.)*

Fig. 67.10 Hyperpigmentation of (A) knuckles and (B) soles in an adolescent female with severe anemia and vitamin B12 deficiency.

Clinical Manifestations

The hematologic manifestations of vitamin B12 deficiency are similar to manifestations of folate deficiency and are discussed in Chapter 503.2. Irritability, hypotonia, developmental delay, developmental regression, and involuntary movements (predominantly coarse tremors) are the common neurologic symptoms in infants. Older children with vitamin B12 deficiency may show poor growth and poor school performance, whereas sensory deficits, paresthesias, peripheral neuritis, and psychosis are seen in adolescents and adults (Fig. 67.9). Hyperpigmentation of the knuckles, palms, and soles is another common observation with B12 deficiency in children and adolescents (Fig. 67.10).

Diagnosis

See Chapter 503.2.

Vitamin B12 deficiency may be present with vitamin B12 levels in the normal or low normal range and without macrocytosis. Ancillary testing of methylmalonic acid and homocysteine levels may enhance the diagnosis.

Treatment

The hematologic symptoms respond promptly to parenteral administration of 250-1,000 µg vitamin B12. Children with severe deficiency and those with neurologic symptoms need repeated doses, daily or on alternate days in the first week, followed by weekly for the first 1-2 months and then monthly. Children with only hematologic presentation recover fully within 2-3 months, whereas those with neurologic disease need at least 6 months of therapy. Children with a continuing malabsorptive state and those with inborn errors of vitamin B12 malabsorption need lifelong treatment. Daily treatment with high-dose (500-1,000 µg) oral vitamin B12 preparations has also been shown to be equally effective in correcting biochemical vitamin B12 deficiency in a few trials in children, but data are inadequate to support use of the oral route in children with neurologic manifestations and severe anemia. The sublingual route has recently been explored in infants and children and has been found to be effective in normalizing serum vitamin B12 levels.

Prevention

Vitamin B12 dietary reference intakes (DRIs) are shown in Table 67.1. In pregnancy the DRI is 2.6 µg/day and in lactation 2.8 µg/day. Pregnant and breastfeeding women should ensure an adequate consumption of animal products to prevent cobalamin deficiency in infants. Strict vegetarians, especially vegans, should ensure regular consumption of vitamin B12. Food fortification with the vitamin helps to prevent deficiency in predominantly vegetarian populations. Though metabolic derangements suggestive of vitamin B12 deficiency are present in a high proportion of infants and children from low-income country settings, routine supplementation with vitamin B12 does not seem to significantly improve their growth, development, or hemoglobin status.

Toxicity

Administration of therapeutic doses, both in oral and parenteral forms, is usually safe. Transient erythroderma and chromaturia have been reported with administration of adult-equivalent doses of intravenous hydroxycobalamin in a child. Acneiform eruptions, palpitations, headache, and insomnia have been occasionally reported in young adults receiving repeated high parenteral doses.

Chapter 68

Vitamin C (Ascorbic Acid) Deficiency and Excess

Dheeraj Shah and H.P.S. Sachdev

Vitamin C is important for synthesis of collagen at the level of hydroxylation of lysine and proline in precollagen. It is also involved in neurotransmitter metabolism (conversion of dopamine to norepinephrine and tryptophan to serotonin), cholesterol metabolism (conversion of cholesterol to steroid hormones and bile acids), and the biosynthesis of carnitine. Vitamin C functions to maintain the iron and copper atoms, cofactors of the metalloenzymes, in a reduced (active) state. Vitamin C is an important antioxidant (electron donor) in the aqueous milieu of the body. Vitamin C enhances nonheme iron absorption, the transfer of iron from transferrin to ferritin, and the formation of tetrahydrofolic acid and thus can affect the cellular and immunologic functions of the hematopoietic system. Though vitamin C has antiinflammatory and immunomodulating effects, there is no evidence of clinical benefit of vitamin C supplementation in pediatric critical illnesses and respiratory tract infections, including COVID-19.

DIETARY NEEDS AND SOURCES OF VITAMIN C

Humans depend on dietary sources for vitamin C. An adequate intake is 40 mg for ages 0-6 months and 50 mg for 6-12 months. For older children, the recommended dietary allowance is 15 mg for ages 1-3 years, 25 mg for 4-8 years, 45 mg for 9-13 years, and 65-75 mg for 14-18 years. The recommended dietary allowances during pregnancy and lactation are 85 mg/day and 120 mg/day, respectively. The requirement for vitamin C is increased during infectious and diarrheal diseases. Children exposed to smoking or environmental tobacco smoke also require increased amounts of foods rich in vitamin C. The best food sources of vitamin C are citrus fruits and fruit juices, peppers, berries, melons, guava, kiwifruit, tomatoes, cauliflower, and green leafy vegetables. Vitamin C is easily destroyed by prolonged storage, overcooking, and processing of foods.

Absorption of vitamin C occurs in the upper small intestine by an active process or by simple diffusion when large amounts are ingested. Vitamin C is not stored in the body but is taken up by all tissues; the highest levels are found in the pituitary and adrenal glands. The brain ascorbate content in the fetus and neonate is markedly higher than the content in the adult brain, a finding probably related to its function in neurotransmitter synthesis.

When a mother's intake of vitamin C during pregnancy and lactation is adequate, the newborn will have adequate tissue levels of vitamin C related to active placental transfer, subsequently maintained by the vitamin C in breast milk or commercial infant formulas. Breast milk contains sufficient vitamin C to prevent deficiency throughout infancy. Infants consuming pasteurized or boiled animal milk are at significant risk of developing deficiency if the other sources of vitamin C are also lacking in the diet. Neonates whose feeding has been delayed because of a clinical condition can also have ascorbic acid deficiency. For patients receiving total parenteral nutrition (TPN), 80 mg/day is recommended for full-term infants and 25 mg/kg/day for preterm infants. Parents and children who choose a limited (selective) diet or those on fad diets are at risk for vitamin C deficiency.

VITAMIN C DEFICIENCY

A deficiency of vitamin C results in the clinical presentation of **scurvy**. Children fed predominantly heat-treated (ultrahigh-temperature or pasteurized) milk or unfortified formulas and not receiving fruits and fruit juices are at significant risk for symptomatic disease. In the last decade, most cases of scurvy from North America and Europe have been reported in children with developmental and behavioral disorders, *especially autism spectrum disorders,* on highly restrictive diets. Such dietary patterns occur mainly due to severe self-imposed dietary restrictions due to child preference or parental belief in unsubstantiated claims of benefit of such restrictions in autism and other developmental disorders. In scurvy, there is defective formation of connective tissues and collagen in skin, cartilage, dentine, bone, and blood vessels, leading to their fragility. In the long bones, osteoid is not deposited by osteoblasts, the cortex is thin, and the trabeculae become brittle and fracture easily.

Clinical Features

The early manifestations of vitamin C deficiency are irritability, loss of appetite, low-grade fever, musculoskeletal pain, and tenderness in the legs. These signs and symptoms are followed by leg swelling—most marked at the knees and the ankles—and **pseudoparalysis**. The infant might lie with the hips and knees semiflexed and the feet rotated outward. Subperiosteal hemorrhages in the lower-limb bones sometimes acutely increase the swelling and pain, and the condition might mimic acute osteomyelitis or arthritis. A "rosary" at the costochondral junctions and depression of the sternum are other typical features (Fig. 68.1). The angulation of scorbutic beads is usually sharper than that of a rachitic rosary. Gum changes are seen in older children after teeth have erupted, manifested as bluish purple, spongy swellings of the mucous membrane, especially over the upper incisors (Fig. 68.2). **Anemia**, a common finding in infants and young children with scurvy, is related to impaired iron absorption and coexistent hematopoietic nutrient deficiencies, including iron, vitamin B_{12}, and folate. Hemorrhagic manifestations of scurvy include petechiae, purpura, and ecchymoses at pressure points; epistaxis; gum bleeding; and the characteristic perifollicular hemorrhages (Fig. 68.3). Other manifestations are poor wound and fracture healing, hyperkeratosis of hair follicles, arthralgia, and muscle weakness.

Laboratory Findings and Diagnosis

The diagnosis of vitamin C deficiency is usually based on the characteristic clinical picture, the radiographic appearance of the long bones, and a history of poor vitamin C intake. A high index of suspicion is required in children on restrictive diets, particularly those with autism and other developmental disorders, and they should be evaluated for scurvy whenever they present with difficulty in walking or bone pains. The typical radiographic changes occur at the distal ends of the long bones and are particularly common at the knees. The shafts of the long bones have a ground-glass appearance because of trabecular atrophy. The cortex is thin and dense, giving the appearance of *pencil outlining* of the diaphysis and epiphysis. The *white line of Fränkel,* an irregular but thickened white line at the metaphysis, represents the zone of well-calcified cartilage. The epiphyseal centers of ossification also have a ground-glass appearance and are surrounded by a sclerotic ring (Fig. 68.4). The more specific but late radiologic feature of scurvy is a zone of rarefaction under the white line at the metaphysis. This zone of rarefaction *(Trümmerfeld zone),* a linear break in the bone that is proximal and parallel to the white line, represents an area of debris of broken-down bone trabeculae and connective tissue. A *Pelkan spur* is a lateral prolongation of the white line and may be present at the cortical ends. Epiphyseal separation can occur along the line of destruction, with either linear displacement or compression of the epiphysis against the shaft (Fig. 68.5). Subperiosteal hemorrhages are not visible using plain radiographs during the active phase of scurvy. However, during healing, the elevated periosteum becomes calcified and radiopaque (see Fig. 68.5), sometimes giving a dumbbell or club shape to the affected bone. MRI can demonstrate both acute and healing subperiosteal hematomas along with periostitis, metaphyseal changes (Fig. 68.4), and heterogeneous bone marrow signal intensity, even in the absence of changes in plain radiographs. Gelatinous transformation of bone marrow on aspiration has been reported in children with suspected malignancy.

Fig. 68.1 Sharp angulation of beading at costochondral junction (scorbutic rosary) in scurvy. (*Courtesy Dr. J.D. MacLean, McGill Centre for Tropical Diseases, Montreal.)*

Fig. 68.2 Clinical photograph showing inflamed marginal gingiva in scurvy. (*From Agarwal A, Shaharyar A, Kumar A, Bhat MS, Mishra M. Scurvy in pediatric age group: a disease often forgotten? J Clin Orthop Trauma. 2015;6:101–107, Fig. 1, p. 103.)*

Biochemical tests are not very useful in the diagnosis of scurvy, because they do not reflect the tissue status. A plasma ascorbate concentration of <0.2 mg/dL usually is considered deficient. Leukocyte concentration of vitamin C is a better indicator of body stores, but this measurement is technically more difficult to perform. Leukocyte concentrations of ≤10 μg/10^8 white blood cells are considered deficient and indicate latent scurvy, even in the absence of clinical signs of deficiency. Saturation of the tissues with vitamin C can be estimated from the urinary excretion of the vitamin after a test dose of ascorbic acid. In healthy children, 80% of the test dose appears in the urine within 3-5 hours after parenteral administration. Generalized nonspecific aminoaciduria is common in scurvy, whereas plasma amino acid levels remain normal.

Differential Diagnosis

Scurvy is often misdiagnosed as infectious or juvenile idiopathic arthritis, osteomyelitis, nonaccidental trauma (child abuse), malignancy, or acrodynia. The early irritability and bone pain are sometimes attributed to nonspecific pains or other nutritional deficiencies. Copper deficiency results in a radiographic picture similar to that of scurvy. Henoch-Schönlein purpura, (IgA vasculitis) thrombocytopenic purpura, or leukemia is sometimes suspected in children presenting with hemorrhagic manifestations.

Treatment

Vitamin C supplements of 100-200 mg/day orally or parenterally ensure rapid and complete cure. The clinical improvement is seen within 1 week in most cases, but the treatment should be continued for up to 3 months for complete recovery.

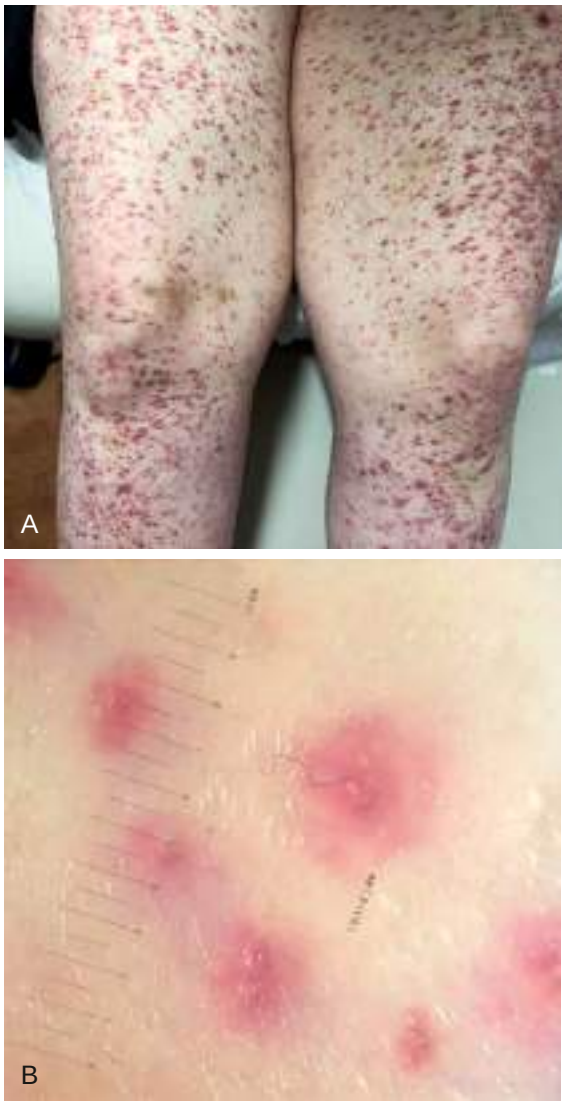

Fig. 68.3 Scurvy. **A,** Perifollicular hemorrhages. **B,** Corkscrew hairs with perifollicular hyperkeratotic papules. (*Modified from Lipner S. A classic case of scurvy. Lancet. 2018;392[10145]:431.)*

Fig. 68.4 **A,** Radiograph of the knee in scurvy demonstrates a radiodense band at the chondroosseous junction (Fränkel line; *long arrows*) and a translucent band in the metaphysis (Trümmerfeld zone; *short arrows*) of the distal femora and the proximal tibiae. **B,** Magnetic resonance imaging (coronal fat saturation T2-weighted imaging) of the knee demonstrates ill-defined T2 hyperintensities in the metaphyses and juxtaosseous soft tissue. The diaphysis was spared. (*From Seya M, Handa A, Hasegawa D, et al. Scurvy: from a selective diet in children with developmental delay. J Pediatr. 2016;177:331, Fig. A and B, p. 331.)*

Fig. 68.5 Large subperiosteal hematoma (SH) with areas of calcification (CAL) is seen along the shaft of the right femur of a child with advanced scurvy. Epiphyseal separation is seen in both knees, with linear displacement (LD) in the left knee and compression (CE) against the shaft in the right knee.

Prevention

Breastfeeding protects against vitamin C deficiency throughout infancy. In children consuming milk formula, fortification with vitamin C must be ensured. Children consuming heat-treated milk or plant-based beverages (e.g., almond milk, soy milk) should consume adequate vitamin C–rich foods in infancy. Dietary or medicinal supplements are required in children on restrictive diets deficient in vitamin C, severely malnourished children, and those with chronic debilitating conditions (e.g., malignancies, neurologic disorders). Providing antenatal supplements of vitamin C to smoking mothers may mitigate some of the harmful effects of smoking on fetal and infant lung development and function.

VITAMIN C TOXICITY

Daily intake of <2 g of vitamin C is generally without adverse effects in adults. Larger doses can cause gastrointestinal problems, such as abdominal pain and osmotic diarrhea. Hemolysis has rarely been reported after high doses of ascorbic acid. Megadoses of vitamin C should be avoided in patients with a history of urolithiasis or conditions related to excessive iron accumulation, such as thalassemia and hemochromatosis. Data are sparse regarding vitamin C toxicity in children. The following values for tolerable upper intake levels are extrapolated from data for adults based on body weight differences: ages 1-3 years, 400 mg; 4-8 years, 650 mg; 9-13 years, 1,200 mg; and 14-18 years, 1,800 mg.

Chapter 69

Vitamin D Deficiency (Rickets) and Excess

Larry A. Greenbaum

RICKETS

Bone consists of a protein matrix called *osteoid* and a mineral phase, principally composed of calcium and phosphate, mostly in the form of *hydroxyapatite*. **Osteomalacia** occurs with inadequate mineralization of bone osteoid in children and adults. **Rickets** is a disease of growing bone caused by unmineralized matrix at the growth plates in children only before fusion of the epiphyses. Because growth plate cartilage and osteoid continue to expand but mineralization is inadequate, the growth plate thickens. Circumference of the growth plate and metaphysis is also greater, increasing bone width at the growth plates and causing classic clinical manifestations, such as widening of the wrists and ankles. The general softening of the bones causes them to bend easily when subject to forces such as weight bearing or muscle pull. This softening leads to a variety of bone deformities.

Rickets is principally caused by vitamin D deficiency. Although largely corrected through public health measures that provided children with adequate vitamin D, rickets remains a persistent problem in developed countries, especially in children with restrictive diets (autism) or elimination diets (fear of allergies). It remains a significant problem in developing countries and may be secondary to nutritional vitamin D deficiency and inadequate intake of calcium (Table 69.1).

Etiology

There are many causes of rickets, including vitamin D disorders, calcium deficiency, phosphorus deficiency, and distal renal tubular acidosis (Table 69.2).

Clinical Manifestations

Most manifestations of rickets are a result of skeletal changes (Table 69.3). **Craniotabes** is a softening of the cranial bones and can be detected by applying pressure at the occiput or over the parietal bones. The sensation is similar to the feel of pressing into a Ping-Pong ball and then releasing. Craniotabes may also be secondary to osteogenesis imperfecta, hydrocephalus, and syphilis. It is a normal finding in many newborns, especially near the suture lines, but typically disappears within a few months of birth. Widening of the costochondral junctions results in a **rachitic "rosary,"** which feels like the beads of a rosary as the examiner's fingers move along the costochondral junctions from rib to rib (Fig. 69.1). Growth plate widening is also responsible for the enlargement at the wrists and ankles (Fig. 69.2). The horizontal depression along the lower anterior chest known as the *Harrison groove* occurs from pulling of the softened ribs by the diaphragm during inspiration. Softening of the ribs also impairs air movement and predisposes patients to atelectasis and pneumonia. Valgus or varus deformities of the legs are common; **windswept deformity** occurs when one leg is in extreme valgus and the other is in extreme varus (Fig. 69.3).

The clinical presentation of rickets may vary based on the etiology. Changes in the lower extremities tend to be the dominant feature in X-linked hypophosphatemic rickets. Symptoms secondary to hypocalcemia occur only in those forms of rickets associated with decreased serum calcium.

Table 69.1 Physical and Metabolic Properties and Food Sources of Vitamins D, E, and K

NAMES AND SYNONYMS	CHARACTERISTICS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	SOURCES
VITAMIN D					
Vitamin D3 (3-cholecalciferol), which is synthesized in the skin, and vitamin D2 (from plants or yeast) are biologically equivalent; 1 μg = 40 IU vitamin D	Fat-soluble, stable to heat, acid, alkali, and oxidation; bile necessary for absorption; hydroxylation in the liver and kidney necessary for biologic activity	Necessary for GI absorption of calcium; also increases absorption of phosphate; direct actions on bone, including mediating resorption	Rickets in growing children; osteomalacia; hypocalcemia can cause tetany and seizures	Hypercalcemia, which can cause emesis, anorexia, pancreatitis, hypertension, arrhythmias, CNS effects, polyuria, nephrolithiasis, renal failure	Exposure to sunlight (UV light); fish oils, fatty fish, egg yolks, and vitamin D–fortified formula, milk, cereals, bread
VITAMIN E					
Group of related compounds with similar biologic activities; α-tocopherol is the most potent and most common form	Fat-soluble; readily oxidized by oxygen, iron, rancid fats; bile acids necessary for absorption	Antioxidant; protection of cell membranes from lipid peroxidation and formation of free radicals	Red cell hemolysis in premature infants; posterior column and cerebellar dysfunction; pigmentary retinopathy	Unknown	Vegetable oils, seeds, nuts, green leafy vegetables, margarine
VITAMIN K					
Group of naphthoquinones with similar biologic activities; K_1 (phylloquinone) from diet; K_2 (menaquinones) from intestinal bacteria	Natural compounds are fat-soluble; stable to heat and reducing agents; labile to oxidizing agent, strong acids, alkali, light; bile salts necessary for intestinal absorption	Vitamin K–dependent proteins include coagulation factors II, VII, IX, and X; proteins C, S, Z; matrix Gla protein, osteocalcin	Hemorrhagic manifestations; long-term bone and vascular health	Not established; analogs (no longer used) caused hemolytic anemia, jaundice, kernicterus, death	Green leafy vegetables, liver, certain legumes and plant oils; widely distributed

CNS, Central nervous system; GI, gastrointestinal; UV, ultraviolet.

Table 69.2 Causes of Rickets

VITAMIN D DISORDERS
- Nutritional vitamin D deficiency
- Congenital vitamin D deficiency
- Secondary vitamin D deficiency
- Malabsorption
- Increased degradation
- Decreased liver 25-hydroxylase
- Vitamin D–dependent rickets types 1A and 1B
- Vitamin D–dependent rickets types 2A and 2B
- Chronic kidney disease

CALCIUM DEFICIENCY
- Low intake
- Diet
- Premature infants (rickets of prematurity)
- Malabsorption
- Primary disease
- Dietary inhibitors of calcium absorption

PHOSPHORUS DEFICIENCY
- Inadequate intake
- Premature infants (rickets of prematurity)
- Aluminum-containing antacids

RENAL LOSSES
- X-linked hypophosphatemic rickets*
- Autosomal dominant hypophosphatemic rickets*
- Autosomal recessive hypophosphatemic rickets types 1, 2, and 3*
- Hereditary hypophosphatemic rickets with hypercalciuria
- Hypophosphatemic rickets with nephrolithiasis and osteoporosis types 1 and 2
- Overproduction of fibroblast growth factor-23
- Tumor-induced rickets*
- McCune-Albright syndrome*
- Epidermal nevus syndrome (cutaneous skeletal hypophosphatemia syndrome)*
- Neurofibromatosis*
- Fanconi syndrome
- Dent disease
- Distal renal tubular acidosis

*Disorders secondary to excess fibroblast growth factor-23.

Table 69.3 Clinical Features of Rickets

GENERAL
- Failure to thrive (malnutrition)
- Listlessness
- Protruding abdomen
- Muscle weakness (especially proximal)
- Hypocalcemic dilated cardiomyopathy
- Fractures (pathologic, minimal trauma)
- Increased intracranial pressure

HEAD
- Craniotabes
- Frontal bossing
- Delayed fontanel closure (usually closed by 2 yr)
- Delayed dentition
  - No incisors by age 10 mo
  - No molars by age 18 mo
- Caries
- Craniosynostosis

CHEST
- Rachitic rosary
- Harrison groove
- Respiratory infections and atelectasis*

BACK
- Scoliosis
- Kyphosis
- Lordosis

EXTREMITIES
- Enlargement of wrists and ankles
- Valgus or varus deformities
- Windswept deformity (valgus deformity of one leg with varus deformity of other leg)
- Anterior bowing of tibia and femur
- Coxa vara
- Leg pain

HYPOCALCEMIC SYMPTOMS†
- Tetany
- Seizures
- Stridor caused by laryngeal spasm

*These features are most frequently associated with the vitamin D deficiency disorders.
†These symptoms develop only in children with disorders that produce hypocalcemia (see Table 69.4).

Fig. 69.1 Rachitic "rosary" in a child with rickets. *(Courtesy Dr. Thomas D. Thacher, Rochester, MN.)*

Fig. 69.2 Hands and forearms of a young child with rickets show prominence above the wrist, resulting from flaring and poor mineralization of lower end of the radius and ulna. *(From Bullough PG. Orthopaedic Pathology, 5th ed. St Louis: Mosby: 2010: Fig 8-31.)*

Fig. 69.3 Windswept deformity of the legs in an older child with rickets. *(From Rickets and osteomalacia. In Hochberg MC, Silman AJ, Smolen JS, et al., eds. Rheumatology, 4th ed. London: Mosby; 2008: Fig 192-6.)*

The chief complaint in a child with rickets is quite variable. Many children present because of skeletal deformities, whereas others have difficulty walking owing to a combination of deformity and weakness. Other common presenting complaints include failure to thrive (malnutrition) and symptomatic hypocalcemia (see Chapters 610-612).

Radiology

Rachitic changes are most easily visualized on posteroanterior radiographs of the wrist, although characteristic rachitic changes can be seen at other growth plates (Figs. 69.4 and 69.5). Decreased calcification leads to thickening of the growth plate. The edge of the metaphysis loses its sharp border, which is described as *fraying*. The edge of the metaphysis changes from a convex or flat surface to a more concave surface. This change to a concave surface is termed *cupping* and is most easily seen at the distal ends of the radius, ulna, and fibula. There is widening of the distal end of the metaphysis, corresponding to the clinical observation of thickened wrists and ankles, as well as the rachitic rosary. Other radiologic features include coarse trabeculation of the diaphysis and generalized rarefaction.

Diagnosis

The diagnosis of rickets is based on the presence of classic radiographic abnormalities. It is supported by physical examination findings, history, and laboratory results consistent with a specific etiology (Table 69.4).

Clinical Evaluation

Because the majority of children with rickets have a nutritional deficiency, the initial evaluation should focus on a **dietary history**, emphasizing intake of both vitamin D and calcium. Most children in industrialized nations receive vitamin D from formula, fortified milk, or vitamin supplements. Along with the amount, the exact composition of the formula or milk is pertinent, because rickets has occurred in children given products that are called "milk" (e.g., soy milk) but are deficient in vitamin D and minerals.

Cutaneous synthesis mediated by sunlight exposure is an important source of vitamin D. It is important to ask about time spent outside, sunscreen use, and clothing, especially if there may be a cultural reason for increased covering of the skin. Because winter sunlight is ineffective at stimulating cutaneous synthesis of vitamin D, the season is an additional consideration. Children with increased skin pigmentation are at increased risk for vitamin D deficiency because of decreased cutaneous synthesis.

The presence of **maternal** risk factors for nutritional vitamin D deficiency, including diet and sun exposure, is an important consideration when a neonate or young infant has rachitic findings, especially if the infant is breastfed (Table 69.5). Determining a child's intake of dairy products, the main dietary source of calcium, provides a general sense of calcium intake. High dietary fiber can interfere with calcium absorption.

The child's **medication** use is relevant, because certain medications, such as the anticonvulsants phenobarbital and phenytoin, increase degradation of vitamin D, and phosphate binders or aluminum-containing antacids interfere with the absorption of phosphate.

Malabsorption of vitamin D is suggested by a history of liver or intestinal disease. Undiagnosed liver or intestinal disease should be suspected if the child has gastrointestinal (GI) symptoms, although occasionally rickets is the presenting complaint. Fat malabsorption is often associated with diarrhea or oily stools, and there may be signs or symptoms suggesting deficiencies of other fat-soluble vitamins (A, E, and K; see Chapters 66, 70, and 71).

A history of **renal disease** (proteinuria, hematuria, urinary tract infections) is an additional significant consideration, given the importance of chronic kidney disease as a cause of rickets. Polyuria can occur in children with chronic kidney disease or Fanconi syndrome.

Children with rickets might have a history of dental caries, poor growth, delayed walking, waddling gait, pneumonia, and hypocalcemic symptoms.

The family history is critical, given the large number of **genetic causes** of rickets, although most of these causes are rare. Along with bone disease, it is important to inquire about leg deformities,

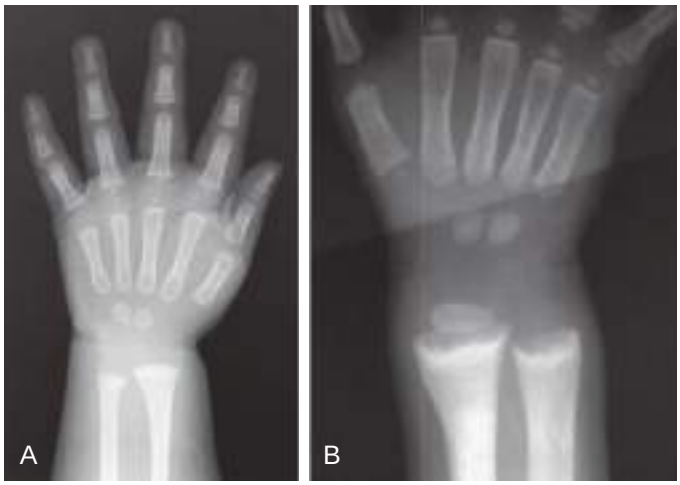

Fig. 69.4 Radiographs of the wrist in normal child (A) and child with rickets (B), who has metaphyseal fraying and cupping of the distal radius and ulna.

Fig. 69.5 Radiographs of the knees in 7-year-old female with distal renal tubular acidosis and rickets. **A,** At initial presentation, there is widening of the growth plate and metaphyseal fraying. **B,** Dramatic improvement after 4 months of therapy with alkali.

Table 69.4 Laboratory Findings in Various Disorders Causing Rickets

DISORDER	Ca	Pi	PTH	25-(OH)D	1,25-$(OH)_2$D	ALP	URINE Ca	URINE Pi
Vitamin D deficiency	N, ↓	↓	↑	↓	↓, N, ↑	↑	↓	↑
VDDR, type 1A	N, ↓	↓	↑	N	↓	↑	↓	↑
VDDR, type 1B	N, ↓	↓	↑	↓	N	↑	↓	↑

Tumor-induced rickets†	N	↓	N	N	RD	↑	↓	↑
Fanconi syndrome	N	↓	N	N	RD or ↑	↑	↓ or ↑	↑
Dent's disease	N	↓	N	N	N	↑	↑	↑
Dietary Ca deficiency	N, ↓	↓	↑	N	↑	↑	↓	↑

*Elevated fibroblast growth factor-23 (FGF-23).
†FGF-23 elevated in some patients.
ADHR, Autosomal dominant hypophosphatemic rickets; ALP, alkaline phosphatase; ARHR, autosomal recessive hypophosphatemic rickets; Ca, calcium; HHRH, hereditary hypophosphatemic rickets with hypercalciuria; N, normal; Pi, inorganic phosphorus; PTH, parathyroid hormone; RD, relatively decreased (because it should be increased given the concurrent hypophosphatemia); VDDR, vitamin D–dependent rickets; XLH, X-linked hypophosphatemic rickets; 1,25-$(OH)_2$D, 1,25-dihydroxyvitamin D; 25-OHD, 25-hydroxyvitamin D; ↓, decreased; ↑, increased; ↑↑, extremely increased.

Table 69.5 Risk Factors for Nutritional Rickets and Osteomalacia and Their Prevention

MATERNAL FACTORS
Vitamin D deficiency
Dark skin pigmentation
Full body clothing cover
High latitude during winter/spring season
Other causes of restricted sun (UVB) exposure (e.g., predominant indoor living, disability, pollution, cloud cover)
Low–vitamin D diet
Low-calcium diet
Poverty, malnutrition, special diets
INFANT/CHILDHOOD FACTORS
Neonatal vitamin D deficiency secondary to maternal deficiency/vitamin D deficiency
Lack of infant supplementation with vitamin D
Prolonged breastfeeding without appropriate complementary feeding from 6 mo
High latitude during winter/spring season
Dark skin pigmentation and/or restricted sun (UVB) exposure (e.g., predominant indoor living, disability, pollution, cloud cover)
Avoidant restrictive food intake disorder
Low–vitamin D diet
Low-calcium diet
Poverty, malnutrition, special diets
PREVENTIVE MEASURES
Sun exposure (UVB content of sunlight depends on latitude and season)
Vitamin D supplementation
Strategic fortification of the habitual food supply
Normal calcium intake

Adapted from Munns CF, Shaw N, Kiely M, et al. Global consensus recommendations on prevention and management of nutritional rickets. *J Clin Endocrinol Metab.* 2016;101:394–415, p. 401.

difficulties with walking, or unexplained short stature, because some parents may be unaware of their diagnosis. Undiagnosed disease in the mother is not unusual in X-linked hypophosphatemia. A history of an unexplained sibling death during infancy may be present in the child with cystinosis, the most common cause of Fanconi syndrome in children.

The physical examination focuses on detecting manifestations of rickets (see Table 69.3). It is important to observe the child's gait, auscultate the lungs to detect atelectasis or pneumonia, and plot the patient's growth. *Alopecia* suggests vitamin D–dependent rickets type 2.

The initial **laboratory tests** in a child with rickets should include serum calcium, phosphorus, alkaline phosphatase (ALP), parathyroid hormone (PTH), 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D (1,25-D), creatinine, and electrolytes (see Table 69.4 for interpretation). Urinalysis is useful for detecting the glycosuria seen with Fanconi syndrome. Evaluation of urinary excretion of calcium (24-hour collection for calcium or calcium:creatinine ratio) is helpful if hereditary hypophosphatemic rickets with hypercalciuria or Dent disease is suspected. Direct measurement of other fat-soluble vitamins (A, E, and K) or indirect assessment of deficiency (prothrombin time for vitamin K deficiency) is appropriate if malabsorption is a consideration.

VITAMIN D DISORDERS

Vitamin D Physiology

Vitamin D can be synthesized in skin epithelial cells and therefore technically is not a vitamin. Cutaneous synthesis is normally the most important source of vitamin D and depends on the conversion of 7-dehydrocholesterol to vitamin D3 (3-cholecalciferol) by ultraviolet B (UVB) radiation from the sun. The efficiency of this process is decreased by melanin; therefore more sun exposure is necessary for vitamin D synthesis in people with increased skin pigmentation. Measures to decrease sun exposure, such as covering the skin with clothing or applying sunscreen, also decrease vitamin D synthesis. Children who spend less time outside have reduced vitamin D synthesis. The winter sun away from the equator is ineffective at stimulating vitamin D synthesis.

There are few natural dietary sources of vitamin D. Fish liver oils have a high vitamin D content. Other good dietary sources include fatty fish and egg yolks. Most children in industrialized countries receive vitamin D via fortified foods, especially formula and milk (both of which contain 400 IU/L) and some breakfast cereals and breads. Supplemental vitamin D may be vitamin D2 (which comes from plants or yeast) or vitamin D3. Breast milk has a low vitamin D content, approximately 12-60 IU/L.

Vitamin D is transported bound to vitamin D–binding protein to the liver, where 25-hydroxlase converts vitamin D into 25-hydroxyvitamin D (25-D), the most abundant circulating form of vitamin D. Because there is little regulation of this liver hydroxylation step, measurement of 25-D is the standard method for determining a patient's vitamin D status. The final step in activation occurs in the kidney, where the enzyme 1α-hydroxylase adds a second hydroxyl group, resulting in 1,25-D. The 1α-hydroxylase is upregulated by PTH and hypophosphatemia and inhibited by hyperphosphatemia and 1,25-D. Most 1,25-D circulates bound to vitamin D–binding protein.

1,25-Dihydroxyvitamin D acts by binding to an intracellular receptor, and the complex affects gene expression by interacting with vitamin D response elements. In the intestine, this binding results in a marked increase in calcium absorption, which is highly dependent on 1,25-D. There is also an increase in phosphorus absorption, but this effect is less significant because most dietary phosphorus absorption is vitamin D independent. 1,25-D also has direct effects on bone, including mediating resorption. 1,25-D directly suppresses PTH secretion by the parathyroid gland, thus completing a negative feedback loop. PTH secretion is also suppressed by the increase in serum calcium mediated by 1,25-D. 1,25-D inhibits its own synthesis in the kidney and increases the synthesis of inactive metabolites.

Nutritional Vitamin D Deficiency

Vitamin D deficiency remains the most common cause of rickets globally and even occurs in industrialized countries. Because vitamin D can be obtained from dietary sources or from cutaneous synthesis, most patients in industrialized countries have a combination of risk factors that lead to vitamin D deficiency.

Etiology

Vitamin D deficiency most frequently occurs in infancy because of a combination of poor intake and inadequate cutaneous synthesis. Transplacental transport of vitamin D, mostly 25-D, typically provides enough vitamin D for the first or second months of life unless there is severe maternal vitamin D deficiency. Infants who receive formula receive adequate vitamin D, even without cutaneous synthesis. Because of the low vitamin D content of breast milk, breastfed infants rely on cutaneous synthesis or vitamin supplements. Cutaneous synthesis can be limited because of the ineffectiveness of the winter sun in stimulating vitamin D synthesis; avoidance of sunlight because of concerns about cancer, neighborhood safety, or cultural practices; and decreased cutaneous synthesis because of increased skin pigmentation.

The effect of skin pigmentation explains why most cases of nutritional rickets in the United States and Northern Europe occur in breastfed children of African descent or other dark-pigmented populations. The additional impact of the winter sun is supported by such infants more often presenting in the late winter or spring. In some groups, complete covering of infants or the practice of not taking infants outside has a significant role, explaining the occurrence of rickets in infants living in areas of abundant sunshine, such as the Middle East. Because the mothers of some infants can

have the same risk factors, decreased maternal vitamin D can also contribute, both by leading to reduced vitamin D content in breast milk and by lessening transplacental delivery of vitamin D. Rickets caused by vitamin D deficiency can also be secondary to dietary practices, such as vegan diets that use unfortified soy milk or rice milk. Children with restrictive food habits (autism) or food elimination diets (fear of allergies) may be at risk for vitamin D deficiency.

Clinical Manifestations

The clinical features are typical of rickets (see Table 69.3), with a significant minority presenting with symptoms of hypocalcemia. Prolonged laryngospasm is occasionally fatal. These children have an increased risk of pneumonia and muscle weakness leading to a delay in motor development.

Laboratory Findings

Table 69.4 summarizes the principal laboratory findings. Hypocalcemia is a variable finding because the elevated PTH acts to increase the serum calcium concentration. The hypophosphatemia is caused by PTH-induced renal losses of phosphate, combined with a decrease in intestinal absorption.

The wide variation in 1,25-D levels (low, normal, or high) is secondary to the upregulation of renal 1α-hydroxylase caused by concomitant hypophosphatemia and hyperparathyroidism. Because serum levels of 1,25-D are much lower than the levels of 25-D, even with low levels of 25-D, there is often enough 25-D still present to act as a precursor for 1,25-D synthesis in the presence of upregulated 1α-hydroxylase. The level of 1,25-D is only low when there is severe vitamin D deficiency.

Some patients have a metabolic acidosis secondary to PTH-induced renal bicarbonate wasting. There may also be generalized aminoaciduria.

Diagnosis and Differential Diagnosis

The diagnosis of nutritional vitamin D deficiency is based on the combination of a history of poor vitamin D intake and risk factors for decreased cutaneous synthesis, radiographic changes consistent with rickets, and typical laboratory findings (see Table 69.4). A normal PTH level almost never occurs with vitamin D deficiency and suggests a primary phosphate disorder.

Treatment

Children with nutritional vitamin D deficiency should receive vitamin D and adequate nutritional intake of calcium and phosphorus. There are two strategies for administration of vitamin D. With **stoss therapy**, vitamin D (300,000-600,000 IU) is administered orally (preferred) or intramuscularly as 2-4 doses over 1 day (vitamin D3 is preferred to D2 because of the longer half-life of D3). Because the doses are observed, stoss therapy is ideal in patients in whom adherence to therapy is questionable. The alternative strategy is daily vitamin D with a minimum dose of 2,000 IU/day for a minimum of 3 months. Either strategy should be followed by daily vitamin D intake of 400 IU/day if <1 year old or 600 IU/day if >1 year old. It is important to ensure that children receive adequate dietary calcium (minimum of 500 mg/day) and phosphorus; this dietary intake is usually provided by milk, formula, and other dairy products, although calcium supplements may be needed in some patients.

Children who have symptomatic hypocalcemia might need intravenous (IV) calcium acutely, followed by oral calcium supplements, which typically can be tapered over 2-6 weeks in children who receive adequate dietary calcium. Transient use of IV or oral 1,25-D (**calcitriol**) is often helpful in reversing hypocalcemia in the acute phase by providing active vitamin D during the delay, as supplemental vitamin D is converted to active vitamin D. Calcitriol doses are typically 0.05 μg/kg/day. IV calcium is initially given as an acute bolus for symptomatic hypocalcemia (20 mg/kg calcium chloride or 100 mg/kg calcium gluconate). Some patients require a continuous IV calcium drip, titrated to maintain the desired serum calcium level. These patients should transition to enteral calcium, and most infants require approximately 1,000 mg of elemental calcium.

Prognosis

Most children with nutritional vitamin D deficiency have an excellent response to treatment, with radiologic healing occurring within a few months. Laboratory test results should also normalize rapidly. Many of the bone malformations improve dramatically, but children with severe disease can have permanent deformities and short stature. Rarely, patients benefit from orthopedic intervention for leg deformities, although this is generally not done until the metabolic bone disease has healed, there is clear evidence that the deformity will not self-resolve, and the deformity is causing functional problems.

Prevention

Most cases of nutritional rickets can be prevented by universal administration of 400 IU of vitamin D to infants <1 year old. Older children with risk factors for inadequate intake should receive 600 IU/day. Vitamin D may be administered as a component of a multivitamin or as a vitamin D supplement.

Congenital Vitamin D Deficiency

Congenital rickets is quite rare in industrialized countries and occurs when there is severe maternal vitamin D deficiency during pregnancy. Maternal risk factors include poor dietary intake of vitamin D, lack of adequate sun exposure, and closely spaced pregnancies. These newborns can have symptomatic hypocalcemia, intrauterine growth restriction, and decreased bone ossification, along with classic rachitic changes (craniotabes, large fontanelle, fractures). In addition, neonates with congenital rickets may have bone pain, weakness, elevated PTH and ALP levels, and hypocalcemia with low serum 25-hydroxyvitamin D levels. Subtler maternal vitamin D deficiency can have an adverse effect on neonatal bone density and birthweight, cause a defect in dental enamel, and predispose infants to neonatal hypocalcemic tetany. Treatment of congenital rickets includes vitamin D supplementation and adequate intake of calcium and phosphorus. Use of prenatal vitamins containing vitamin D (600 IU) prevents this entity.

Secondary Vitamin D Deficiency

Etiology

Along with inadequate intake, vitamin D deficiency can result from inadequate absorption, decreased hydroxylation in the liver, and increased degradation. Because vitamin D is fat soluble, its absorption may be decreased in patients with a variety of liver and GI diseases, including cholestatic liver disease, defects in bile acid metabolism, cystic fibrosis and other causes of pancreatic dysfunction, celiac disease, and Crohn disease. Malabsorption of vitamin D can also occur with intestinal lymphangiectasia and after intestinal resection.

Severe liver disease, which usually is also associated with malabsorption, can cause a decrease in 25-D formation as a result of insufficient enzyme activity. Because of the large reserve of 25-hydroxlase activity in the liver, vitamin D deficiency caused by liver disease usually requires a loss of >90% of liver function. A variety of medications increase the degradation of vitamin D by inducing the cytochrome P450 (CYP) system. Rickets from vitamin D deficiency can develop in children receiving anticonvulsants (e.g., phenobarbital, phenytoin) or antituberculosis medications (e.g., isoniazid, rifampin).

Treatment

Treatment of vitamin D deficiency attributable to malabsorption requires high doses of vitamin D. Because of its better absorption, 25-D (25-50 μg/day or 5-7 μg/kg/day) is superior to vitamin D3. The dose is adjusted based on monitoring of serum levels of 25-D. Alternatively,

patients may be treated with 1,25-D, which also is better absorbed in the presence of fat malabsorption, or with parenteral vitamin D. Children with rickets as a result of increased degradation of vitamin D by the CYP system require the same acute therapy as indicated for nutritional deficiency (discussed earlier), followed by long-term administration of high doses of vitamin D (e.g., 1,000 IU/day), with dosing titrated based on serum levels of 25-D. Some patients require as much as 4,000 IU/day.

Vitamin D–Dependent Rickets, Type 1

Children with vitamin D–dependent rickets **type 1A**, an autosomal recessive disorder, have pathologic gene variants in *CYP27B,* which encodes the renal 1α-hydroxylase, preventing conversion of 25-D into 1,25-D. These patients normally present during the first 2 years of life and can have any of the classic features of rickets (see Table 69.3), including symptomatic hypocalcemia. They have normal levels of 25-D but low levels of 1,25-D (see Table 69.4). Occasionally, 1,25-D levels are at the lower limit of normal, inappropriately low given the high PTH and low serum phosphorus levels, both of which should increase the activity of renal 1α-hydroxylase and cause elevated levels of 1,25-D. As in nutritional vitamin D deficiency, renal tubular dysfunction can cause a metabolic acidosis and generalized aminoaciduria.

Vitamin D–dependent rickets **type 1B** is secondary to pathologic variants in the gene (*CYP2R1*) for the principal 25-hydroxylase. Patients have low levels of 25-D but normal levels of 1,25-D (see Table 69.4).

Treatment

Vitamin D–dependent rickets type 1A responds to long-term treatment with 1,25-D (calcitriol). Initial doses are 0.25-2 μg/day, and lower doses are used once the rickets has healed. Especially during initial therapy, it is important to ensure adequate intake of calcium. The dose of calcitriol is adjusted to maintain a low-normal serum calcium level, a normal serum phosphorus level, and a high-normal serum PTH level. Targeting a low-normal calcium concentration and a high-normal PTH level avoids excessive dosing of calcitriol, which can cause hypercalciuria and nephrocalcinosis. Therefore patient monitoring includes periodic assessment of urinary calcium excretion, with a target of <4 mg/kg/day.

Vitamin D–dependent rickets type 1B may respond to pharmacologic doses of vitamin D2 (3,000 U/day) as a result of alternative enzymes with 25-hydroxylase activity or residual activity of the abnormal protein.

Vitamin D–Dependent Rickets, Type 2

Patients with vitamin D–dependent rickets **type 2A** have pathologic variants in *VDR,* the gene encoding the vitamin D receptor, preventing a normal physiologic response to 1,25-D. Levels of 1,25-D are extremely elevated in this autosomal recessive disorder (see Table 69.4). Most patients present during infancy, although rickets in less severely affected patients might not be diagnosed until adulthood. Less severe disease is associated with a partially functional vitamin D receptor. Approximately 50–70% of children have **alopecia**, which tends to be associated with a more severe form of the disease and can range from alopecia areata to alopecia totalis. Epidermal cysts are a less common manifestation.

Vitamin D–dependent rickets **type 2B** appears to result from overexpression of a hormone response element–binding protein that interferes with the actions of 1,25-D. Alopecia may be present.

Treatment

Some patients respond to extremely high doses of vitamin D2 (25-D or 1,25-D), especially patients without alopecia. This response is caused by a partially functional vitamin D receptor in patients with vitamin D–dependent rickets type 2A, but may also occur in vitamin D–dependent rickets type 2B. All patients should be given a 3- to 6-month trial of high-dose vitamin D and oral calcium. The initial dose of 1,25-D should be 2 μg/day, but some patients require doses as high as 50-60 μg/day. Calcium doses are 1,000-3,000 mg/day. Patients who do not respond to high-dose vitamin D may be treated with long-term IV calcium, with possible transition to very high-dose oral calcium supplements. Treatment of patients who do not respond to vitamin D is difficult.

Chronic Kidney Disease

With chronic kidney disease, there is decreased activity of 1α-hydroxylase in the kidney, leading to diminished production of 1,25-D. In chronic kidney disease, unlike the other causes of vitamin D deficiency, patients have hyperphosphatemia as a result of decreased renal excretion (see Table 69.4 and Chapter 572.2).

Treatment

Therapy requires the use of a form of vitamin D that can act without 1-hydroxylation by the kidney (calcitriol), which both permits adequate absorption of calcium and directly suppresses the parathyroid gland. Because hyperphosphatemia is a stimulus for PTH secretion, normalization of the serum phosphorus level through a combination of dietary phosphorus restriction and use of oral phosphate binders is as important as the use of activated vitamin D.

CALCIUM DEFICIENCY

Pathophysiology

Rickets secondary to inadequate dietary calcium is a significant problem in some countries in Africa, although there are cases in other regions of the world, including industrialized countries. Because breast milk and formula are excellent sources of calcium, this form of rickets develops after children have been weaned from breast milk or formula and is more likely to occur in children who are weaned early. Rickets develops because the diet has low calcium content, typically <200 mg/day if <12 months old or <300 mg/day if >12 months old. The child has minimal intake of dairy products or other sources of calcium. In addition, because of reliance on grains and green leafy vegetables, the diet may be high in phytate, oxalate, and phosphate, which decrease absorption of dietary calcium. In industrialized countries, rickets caused by calcium deficiency can occur in children who consume an unconventional diet. Examples include children with milk allergy who have low dietary calcium and children who transition from formula or breast milk to juice, soda, or a calcium-poor soy drink, without an alternative source of dietary calcium.

This type of rickets can develop in children who receive IV nutrition without adequate calcium. Malabsorption of calcium can occur in celiac disease, intestinal abetalipoproteinemia, and after small bowel resection. There may be concurrent malabsorption of vitamin D.

Clinical Manifestations

Children with calcium deficiency have the classic signs and symptoms of rickets (see Table 69.3). Presentation can occur during infancy or early childhood, although some cases are diagnosed in teenagers. Because calcium deficiency occurs after the cessation of breastfeeding, it tends to occur later than the nutritional vitamin D deficiency that is associated with breastfeeding. In Nigeria, nutritional vitamin D deficiency is most common at 4-15 months of age, whereas calcium deficiency rickets typically occurs at 15-25 months.

Diagnosis

Laboratory findings include increased levels of ALP, PTH, and 1,25-D (see Table 69.4). Calcium levels may be normal or low, although symptomatic hypocalcemia is uncommon. There is decreased urinary excretion of calcium, and serum phosphorus levels may be low as a result of renal wasting of phosphate from secondary hyperparathyroidism. In some children, there is coexisting nutritional vitamin D deficiency, with low 25-D levels.

Treatment

Treatment focuses on providing adequate calcium, typically as a dietary supplement (doses of 700 [age 1-3 years], 1,000 [4-8 years],

and 1,300 [9-18 years] mg/day of elemental calcium are effective). Vitamin D supplementation is necessary if there is concurrent vitamin D deficiency (discussed earlier). Prevention strategies include discouraging early cessation of breastfeeding and increasing dietary sources of calcium. In countries such as Kenya, where many children have diets high in cereal with negligible intake of cow's milk, school-based milk programs have been effective in reducing the prevalence of rickets.

PHOSPHORUS DEFICIENCY

Inadequate Intake

With the exception of starvation or severe anorexia, it is almost impossible to have a diet that is deficient in phosphorus, because phosphorus is present in most foods. Decreased phosphorus absorption can occur in diseases associated with malabsorption (celiac disease, cystic fibrosis, cholestatic liver disease), but if rickets develops, the primary problem is usually malabsorption of vitamin D and/or calcium.

Isolated malabsorption of phosphorus occurs in patients with long-term use of **aluminum-containing antacids**. These compounds are very effective at chelating phosphate in the GI tract, leading to decreased absorption. This decreased absorption results in hypophosphatemia with secondary osteomalacia in adults and rickets in children. This entity responds to discontinuation of the antacid and short-term phosphorus supplementation.

Fibroblast Growth Factor-23

Fibroblast growth factor-23 (**FGF-23**) is a humoral mediator that decreases renal tubular reabsorption of phosphate and therefore decreases serum phosphorus. FGF-23, synthesized by osteocytes, also decreases the activity of renal 1α-hydroxylase, resulting in a decrease in the production of 1,25-D. Increased levels of FGF-23 cause many of the renal phosphate-wasting diseases (see Table 69.2).

X-Linked Hypophosphatemic Rickets

Among the genetic disorders causing rickets because of hypophosphatemia, X-linked hypophosphatemic rickets (**XLH**) is the most common, with a prevalence of 1/20,000. The defective gene is on the X chromosome, but female carriers are affected, so it is an X-linked–dominant disorder.

Pathophysiology

The pathologic variants are in a gene called *PHEX* because it is a *ph*osphate-regulating gene with homology to *e*ndopeptidases on the *X* chromosome. The product of this gene appears to have an indirect role in inactivating FGF-23. Thus pathologic variants in *PHEX* lead to increased levels of FGF-23. Because the actions of FGF-23 include inhibition of phosphate reabsorption in the proximal tubule, phosphate excretion is increased. FGF-23 also inhibits renal 1α-hydroxylase, leading to decreased production of 1,25-D.

Clinical Manifestations

These patients have rickets, but abnormalities of the lower extremities and poor growth are the dominant features. Delayed dentition and tooth abscesses are also common. Some patients have hypophosphatemia and short stature without clinically evident bone disease.

Laboratory Findings

Patients have high renal excretion of phosphate, hypophosphatemia, and increased ALP; PTH and serum calcium levels are normal (see Table 69.4). Hypophosphatemia normally upregulates renal 1α-hydroxylase and should lead to an increase in 1,25-D, but these patients have low or inappropriately normal levels of 1,25-D.

Treatment

Burosumab is a monoclonal antibody to FGF-23 that is approved for treating XLH in children >1 year, although cost may limit its availability in low-resourced countries. Outcomes are better and side effects decreased when compared with conventional therapy. The dose of burosumab is titrated to normalize the serum phosphorus; it is contraindicated in patients with severe renal impairment.

Conventional treatment is a combination of oral phosphorus and 1,25-D (calcitriol). The daily need for phosphorus supplementation is 1-3 g of elemental phosphorus divided into four or five doses. Frequent dosing helps to prevent prolonged decrements in serum phosphorus because there is a rapid decline after each dose. In addition, frequent dosing decreases diarrhea, a complication of high-dose oral phosphorus. Calcitriol is administered at 30-70 ng/kg/day in two doses.

Complications of conventional treatment occur when there is not an adequate balance between phosphorus supplementation and calcitriol. Excess phosphorus, by decreasing enteral calcium absorption, leads to secondary hyperparathyroidism, with worsening of the bone lesions. In contrast, excess calcitriol causes hypercalciuria and nephrocalcinosis and can even cause hypercalcemia. Therefore laboratory monitoring of treatment includes serum calcium, phosphorus, ALP, PTH, and urinary calcium, as well as periodic renal ultrasound to evaluate patients for nephrocalcinosis. Because of variation in the serum phosphorus level and the importance of avoiding excessive phosphorus dosing, normalization of ALP levels is a more useful method of assessing the therapeutic response than measuring serum phosphorus. For children with significant short stature, growth hormone is an effective option. Children with severe deformities might need osteotomies, but these procedures should be done only when treatment has led to resolution of the bone disease.

Prognosis

The response to therapy is usually good, although frequent dosing can lead to problems with compliance with conventional therapy. Girls generally have less severe disease than boys, probably because of the X-linked inheritance. Short stature can persist despite healing of the rickets. Adults generally do well with less aggressive treatment, and options include burosumab, conventional treatment, and no treatment. Adults with bone pain, poorly healing fractures, or other symptoms improve with treatment.

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (**ADHR**) is much less common than XLH. There is incomplete penetrance and variable age of onset. Patients with ADHR have a pathologic variant in the gene encoding FGF-23 *(FGF23)*. The pathologic variant prevents degradation of FGF-23 by proteases, leading its level to increase. The actions of FGF-23 include decreased reabsorption of phosphate in the renal proximal tubule, which results in hypophosphatemia, and inhibition of 1α-hydroxylase in the kidney, causing a decrease in 1,25-D synthesis.

In ADHR, as in XLH, abnormal laboratory findings are hypophosphatemia, elevated ALP level, and a low or inappropriately normal 1,25-D level (see Table 69.4). Treatment is similar to the conventional approach with phosphate supplementation and calcitriol used in XLH. However, iron deficiency, which upregulates FGF-23 synthesis, should be corrected if present.

Autosomal Recessive Hypophosphatemic Rickets

Autosomal recessive hypophosphatemic rickets (**ARHR**) **type 1** is an extremely rare disorder caused by pathologic variants in the *DMP1* gene. ARHR **type 2** occurs in patients with pathologic variants in *ENPP1*. Pathologic variants in *ENPP1* also cause generalized arterial calcification of infancy. **Raine syndrome**, also called **ARHR type 3**, is an autosomal recessive disorder caused by pathologic variants in *FAM20C* and is an osteosclerotic bone dysplasia that is often fatal in the neonatal period. However, patients who survive into childhood may develop rickets.

The three types of ARHR are associated with elevated levels of FGF-23, leading to renal phosphate wasting, hypophosphatemia, and low or inappropriately normal levels of 1,25-D. Treatment is similar to the approach used in XLH, although monitoring for arterial calcification is prudent in patients with *ENPP1* pathologic variants.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria (**HHRH**) is a rare disorder that is mainly found in the Middle East.

Pathophysiology

This autosomal recessive disorder is caused by pathologic variants in the gene for a sodium-phosphate co-transporter in the proximal tubule *(SLC34A3)*. The renal phosphate leak causes hypophosphatemia, which then stimulates production of 1,25-D. The high level of 1,25-D increases intestinal absorption of calcium, suppressing PTH. Hypercalciuria ensues as a result of the high absorption of calcium and the low level of PTH, which normally decreases renal excretion of calcium.

Clinical Manifestations

The dominant symptoms of HHRH are rachitic leg abnormalities (see Table 69.3), muscle weakness, and bone pain. Patients can have short stature, with a disproportionate decrease in the length of the lower extremities. The severity of the disease varies, and some family members have no evidence of rickets but have kidney stones secondary to hypercalciuria.

Laboratory Findings

Laboratory findings include hypophosphatemia, renal phosphate wasting, elevated serum ALP levels, and elevated 1,25-D levels. PTH levels are low (see Table 69.4).

Treatment

Therapy for HHRH patients relies on oral phosphorus replacement (1-2.5 g/day of elemental phosphorus in five divided doses). Treatment of the hypophosphatemia decreases serum levels of 1,25-D and corrects the hypercalciuria. The response to therapy is usually excellent, with resolution of pain, weakness, and radiographic evidence of rickets.

Hypophosphatemic Rickets with Nephrolithiasis and Osteoporosis Types 1 and 2

Hypophosphatemic rickets with nephrolithiasis and osteoporosis type 1 is an autosomal recessive disorder caused by pathologic variants of *SL34A1,* which encodes a phosphate transporter in the proximal tubule. Pathologic variants in the same gene can also cause Fanconi syndrome and infantile hypercalcemia. Hypophosphatemic rickets with nephrolithiasis and osteoporosis type 2 is an autosomal dominant disorder resulting from pathologic variants in *SLC9A3R1* that cause renal phosphate wasting. Laboratory findings and treatment for these disorders are similar to HHRH, with the exception of the features of Fanconi syndrome (see later and Chapter 569) in some patients with the type 1 disorder.

Overproduction of FGF-23

Tumor-induced osteomalacia is more common in adults; in children it can produce classic rachitic findings. Most tumors are mesenchymal in origin and are usually benign, small, and located in bone. These tumors secrete FGF-23 and produce a biochemical phenotype similar to XLH, including urinary phosphate wasting, hypophosphatemia, elevated ALP levels, and low or inappropriately normal 1,25-D levels (see Table 69.4). Curative treatment is excision of the tumor. If the tumor cannot be removed, treatment is identical to that for XLH, including use of burosumab.

Renal phosphate wasting leading to hypophosphatemia and rickets (or osteomalacia in adults) is a potential complication in **McCune-Albright syndrome**, an entity that includes the triad of polyostotic fibrous dysplasia, hyperpigmented macules, and polyendocrinopathy (see Chapter 600.06). Affected patients have inappropriately low levels of 1,25-D and elevated ALP levels. The renal phosphate wasting and inhibition of 1,25-D synthesis are related to the polyostotic fibrous dysplasia. Patients have elevated FGF-23, presumably caused by the dysplastic bone. Hypophosphatemic rickets can also occur in children with isolated polyostotic fibrous dysplasia. Although it is rarely possible, removal of the abnormal bone can cure this disorder in children with McCune-Albright syndrome. Most patients receive the same conventional treatment as children with XLH, with case reports describing off-label treatment with burosumab. Bisphosphonate treatment decreases the pain and fracture risk associated with the bone lesions.

Rickets is an unusual complication of **epidermal nevus syndrome**, which is caused by somatic pathologic variants (Ras family of genes and others). It is called **cutaneous skeletal hypophosphatemia syndrome** when associated with hypophosphatemic rickets or osteomalacia (see Chapter 692). Excessive production of FGF-23 causes renal phosphate wasting and an inappropriately normal or low level of 1,25-D. The timing of presentation with rickets varies from infancy to early adolescence. Hypophosphatemia and rickets have resolved after excision of the epidermal nevi in some patients, but not in others. In most the skin lesions are too extensive to be removed, necessitating treatment with phosphorus supplementation and 1,25-D. Rickets caused by phosphate wasting is an extremely rare complication in children with **neurofibromatosis** (see Chapter 636.1).

Fanconi Syndrome

Fanconi syndrome is secondary to generalized dysfunction of the renal proximal tubule (see Chapter 569.1). There are renal losses of phosphate, amino acids, bicarbonate, glucose, urate, and other molecules that are normally reabsorbed in the proximal tubule. Some patients have partial dysfunction, with less generalized losses. The most clinically relevant consequences are hypophosphatemia caused by phosphate losses and proximal renal tubular acidosis caused by bicarbonate losses. Patients have rickets as a result of hypophosphatemia, with exacerbation from the chronic metabolic acidosis, which causes bone dissolution. Failure to thrive is a consequence of both rickets and renal tubular acidosis. Treatment is dictated by the etiology (see Chapter 569).

Dent Disease

Dent disease is an X-linked disorder usually caused by pathologic variants in the gene encoding a chloride channel expressed in the kidney *(CLCN5)*. Some patients have pathologic variants in the *OCRL1* gene, which can also cause Lowe syndrome (see Chapter 571.3). Affected males have variable manifestations, including hematuria, nephrolithiasis, nephrocalcinosis, rickets, and chronic kidney disease. Almost all patients have low-molecular-weight proteinuria and hypercalciuria. Other, less universal abnormalities are aminoaciduria, glycosuria, hypophosphatemia, and hypokalemia. Rickets occurs in approximately 25% of patients, and it responds to oral phosphorus supplements. Some patients also need 1,25-D, but this treatment should be used cautiously because it can worsen the hypercalciuria.

RICKETS OF PREMATURITY

Rickets in very low birthweight infants has become a significant problem as the survival rate for this group of infants has increased (see Chapter 119.2).

Pathogenesis

The transfer of calcium and phosphorus from mother to fetus occurs throughout pregnancy, but 80% occurs during the third trimester. Premature birth interrupts this process, with rickets developing when the premature infant does not have an adequate supply of calcium and phosphorus to support mineralization of the growing skeleton.

Most cases of rickets of prematurity occur in infants with a birthweight <1,000 g. It is more likely to develop in infants with lower

birthweight and younger gestational age. Rickets occurs because unsupplemented breast milk and standard infant formula do not contain enough calcium and phosphorus to supply the needs of the premature infant. Other risk factors include cholestatic jaundice, a complicated neonatal course, prolonged use of parenteral nutrition, the use of soy formula, and medications such as diuretics and corticosteroids.

Clinical Manifestations

Rickets of prematurity occurs 1-4 months after birth. Infants can have nontraumatic fractures, especially of the legs, arms, and ribs. Most fractures are not suspected clinically. Because fractures and softening of the ribs lead to decreased chest compliance, some infants have respiratory distress from atelectasis and poor ventilation. This rachitic respiratory distress usually develops >5 weeks after birth, distinguishing it from the early-onset respiratory disease of premature infants. These infants have poor linear growth, with negative effects on growth persisting beyond 1 year of age. An additional long-term effect is enamel hypoplasia. Poor bone mineralization can contribute to dolichocephaly. There may be classic rachitic findings, such as frontal bossing, rachitic rosary (see Fig. 69.1), craniotabes, and widened wrists and ankles (see Table 69.3). Most infants with rickets of prematurity have no clinical manifestations, and the diagnosis is based on radiographic and laboratory findings.

Laboratory Findings

Because of inadequate intake, the serum phosphorus level is low or low-normal in patients with rickets of prematurity. The renal response is appropriate, with conservation of phosphate leading to a low urine phosphate level; tubular reabsorption of phosphate is >95%. Most patients have normal levels of 25-D unless there has been inadequate intake or poor absorption (discussed earlier). The hypophosphatemia stimulates renal 1α-hydroxylase, so levels of 1,25-D are high or high-normal. These high levels can contribute to bone demineralization because 1,25-D stimulates bone resorption. Serum levels of calcium are low, normal, or high, and patients often have hypercalciuria. Elevated serum calcium levels and hypercalciuria are secondary to increased intestinal absorption and bone dissolution caused by elevated 1,25-D levels and inability to deposit calcium in bone because of an inadequate phosphorus supply. The hypercalciuria indicates that phosphorus is the limiting nutrient for bone mineralization, although increased provision of phosphorus alone often cannot correct the mineralization defect; increased calcium is also necessary. Thus there is an inadequate supply of calcium and phosphorus, but the deficiency in phosphorus is greater.

Alkaline phosphatase levels are often elevated, but some affected infants have normal levels. In some cases, normal ALP levels may be secondary to resolution of the bone demineralization because of an adequate mineral supply despite the continued presence of radiologic changes, which take longer to resolve. However, ALP levels may be normal despite active disease. No single blood test is 100% sensitive for the diagnosis of rickets. The diagnosis should be suspected in infants with ALP >5-6 times the upper limit of normal (UL) for adults (unless there is concomitant liver disease) or phosphorus <5.6 mg/dL. The diagnosis is confirmed by radiologic evidence of rickets, which is best seen on radiographs of the wrists and ankles. Films of the arms and legs might reveal fractures. The rachitic rosary may be visible on chest radiograph. Unfortunately, radiographs cannot show early demineralization of bone because changes are not evident until there is >20–30% reduction in the bone mineral content.

Diagnosis

Because many premature infants have no overt clinical manifestations of rickets, screening tests are recommended. These tests should include weekly measurements of calcium, phosphorus, and ALP. Periodic measurement of the serum bicarbonate concentration is also important because metabolic acidosis causes dissolution of bone. At least one screening radiograph for rickets at 6-8 weeks of age is appropriate in infants who are at high risk for it; additional films may be indicated in high-risk infants.

Prevention

Provision of adequate amounts of calcium, phosphorus, and vitamin D significantly decreases the risk of rickets of prematurity. Parenteral nutrition is often necessary initially in very premature infants. In the past, adequate parenteral calcium and phosphorus delivery was difficult because of limits secondary to insolubility of these ions when their concentrations were increased. Current amino acid preparations allow higher concentrations of calcium and phosphate, decreasing the risk of rickets. Early transition to enteral feedings is also helpful. These infants should receive either human milk fortified with calcium and phosphorus or preterm infant formula, which has higher concentrations of calcium and phosphorus than standard formula. Soy formula should be avoided because there is decreased bioavailability of calcium and phosphorus. Increased mineral feedings should continue until the infant weighs 3-3.5 kg. These infants should also receive approximately 400 IU/day of vitamin D through formula and vitamin supplements.

Treatment

Therapy for rickets of prematurity focuses on ensuring adequate delivery of calcium, phosphorus, and vitamin D. If mineral delivery has been good and there is no evidence of healing, it is important to screen for vitamin D deficiency by measuring serum 25-D. Measurement of PTH, 1,25-D, and urinary calcium and phosphorus may be helpful in some cases.

DISTAL RENAL TUBULAR ACIDOSIS

Distal renal tubular acidosis usually manifests with failure to thrive. Patients have a metabolic acidosis with an inability to acidify the urine appropriately. Hypercalciuria and nephrocalcinosis are typically present. The many etiologies include autosomal recessive and autosomal dominant forms. Rickets is variable and responds to alkali therapy (see Fig. 69.5 and Chapter 569.2).

HYPERVITAMINOSIS D

Etiology

Hypervitaminosis D is caused by excessive intake of vitamin D. It can occur with long-term high intake or with a substantial, acute ingestion (see Table 69.1). Most cases are secondary to misuse of prescribed or nonprescription vitamin D supplements, but other cases have been secondary to accidental overfortification of milk, contamination of table sugar, and inadvertent use of vitamin D supplements as cooking oil. The recommended upper limits for long-term vitamin D intake are 1,000 IU for children <1 year old and 2,000 IU for older children and adults.

Hypervitaminosis D can also result from excessive intake of synthetic vitamin D analogs (25-D, 1,25-D). Vitamin D intoxication is never secondary to excessive exposure to sunlight, probably because ultraviolet irradiation can transform vitamin D3 and its precursor into inactive metabolites.

Pathogenesis

Although vitamin D increases intestinal absorption of calcium, the dominant mechanism of the hypercalcemia is excessive bone resorption.

Clinical Manifestations

The signs and symptoms of vitamin D intoxication are secondary to hypercalcemia. GI manifestations include nausea, vomiting, poor feeding, constipation, abdominal pain, and pancreatitis.

Possible cardiac findings are hypertension, decreased QT interval, and arrhythmias. The central nervous system effects of hypercalcemia include lethargy, hypotonia, confusion, disorientation, depression, psychosis, hallucinations, and coma. Hypercalcemia impairs renal concentrating mechanisms, which can lead to polyuria, dehydration, and hypernatremia. Hypercalcemia can also lead to acute kidney injury, nephrolithiasis, and nephrocalcinosis, which can result in chronic kidney disease. Deaths are usually associated with arrhythmias or dehydration.

Laboratory Findings

The classic findings in vitamin D intoxication are hypercalcemia, elevated levels of 25-D (>100 ng/mL), hypercalciuria, and suppressed PTH. Hyperphosphatemia is also common. Hypercalciuria can lead to nephrocalcinosis, which is visible on renal ultrasound. Hypercalcemia and nephrocalcinosis can lead to renal insufficiency.

Surprisingly, levels of 1,25-D are usually normal. This may result from downregulation of renal 1α-hydroxylase by the combination of low PTH, hyperphosphatemia, and a direct effect of 1,25-D. The level of free 1,25-D may be high because of displacement from vitamin D–binding proteins by 25-D. Anemia is sometimes present; the mechanism is unknown.

Diagnosis and Differential Diagnosis

The diagnosis is based on the presence of hypercalcemia and an elevated serum 25-D level, although children with excess intake of 1,25-D or another synthetic vitamin D preparation have normal levels of 25-D. With careful sleuthing, there is usually a history of excess intake of vitamin D, although in some situations (overfortification of milk by a dairy), the patient and family may be unaware.

The differential diagnosis of vitamin D intoxication focuses on **other causes of hypercalcemia**. Hyperparathyroidism produces hypophosphatemia, whereas vitamin D intoxication usually causes hyperphosphatemia. Williams syndrome is often suggested by phenotypic features and accompanying cardiac disease. Idiopathic infantile hypercalcemia occurs in children taking appropriate doses of vitamin D. Subcutaneous fat necrosis is a common cause of hypercalcemia in young infants; skin findings are usually present. The hypercalcemia of familial benign hypocalciuric hypercalcemia is mild, asymptomatic, and associated with hypocalciuria. Hypercalcemia of malignancy is an important consideration. Hypercalcemia may occur on a ketogenic diet. High intake of calcium can also cause hypercalcemia, especially in the presence of renal insufficiency. Inquiring about calcium intake should be part of the history in a patient with hypercalcemia. Occasionally, patients are intentionally taking high doses of calcium and vitamin D.

Treatment

The treatment of vitamin D intoxication focuses on control of hypercalcemia. Many patients with hypercalcemia are dehydrated as a result of polyuria from nephrogenic diabetes insipidus, poor oral intake, and vomiting. Rehydration lowers the serum calcium level by dilution and corrects prerenal azotemia. The resultant increased urine output increases urinary calcium excretion. Urinary calcium excretion is also increased by high urinary sodium excretion. The mainstay of the initial treatment is aggressive therapy with normal saline, often in conjunction with a loop diuretic to further increase calcium excretion; this is often adequate for treating mild or moderate hypercalcemia. More significant hypercalcemia usually requires other therapies. Glucocorticoids decrease intestinal absorption of calcium by blocking the action of 1,25-D. There is also a decrease in the levels of 25-D and 1,25-D. The usual dosage of prednisone is 1-2 mg/kg/24 hr.

Calcitonin, which lowers calcium by inhibiting bone resorption, is a useful adjunct, but its effect is usually not dramatic. There is an excellent response to IV or oral bisphosphonates in vitamin D intoxication. Bisphosphonates inhibit bone resorption through their effects on osteoclasts. Hemodialysis using a low or zero dialysate calcium can rapidly lower serum calcium in patients with severe hypercalcemia that is refractory to other measures.

Along with controlling hypercalcemia, it is imperative to eliminate the source of excess vitamin D. Additional sources of vitamin D such as multivitamins and fortified foods should be eliminated or reduced. Avoidance of sun exposure, including the use of sunscreen, is prudent. The patient should also restrict calcium intake.

Prognosis

Most children make a full recovery, but hypervitaminosis D may be fatal or can lead to chronic kidney disease. Because vitamin D is stored in fat, levels can remain elevated for months, necessitating regular monitoring of 25-D, serum calcium, and urine calcium.

Chapter 70

Vitamin E Deficiency

Larry A. Greenbaum

Vitamin E is a fat-soluble vitamin and functions as an antioxidant, but its precise biochemical functions are not known. Vitamin E deficiency can cause hemolysis or neurologic manifestations and occurs in premature infants, in patients with malabsorption, and in an autosomal recessive disorder affecting vitamin E transport. Because of its role as an antioxidant, there is considerable research on vitamin E supplementation in chronic illnesses.

PATHOGENESIS

The term *vitamin E* denotes a group of 8 compounds with similar structures and antioxidant activity. The most potent member of these compounds is α-**tocopherol**, which is also the main form in humans. The best dietary sources of vitamin E are vegetable oils, seeds, nuts, green leafy vegetables, and margarine (see Table 69.1).

The majority of vitamin E is located within cell membranes, where it prevents lipid peroxidation and the formation of free radicals. Other antioxidants, such as ascorbic acid, enhance the antioxidant activity of vitamin E. The importance of other functions of vitamin E is still being delineated.

Premature infants are particularly susceptible to vitamin E deficiency because there is significant transfer of vitamin E during the last trimester of pregnancy. Vitamin E deficiency in premature infants causes thrombocytosis, edema, and hemolysis, potentially causing anemia. The risk of symptomatic vitamin E deficiency was increased by the use of formulas for premature infants that had a high content of polyunsaturated fatty acids (PUFAs). These formulas led to a high content of PUFAs in red blood cell membranes, making them more susceptible to oxidative stress, which could be ameliorated by vitamin E. Oxidative stress was augmented by aggressive use of iron supplementation; iron increases the production of oxygen radicals. The incidence of hemolysis as a result of vitamin E deficiency in premature infants decreased secondary to the use of formulas with a lower content of PUFAs, less aggressive use of iron, and provision of adequate vitamin E.

Because vitamin E is plentiful in common foods, primary dietary deficiency is rare except in premature infants and in severe, generalized malnutrition. Vitamin E deficiency does occur in children with fat malabsorption secondary to the bile acid needed for vitamin E absorption. Although symptomatic disease is most common in children with cholestatic liver disease, it can occur in patients with

cystic fibrosis, celiac disease, short bowel syndrome, and Crohn disease. The autosomal recessive disorder **abetalipoproteinemia** causes fat malabsorption, and vitamin E deficiency is a common complication (see Chapter 106).

In **ataxia with isolated vitamin E deficiency (AVED)**, a rare autosomal recessive disorder, there are pathologic variants in *TTPA*, the gene for α-tocopherol transfer protein. Patients with this disorder are unable to incorporate vitamin E into lipoproteins before their release from the liver, leading to reduced serum levels of vitamin E. There is no associated fat malabsorption, and absorption of vitamin E from the intestine occurs normally.

CLINICAL MANIFESTATIONS

A severe, progressive neurologic disorder occurs in patients with prolonged vitamin E deficiency. Clinical manifestations do not appear until after 1 year of age, even in children with cholestasis since birth. Patients may have cerebellar disease, posterior column dysfunction, and retinal disease. Loss of deep tendon reflexes is usually the initial finding. Subsequent manifestations include limb ataxia (intention tremor, dysdiadochokinesia), truncal ataxia (wide-based, unsteady gait), dysarthria, ophthalmoplegia (limited upward gaze), nystagmus, decreased proprioception (positive Romberg test), decreased vibratory sensation, and dysarthria. Some patients have pigmentary retinopathy. Visual field constriction can progress to blindness. Cognition and behavior can also be affected. Myopathy and cardiac arrhythmias are less common findings.

In premature infants, hemolysis as a result of vitamin E deficiency typically develops during the second month of life. Edema may also be present.

LABORATORY FINDINGS

Serum vitamin E levels increase in the presence of high serum lipid levels, even when vitamin E deficiency is present. Therefore vitamin E status is best determined by measuring the ratio of vitamin E to serum lipids; a ratio <0.8 mg/g is abnormal in older children and adults; <0.6 mg/g is abnormal in infants <1 year. Premature infants with hemolysis caused by vitamin E deficiency also often have elevated platelet counts.

Neurologic involvement can cause abnormal somatosensory evoked potentials and nerve conduction studies. Abnormalities on electroretinography can precede physical examination findings in patients with retinal involvement.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Premature infants with unexplained hemolytic anemia after the first month of life, especially if thrombocytosis is present, either should be empirically treated with vitamin E or should have serum vitamin E and lipid levels measured. Children with neurologic findings and a disease that causes fat malabsorption should have their vitamin E status evaluated.

Because children with AVED do not have symptoms of malabsorption, a correct diagnosis requires a high index of suspicion. **Friedreich ataxia** has been misdiagnosed in some patients (see Chapter 637.1). Children with unexplained ataxia should be screened for vitamin E deficiency.

TREATMENT

For correction of deficiency in neonates, the dose of vitamin E is 25-50 units/day for 1 week, followed by adequate dietary intake. Children with deficiency as a result of malabsorption should receive 1 unit/kg/day, with the dose adjusted based on levels; ongoing treatment is necessary. Children with AVED normalize their serum vitamin E levels with high doses of vitamin E and require ongoing treatment.

PROGNOSIS

The hemolytic anemia in infants resolves with correction of the vitamin E deficiency. Some neurologic manifestations of vitamin E deficiency may be reversible with early treatment, but many patients have little or no improvement. Importantly, treatment prevents progression.

PREVENTION

Premature infants should receive sufficient vitamin E through formula or breast milk fortifier and formula without a high content of PUFAs. Children at risk for vitamin E deficiency as a result of malabsorption should be screened for deficiency and given adequate vitamin E supplementation. Vitamin preparations with high content of all the fat-soluble vitamins are available.

Chapter 71

Vitamin K Deficiency

Larry A. Greenbaum

Vitamin K is necessary for the synthesis of clotting factors II, VII, IX, and X; deficiency of vitamin K can result in clinically significant bleeding. Vitamin K deficiency typically affects infants, who experience a transient deficiency related to inadequate intake, or patients of any age who have decreased vitamin K absorption. Mild vitamin K deficiency can affect long-term bone and vascular health (see Chapters 142 and 529).

PATHOGENESIS

Vitamin K is a group of compounds that have a common naphthoquinone ring structure (see Table 69.1). **Phylloquinone**, called *vitamin K_1*, is present in a variety of dietary sources, with green leafy vegetables, liver, and certain legumes and plant oils having the highest content. Vitamin K_1 is the form used to fortify foods and as a medication in the United States. *Vitamin K_2* is a group of compounds called **menaquinones**, which are produced by intestinal bacteria. There is uncertainty regarding the relative importance of intestinally produced vitamin K_2. Menaquinones are also present in meat, especially liver, and cheese. A menaquinone is used pharmacologically in some countries.

Vitamin K is a cofactor for γ-glutamyl carboxylase, an enzyme that performs posttranslational carboxylation, converting glutamate residues in proteins to **γ-carboxyglutamate (Gla)**. The Gla residues, by facilitating calcium binding, are necessary for protein function.

The classic Gla-containing proteins involved in blood coagulation that are decreased in vitamin K deficiency are factors II (prothrombin), VII, IX, and X. Vitamin K deficiency causes a decrease in proteins C and S, which inhibit blood coagulation, and protein Z, which also has a role in coagulation. All these proteins are made only in the liver, except for protein S, a product of various tissues.

Gla-containing proteins are also involved in bone biology (osteocalcin and protein S) and vascular biology (matrix Gla protein and protein S). Based on the presence of reduced levels of Gla, these proteins appear more sensitive than the coagulation proteins to subtle vitamin K deficiency. Evidence suggests that mild vitamin K deficiency might have a deleterious effect on long-term bone strength and vascular health.

Because it is fat soluble, vitamin K requires the presence of bile salts for its absorption. Unlike other fat-soluble vitamins, there are

limited body stores of vitamin K. In addition, there is high turnover of vitamin K, and the vitamin K–dependent clotting factors have a short half-life. Thus symptomatic vitamin K deficiency can develop within weeks when there is inadequate supply because of low intake or malabsorption.

There are three forms of **vitamin K deficiency bleeding (VKDB)** of the newborn (see Chapter 142). **Early VKDB** was formerly called *classic hemorrhagic disease of the newborn* and occurs at 1-14 days of age. Early VKDB is secondary to low stores of vitamin K at birth as a result of the poor transfer of vitamin K across the placenta and inadequate intake during the first few days of life. In addition, there is no intestinal synthesis of vitamin K_2 because the newborn gut is sterile. Early VKDB occurs mostly in breastfed infants as a consequence of the low vitamin K content of breast milk (formula is fortified). Delayed feeding is an additional risk factor.

Late VKDB most often occurs at 2-12 weeks of age, although cases can occur up to 6 months after birth. Almost all cases are in breastfed infants because of the low vitamin K content of breast milk. An additional risk factor is occult malabsorption of vitamin K, as occurs in children with undiagnosed cystic fibrosis or cholestatic liver disease (e.g., biliary atresia, α_1-antitrypsin deficiency). Without vitamin K prophylaxis, the incidence is 4-10 per 100,000 newborns.

The third form of VKDB of the newborn occurs **at birth** or shortly thereafter. It is secondary to maternal intake of medications (warfarin, phenobarbital, phenytoin) that cross the placenta and interfere with vitamin K function.

VKDB as a result of fat malabsorption can occur in children of any age. Potential etiologies include cholestatic liver disease, pancreatic disease, and intestinal disorders (celiac sprue, inflammatory bowel disease, short bowel syndrome). Prolonged diarrhea can cause vitamin K deficiency, especially in breastfed infants. Children with cystic fibrosis are most likely to have vitamin K deficiency if they have pancreatic insufficiency and liver disease.

Beyond infancy, low dietary intake by itself never causes vitamin K deficiency. However, the combination of poor intake and the use of broad-spectrum antibiotics that eliminate the intestine's vitamin K_2–producing bacteria can cause vitamin K deficiency. This scenario is especially common in the intensive care unit. Vitamin K deficiency can also occur in patients who receive total parenteral nutrition (TPN) without vitamin K supplementation.

CLINICAL MANIFESTATIONS

In early VKDB, the most common sites of bleeding are the gastrointestinal (GI) tract, mucosal and cutaneous tissue, umbilical stump, and the postcircumcision site; intracranial bleeding is less common. GI blood loss can be severe enough to require a transfusion. In contrast, the most common site of bleeding in late VKDB is intracranial, although cutaneous and GI bleeding may be the initial manifestation. Intracranial bleeding can cause convulsions, permanent neurologic sequelae, or death. In some patients with late VKDB, the presence of an underlying disorder may be suggested by jaundice or failure to thrive (malnutrition). Older children with vitamin K deficiency can present with bruising, mucocutaneous bleeding, or more serious bleeding.

Laboratory Findings

In patients with bleeding as a result of vitamin K deficiency, the prothrombin time (PT) is prolonged. The PT must be interpreted based on the patient's age because it is normally prolonged in newborns (see Chapters 142 and 524). The partial thromboplastin time (PTT) is usually prolonged, but may be normal in early deficiency. Factor VII has the shortest half-life of the coagulation factors and is the first to be affected by vitamin K deficiency, but isolated factor VII deficiency does not affect PTT. The platelet count and fibrinogen level are normal.

When there is mild vitamin K deficiency, the PT is normal, but there are elevated levels of the undercarboxylated forms of the proteins that are normally carboxylated in the presence of vitamin K. These undercarboxylated proteins are called *proteins induced by vitamin K absence* (PIVKA). Measurement of undercarboxylated factor II (PIVKA-II) can be used to detect mild vitamin K deficiency. Determination of blood vitamin K levels is less useful because of significant variation based on recent dietary intake; levels do not always reflect tissue stores.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is established by the presence of a prolonged PT that corrects rapidly after administration of vitamin K, which stops the active bleeding. Other possible causes of bleeding and a prolonged PT include disseminated intravascular coagulation (DIC), liver failure, and rare hereditary deficiencies of clotting factors. DIC, which is usually secondary to sepsis, is associated with thrombocytopenia, low fibrinogen, and elevated D-dimers. Severe liver disease results in decreased production of clotting factors; the PT does not fully correct with administration of vitamin K. Children with a hereditary disorder have a deficiency in a specific clotting factor (I, II, V, VII, X).

Coumarin derivatives inhibit the action of vitamin K by preventing its recycling to an active form after it functions as a cofactor for γ-glutamyl carboxylase. Bleeding can occur with overdosage of the common anticoagulant **warfarin** or with ingestion of rodent poison, which contains a coumarin derivative. High doses of salicylates also inhibit vitamin K regeneration, potentially leading to a prolonged PT and clinical bleeding.

TREATMENT

Infants with VKDB should receive 1 mg of parenteral vitamin K. The PT should decrease within 6 hours and normalize within 24 hours. For rapid correction in adolescents, the parenteral dose is 2.5-10 mg. In addition to vitamin K, a patient with severe, life-threatening bleeding should receive an infusion of fresh-frozen plasma (FFP), which corrects the coagulopathy rapidly. Children with vitamin K deficiency caused by malabsorption require chronic administration of high doses of oral vitamin K (2.5 mg twice/week to 5 mg/day). Parenteral vitamin K may be necessary if oral vitamin K is ineffective.

PREVENTION

Administration of either oral or parenteral vitamin K soon after birth prevents early VKDB of the newborn. In contrast, a single dose of oral vitamin K does not prevent a substantial number of cases of late VKDB. However, a single intramuscular (IM) injection of vitamin K (1 mg), the current practice in the United States, is almost universally effective, except in children with severe malabsorption. This increased efficacy of the IM form is thought to be the result of a depot effect. Concerns about an association between parenteral vitamin K at birth and the later development of malignancy are unsubstantiated. Oral vitamin K is a less effective alternative for parents who refuse IM vitamin K, but multiple doses are necessary and rely on home administration.

Discontinuing the offending medications before delivery can prevent VKDB attributable to maternal medications. If this is not possible, administration of vitamin K to the mother may be helpful. In addition, the neonate should receive parenteral vitamin K immediately after birth. If parenteral vitamin K does not correct the coagulopathy rapidly, the child should receive FFP.

Children who are at high risk for malabsorption of vitamin K should receive supplemental vitamin K and periodic measurement of the PT.

Chapter 72

Micronutrient Mineral Deficiencies

Larry A. Greenbaum

Micronutrients include vitamins (see Chapters 66-71) and trace elements. By definition, a **trace element** is <0.01% of the body weight. Trace elements have a variety of essential functions (Table 72.1), although the evidence is not always strong (chromium). With the exception of iron deficiency, trace element deficiency is uncommon in developed countries, but some deficiencies (iodine, zinc, selenium) are important public health problems in a number of developing countries. Because of low nutritional requirements and plentiful supply, deficiencies of some of the trace elements are extremely rare in humans and typically occur in patients receiving unusual diets or prolonged total parenteral nutrition without adequate delivery of a specific trace element. Trace element deficiencies can also occur in children with short bowel syndrome or malabsorption. Excess intake of trace elements is uncommon, but can result from environmental exposure or overuse of supplements (see Table 72.1).

For a number of reasons, children are especially susceptible to trace element deficiency. First, growth creates an increased demand for most trace elements. Second, some organs are more likely to sustain permanent damage because of trace element deficiency during childhood. The developing brain is particularly vulnerable to the consequences of certain deficiency states (iron, iodide). Similarly, adequate fluoride is most critical for dental health during childhood. Third, children, especially in the developing world, are more prone to gastrointestinal disorders that can cause trace element deficiencies because of malabsorption.

A normal diet provides adequate intake of most trace elements. However, the intake of certain trace elements varies significantly in different geographic locations. Iodide-containing food is plentiful near the ocean, but inland areas often have inadequate sources, leading to goiter and **hypothyroidism**. **Iodine deficiency** is not a problem in the United States because of the widespread use of iodized salt; however, symptomatic

Table 72.1 Trace Elements

ELEMENT	PHYSIOLOGY	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	DIETARY SOURCES
Chromium	Potentiates the action of insulin	Impaired glucose tolerance, peripheral neuropathy, and encephalopathy	Unknown	Meat, grains, fruits, and vegetables
Copper	Absorbed via specific intestinal transporter Circulates bound to ceruloplasmin Enzyme cofactor (superoxide dismutase, cytochrome oxidase, and enzymes involved in iron metabolism and connective tissue formation)	Microcytic anemia, osteoporosis, neutropenia, neurologic symptoms, depigmentation of hair and skin	Acute: nausea, emesis, abdominal pain, coma, and hepatic necrosis Chronic toxicity (liver and brain injury) occurs in **Wilson disease** (see Chapter 405.2) and secondary to excess intake (see Chapter 405.3)	Vegetables, grains, nuts, liver, margarine, legumes, corn oil
Fluoride	Incorporated into bone	Dental caries (see Chapter 358)	Chronic: dental fluorosis (see Chapter 353)	Toothpaste, fluoridated water
Iodine	Component of thyroid hormone (see Chapter 580)	Hypothyroidism (see Chapters 601 and 603)	Hypothyroidism and goiter (see Chapters 603 and 605); maternal excess can cause congenital hypothyroidism and goiter (see Chapter 603.1)	Saltwater fish, iodized salt
Iron	Component of hemoglobin, myoglobin, cytochromes, and other enzymes	Anemia (see Chapter 504), decreased alertness, impaired learning	Acute (see Chapter 94): nausea, vomiting, diarrhea, abdominal pain, and hypotension Chronic excess usually secondary to hereditary disorders (see Chapter 511); causes organ dysfunction	Meat, fortified foods Deficiency can also result from blood loss (hookworm infestation, menorrhagia)
Manganese	Enzyme cofactor	Hypercholesterolemia, weight loss, decreased clotting proteins*	Neurologic manifestations, cholestatic jaundice	Nuts, meat, grains, tea
Molybdenum	Enzyme cofactor (xanthine oxidase and others)	Tachycardia, tachypnea, night blindness, irritability, coma*	Hyperuricemia and increased risk of gout	Legumes, grains, liver
Selenium	Enzyme cofactor (prevents oxidative damage)	Cardiomyopathy (**Keshan disease**), myopathy	Nausea, diarrhea, neurologic manifestations, nail and hair changes, garlic odor	Meat, seafood, whole grains, garlic
Zinc	Enzyme cofactor Constituent of zinc-finger proteins, which regulate gene transcription	Decreased growth, dermatitis of extremities and around orifices, impaired immunity, poor wound healing, hypogonadism, diarrhea Supplements are beneficial in diarrhea and improve neurodevelopmental outcomes	Abdominal pain, diarrhea, vomiting Can worsen copper deficiency	Meat, shellfish, whole grains, legumes, cheese

*These deficiency states have been reported only in case reports associated with parenteral nutrition or highly unusual diets.

iodine deficiency (goiter, hypothyroidism) is common in many developing countries. Selenium content of the soil and consequently of food is also quite variable. Dietary **selenium deficiency** (associated with cardiomyopathy) occurs in certain locations, such as some parts of China.

The consequences of severe isolated trace mineral deficiency are illustrated in certain genetic disorders. The manifestations of **Menkes disease** are caused by pathologic variants in the gene coding for a protein that facilitates intestinal copper absorption (see Chapters 639.5 and 703). These pathologic variants result in severe copper deficiency; subcutaneous copper is an effective treatment. Nutritional copper deficiency has been reported in children receiving unsupplemented parenteral nutrition and in children on a ketogenic diet (with associated neutropenia and anemia). The recessive disorder **acrodermatitis enteropathica** is secondary to malabsorption of zinc (see Chapter 712). These patients respond dramatically to zinc supplementation.

Children can have apparently asymptomatic deficiencies of certain trace elements but still benefit from supplementation. As an example, zinc is highly effective in treating children before or during diarrheal illnesses in the developing world.

Zinc deficiency is quite common in the developing world and is often associated with malnutrition or other micronutrient deficiencies (iron). Chronic zinc deficiency is associated with dwarfism, hypogonadism, dermatitis, and T-cell immunodeficiency. Diets rich in phytates bind zinc, impairing its absorption. Zinc supplementation in at-risk children reduces the incidence and severity of diarrhea, pneumonia, and possibly malaria. In developing countries, children who have diarrhea may benefit from zinc supplementation, especially if there is underlying malnutrition.

Fluid and Electrolyte Disorders

PART VI

Chapter 73

Electrolyte and Acid-Base Disorders

73.1 Composition of Body Fluids

Larry A. Greenbaum

TOTAL BODY WATER

Total body water (TBW) as a percentage of body weight varies with age (Fig. 73.1). The fetus has very high TBW, which gradually decreases to approximately 75% of birthweight for a term infant. Premature infants have higher TBW than term infants. During the first year of life, TBW decreases to approximately 60% of body weight and remains at this level until puberty. At puberty, the fat content of females increases more than that in males, who acquire more muscle mass than females. Because fat has very low water content and muscle has high water content, by the end of puberty TBW in males remains at 60%, but TBW in females decreases to approximately 50% of body weight. The high fat content in overweight children causes a decrease in TBW as a percentage of body weight. During dehydration, TBW decreases and thus is a smaller percentage of body weight.

FLUID COMPARTMENTS

TBW is divided between two main compartments: **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. In the fetus and newborn, the ECF volume is larger than the ICF volume (see Fig. 73.1). The normal postnatal diuresis causes an immediate decrease in the ECF volume. This is followed by continued expansion of the ICF volume, which results from cellular growth. By 1 year of age, the ratio of ICF volume to ECF volume approaches adult levels. The ECF volume is approximately 20–25% of body weight, and the ICF volume is approximately 30–40% of body weight, close to twice the ECF volume (Fig. 73.2). With puberty, the increased muscle mass of males causes them to have a higher ICF volume than females. There is no significant difference in the ECF volume between postpubertal females and males.

The ECF is further divided into the plasma water and the interstitial fluid (see Fig. 73.2). The *plasma water* is 5% of body weight. The blood volume, given a hematocrit of 40%, is usually 8% of body weight, although it is higher in newborns and young infants; in premature newborns it is approximately 10% of body weight. The volume of plasma water can be altered by pathologic conditions, including dehydration, anemia, polycythemia, heart failure, abnormal plasma osmolality, and hypoalbuminemia. The *interstitial fluid*, normally 15% of body weight, can increase dramatically in diseases associated with edema, such as heart failure, protein-losing enteropathy, liver failure, nephrotic syndrome, and sepsis. An increase in interstitial fluid also occurs in patients with ascites or pleural effusions.

There is a delicate equilibrium between the intravascular fluid and the interstitial fluid. The balance between hydrostatic and

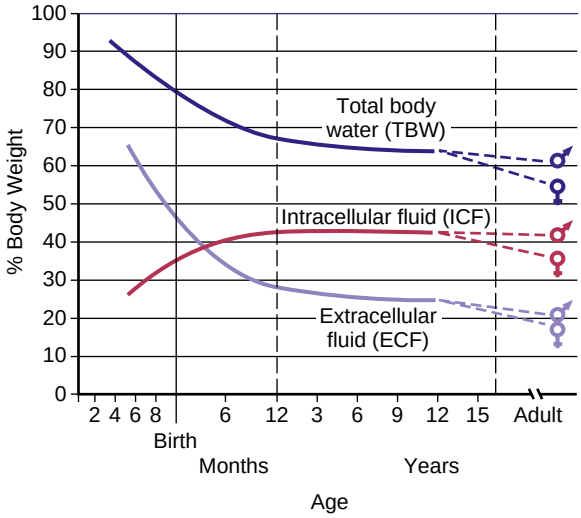

Fig. 73.1 Total body water, intracellular fluid, and extracellular fluid as a percentage of body weight as a function of age. *(From Winters RW. Water and electrolyte regulation. In: Winters RW, ed. The Body Fluids in Pediatrics. Little, Brown; 1973.)*

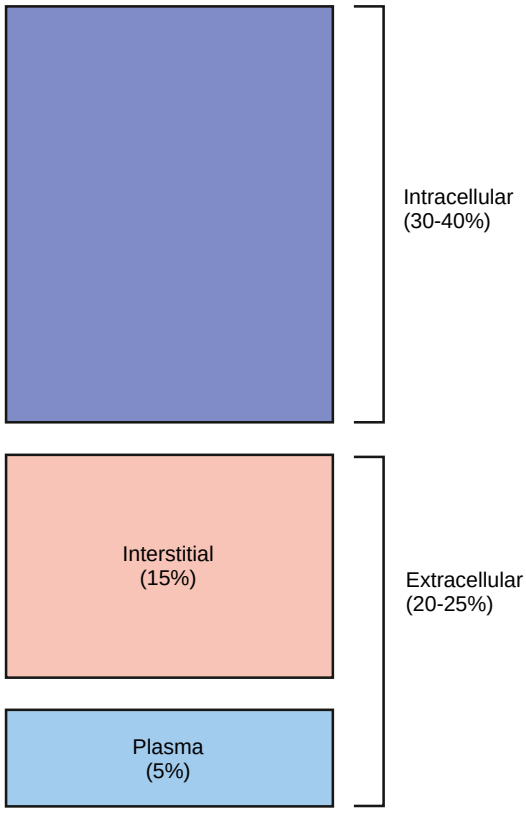

Fig. 73.2 Compartments of total body water, expressed as percentages of body weight, in an older child or adult.

oncotic forces regulates the intravascular volume, which is critical for proper tissue perfusion. The *intravascular fluid* has a higher concentration of albumin than the interstitial fluid, and the consequent oncotic force draws water into the intravascular space. The maintenance of this gradient depends on the limited permeability of albumin across the capillaries. The hydrostatic pressure of the intravascular space, which is caused by the pumping action of the heart, drives fluid out of the intravascular space. These forces favor movement into the interstitial space at the arterial ends of the capillaries. The decreased hydrostatic forces and increased oncotic forces, which result from the dilutional increase in albumin concentration, cause movement of fluid into the venous ends of the capillaries. Overall, there is usually a net movement of fluid out of the intravascular space to the interstitial space, but this fluid is returned to the circulation via the *lymphatics*.

An imbalance in these forces may cause expansion of the interstitial volume at the expense of the intravascular volume. In children with hypoalbuminemia, the decreased oncotic pressure of the intravascular fluid contributes to the development of **edema**. Loss of fluid from the intravascular space may compromise the intravascular volume, placing the child at risk for inadequate blood flow to vital organs. This is especially likely in diseases in which capillary leak occurs because the loss of albumin from the intravascular space is associated with an increase in the albumin concentration in the interstitial space, further compromising the oncotic forces that normally maintain intravascular volume. In contrast, with **heart failure**, there is an increase in venous hydrostatic pressure from expansion of the intravascular volume, which is caused by impaired pumping by the heart, and the increase in venous pressure causes fluid to move from the intravascular space to the interstitial space. Expansion of the intravascular volume and increased intravascular pressure also cause the edema that occurs with acute glomerulonephritis.

ELECTROLYTE COMPOSITION

The composition of the solutes in the ICF and ECF are very different (Fig. 73.3). **Sodium** (Na^+) and **chloride** (Cl^-) are the dominant cation and anion, respectively, in ECF. The sodium and chloride concentrations ([Na^+], [Cl^-]) in the ICF are much lower. **Potassium** (K^+) is the most abundant cation in the ICF, and its concentration ([K^+]) within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is largely determined by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast, the difference in the distribution of cations (Na^+ and K^+) relies on activity of the Na^+,K^+-adenosine triphosphatase (ATPase) pump and membrane ion channels.

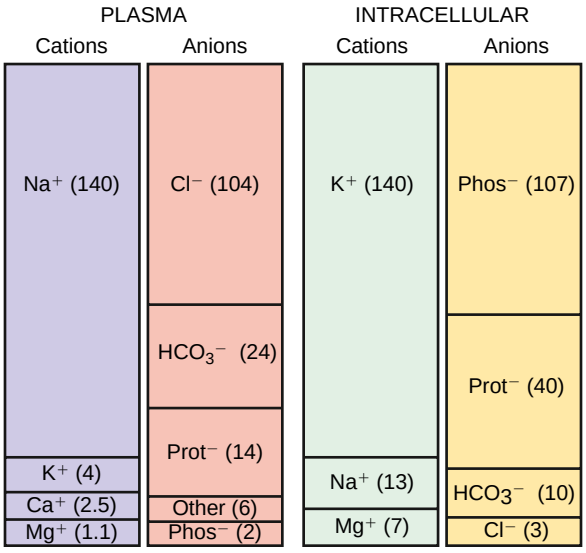

Fig. 73.3 Concentrations of the major cations and anions in the intracellular space and the plasma, expressed in mEq/L.

The difference in the electrolyte compositions of the ECF and the ICF has important ramifications in the evaluation and treatment of electrolyte disorders. Serum concentrations of electrolytes ([Na^+], [K^+], and [Cl^-]) do not always reflect total body content. Intracellular [K^+] is much higher than the serum concentration. A shift of K^+ from the **intracellular space (ICS)** can maintain a normal or even an elevated serum [K^+] despite massive losses of K^+ from the ICS. This effect is seen in diabetic ketoacidosis, in which significant K^+ depletion is masked by transmembrane shift of K^+ from the ICF to the ECF. Therefore, for K^+ and phosphorus, electrolytes with a high intracellular concentration, serum level may not reflect total body content. Similarly, the serum **calcium** concentration ([Ca^{2+}]) does not reflect total body content of Ca^{2+}, which is largely contained in bone (see Chapter 69).

OSMOLALITY

The ICF and the ECF are in **osmotic equilibrium** because the cell membrane is permeable to water. If the osmolality in one compartment changes, then water movement leads to a rapid equalization of osmolality, with a shift of water between the ICS and **extracellular space (ECS)**. Clinically, the primary process is usually a change in the osmolality of the ECF, with resultant shift of water into the ICF if ECF osmolality decreases, or vice versa if ECF osmolality increases. The *ECF osmolality* can be determined and *usually equals ICF osmolality*. **Plasma osmolality**, normally 285-295 mOsm/kg, is measured by the degree of freezing-point depression. The plasma osmolality can also be *estimated* by a calculation based on the following formula:

$$\text{Osmolality} = 2 \times [\text{Na}] + [\text{glucose}]/18 + [\text{BUN}]/2.8$$

Glucose and blood urea nitrogen (BUN) are reported in mg/dL. Division of these values by 18 and 2.8, respectively, converts the units into mmol/L. Multiplication of the [Na^+] value by 2 accounts for its accompanying anions, principally Cl^- and bicarbonate. The calculated osmolality is usually slightly lower than measured osmolality.

Urea is not confined to the ECS because it readily crosses the cell membrane, and its intracellular concentration approximately equals its extracellular concentration. Whereas an elevated [Na^+] causes a shift of water from the ICS, with **uremia** there is no osmolar gradient between the two compartments and consequently no movement of water. The only exception is during **hemodialysis**, when the decrease in extracellular urea is so rapid that intracellular urea does not have time to equilibrate. **Disequilibrium syndrome** during hemodialysis may result in a shift of water into brain cells and lead to severe symptoms. Ethanol, because it freely crosses cell membranes, is another ineffective osmole. Hence, the effective osmolality can be calculated as follows:

$$\text{Effective osmolality} = 2 \times [\text{Na}] + [\text{glucose}]/18$$

The *effective osmolality* determines the osmotic force that is mediating the shift of water between the ECF and the ICF.

Hyperglycemia causes an increase in the plasma osmolality because it is not in equilibrium with the ICS. During hyperglycemia, there is shift of water from the ICS to the ECS. This shift causes dilution of the Na^+ in the ECS, causing hyponatremia despite elevated plasma osmolality. The magnitude of this effect can be calculated as follows:

$$[Na]_{corrected} = [Na]_{measured} + 1.6 \times ([glucose] - 100 \ \ mg/dL)/100$$

where $[Na]_{measured}$ = Na^+ concentration measured by the clinical laboratory and $[Na]_{corrected}$ = corrected Na^+ concentration (the Na^+ concentration if the glucose concentration were normal and its accompanying water moved back into the cells). The $[Na]_{corrected}$ is the more reliable indicator of the ratio of total body Na^+ to TBW, the usual determinant of the $[Na^+]$.

Normally, measured osmolality and calculated osmolality are within 10 mOsm/kg. However, there are some clinical situations in which this difference does not occur. The presence of **unmeasured osmoles** causes measured osmolality to be significantly elevated in comparison with the calculated osmolality. An **osmolal gap** is present when the difference between measured osmolality exceeds calculated osmolality by >10 mOsm/kg. Examples of unmeasured osmoles include ethanol, ethylene glycol, methanol, sucrose, sorbitol, and mannitol. These substances increase measured osmolality but are not part of the equation for calculating osmolality. The presence of an osmolal gap is a clinical clue to the presence of unmeasured osmoles and may be diagnostically useful when there is clinical suspicion of poisoning with methanol or ethylene glycol.

Pseudohyponatremia is a second situation in which there is discordance between measured osmolality and calculated osmolality. Lipids and proteins are the solids of the serum. In patients with elevated serum lipids or proteins, the water content of the serum decreases because water is displaced by the larger amounts of solids. Some instruments measure $[Na^+]$ by determining the amount of Na^+ per liter of serum, including the solid component. When the solid component increases, there is a decrease in $[Na^+]$ per liter of serum, despite a normal concentration when based on the amount of Na^+ per liter of serum water. *It is the concentration of Na^+ in serum water that is physiologically relevant.* A similar problem occurs when using instruments that require dilution of the sample before measurement of Na^+ (indirect potentiometry). In both situations, the plasma osmolality is normal despite the presence of pseudohyponatremia, because the method for measuring osmolality is not appreciably influenced by the percentage of serum that is composed of lipids and proteins. Pseudohyponatremia is diagnosed by the finding of a normal measured plasma osmolality despite hyponatremia. This laboratory artifact does not occur if the $[Na^+]$ in water is measured directly with an ion-specific electrode, as with arterial blood gas (ABG) analyzers. **Pseudohypernatremia** may occur in patients with very low levels of serum proteins by a similar mechanism.

When there are no unmeasured osmoles and pseudohyponatremia is not a concern, the calculated osmolality provides an accurate estimate of the plasma osmolality. Measurement of plasma osmolality is useful for detecting or monitoring unmeasured osmoles and confirming the presence of true hyponatremia. Whereas many children with high plasma osmolality are dehydrated—as seen with hypernatremic dehydration or diabetic ketoacidosis—high osmolality does not always equate with dehydration. A child with salt poisoning or uremia has an elevated plasma osmolality but may be volume overloaded.

POINT-OF-CARE TESTING

Point-of-care (POC) testing offers a number of advantages, including rapid turnaround and usually smaller blood sample volume required. POC devices may provide more accurate results in certain situations, such as pseudohyponatremia (see earlier) and pseudohyperkalemia (see Chapter 73.4). However, the agreement between POC and the laboratory is variable, and thus caution is needed when interpreting results. Because of bias, POC and laboratory results should not be used on an alternating basis when following critical trends (e.g., during correction of hypernatremia or hyponatremia; see Chapter 73.3).

73.2 Regulation of Osmolality and Volume

Larry A. Greenbaum

The regulation of plasma **osmolality** and the intravascular **volume** is controlled by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Maintenance of normal osmolality depends on control of water balance. Control of volume status depends on regulation of sodium balance. When present, volume depletion takes precedence over regulation of osmolality, and retention of water contributes to the maintenance of intravascular volume.

REGULATION OF OSMOLALITY

The plasma osmolality is tightly regulated and maintained at 285-295 mOsm/kg. Modification of water intake and excretion maintains normal plasma osmolality. In the steady state, the combination of water intake and water produced by the body from oxidation balances water losses from the skin, lungs, urine, and gastrointestinal (GI) tract. Only water intake and urinary losses can be regulated.

Osmoreceptors in the hypothalamus sense plasma osmolality (see Chapter 594). An elevated effective osmolality leads to secretion of **antidiuretic hormone (ADH)** by neurons in the supraoptic and paraventricular nuclei in the hypothalamus. The axons of these neurons terminate in the posterior pituitary. Circulating ADH binds to its V_2 receptors in the collecting duct cells of the kidney and causes insertion of water channels (aquaporin-2) into the renal collecting duct cells. This produces increased permeability to water, permitting resorption of water into the hypertonic renal medulla. Urine concentration increases and water excretion decreases. Urinary water losses cannot be eliminated because there is obligatory excretion of urinary solutes, such as urea and sodium. The regulation of ADH secretion is tightly linked to plasma osmolality, responses being detectable with a 1% change in osmolality. ADH secretion virtually disappears when plasma osmolality is low, allowing excretion of maximally dilute urine. The resulting loss of free water (i.e., water without Na^+) corrects plasma osmolality. ADH secretion is not an all-or-nothing response; there is a graded adjustment as the osmolality changes.

Water intake is regulated by hypothalamic osmoreceptors, which stimulate thirst when the serum osmolality increases. Thirst occurs with a small increase in the serum osmolality. *Control of osmolality is subordinate to maintenance of an adequate intravascular volume.* When volume depletion is present, both ADH secretion and thirst are stimulated, regardless of the plasma osmolality. The sensation of thirst requires moderate volume depletion but only a 1–2% change in the plasma osmolality.

A number of conditions can limit the kidney's ability to excrete adequate water to correct low plasma osmolality. In the **syndrome of inappropriate antidiuretic hormone (SIADH)**, ADH continues to be produced despite a low plasma osmolality (see Chapters 73.3 and 597).

The glomerular filtration rate (GFR) affects the kidney's ability to eliminate water. With a decrease in the GFR, less water is delivered to

the collecting duct, limiting the amount of water that can be excreted. The impairment in the GFR must be quite significant to limit the kidney's ability to respond to an excess of water.

The **minimum urine osmolality** is approximately 30-50 mOsm/kg. This places an upper limit on the kidney's ability to excrete water; sufficient solute must be present to permit water loss. Massive water intoxication may exceed this limit, whereas a lesser amount of water is necessary in the child with a diet that has very little solute. This can produce severe hyponatremia in children who receive little salt and have minimal urea production as a result of inadequate protein intake. Volume depletion is an extremely important cause of decreased water loss by the kidney despite a low plasma osmolality. This "appropriate" secretion of ADH occurs because volume depletion takes precedence over the osmolality in the regulation of ADH.

The **maximum urine osmolality** is approximately 1,200 mOsm/kg. The obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute kidney injury. An increase in urinary solute and thus water losses occurs with an **osmotic diuresis**, which results classically from glycosuria in diabetes mellitus as well as iatrogenically after mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, especially a premature newborn, is less than that in an older infant or child. This limits the ability to conserve water and makes such a patient more vulnerable to hypernatremic dehydration. Very high fluid intake, as seen with **psychogenic polydipsia**, can dilute the high osmolality in the renal medulla, which is necessary for maximal urinary concentration. If fluid intake is restricted in patients with this condition, the kidney's ability to concentrate the urine may be somewhat impaired, although this defect corrects after a few days without polydipsia. This may also occur during the initial treatment of central diabetes insipidus with desmopressin acetate; the renal medulla takes time to achieve its normal maximum osmolality.

REGULATION OF VOLUME

An appropriate intravascular volume is critical for survival; both volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The principal extracellular anion, Cl^-, is also necessary, but for simplicity, Na^+ balance is considered the main regulator of volume status because body content of sodium and that of chloride usually change proportionally, given the need for equal numbers of cations and anions. In some situations, Cl^- depletion is considered the dominant derangement causing volume depletion (metabolic alkalosis with volume depletion).

The kidney determines sodium balance because there is little homeostatic control of sodium intake, even though **salt craving** does occasionally occur, typically in children with chronic renal salt loss. The kidney regulates Na^+ balance by altering the percentage of filtered Na^+ that is resorbed along the nephron. Normally, the kidney excretes <1% of the Na^+ filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output match intake, with the kidney having the capacity to adapt to large variations in sodium intake. When necessary, urinary sodium excretion can be reduced to virtually undetectable levels or increased dramatically.

The most important determinant of renal Na^+ excretion is the volume status of the child; it is the effective intravascular volume that influences urinary Na^+ excretion. The *effective intravascular volume* is the volume status that is sensed by the body's regulatory mechanisms. Heart failure is a state of volume overload, but the effective intravascular volume is low because poor cardiac function prevents adequate perfusion of the kidneys and other organs. This explains the avid renal Na^+ retention often present in patients with heart failure.

The **renin-angiotensin system** is an important regulator of renal Na^+ excretion. The juxtaglomerular apparatus produces renin in response to decreased effective intravascular volume. Specific stimuli for renin release are decreased perfusion pressure in the afferent arteriole of the glomerulus, decreased delivery of sodium to the distal nephron, and β_1-adrenergic agonists, which increase in response to intravascular volume depletion. Renin, a proteolytic enzyme, cleaves angiotensinogen, producing angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium resorption *and* stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron—specifically, the late distal convoluted tubule and the collecting duct—aldosterone increases sodium resorption. Aldosterone also stimulates potassium excretion, increasing urinary losses. Along with decreasing urinary loss of sodium, angiotensin II acts as a vasoconstrictor, which helps maintain adequate blood pressure in the presence of volume depletion.

Volume expansion stimulates the synthesis of **atrial natriuretic peptide (ANP)**, which is produced by the atria in response to atrial wall distention. Along with increasing the GFR, ANP inhibits Na^+ resorption in the medullary portion of the collecting duct, facilitating an increase in urinary Na^+ excretion.

Volume overload occurs when Na^+ intake exceeds output. Children with kidney failure have impaired ability to excrete Na^+. The GFR is low at birth, limiting a newborn's ability to excrete a Na^+ load. In other situations, there is a loss of the appropriate regulation of renal Na^+ excretion. This loss of regulation occurs in patients with excessive aldosterone, as seen in primary hyperaldosteronism or renal artery stenosis, where excess renin production leads to high aldosterone levels. In acute glomerulonephritis, even without significantly reduced GFR, the normal intrarenal mechanisms that regulate Na^+ excretion malfunction, causing excessive renal retention of Na^+ and volume overload.

Renal retention of Na^+ occurs during volume depletion, but this appropriate response causes the severe excess in total body Na^+ that is present in heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. In these diseases, the effective intravascular volume is decreased, causing the kidney and the various regulatory systems to respond, leading to renal Na^+ retention and edema formation.

Volume depletion usually occurs when Na^+ losses exceed intake. The most common etiology in children is gastroenteritis. Excessive losses of sodium may also occur from the skin in children with burns, in sweat from patients with cystic fibrosis, or after vigorous exercise. Inadequate intake of Na^+ is uncommon except in neglect, in famine, or with an inappropriate choice of liquid diet in a child who cannot take solids. Urinary Na^+ wasting may occur in a range of renal diseases, from renal dysplasia to tubular disorders, such as Bartter syndrome. The neonate, especially if premature, has a mild impairment in the ability to conserve Na^+. Iatrogenic renal Na^+ wasting takes place during diuretic therapy. Renal Na^+ loss occurs as a result of derangement in the normal regulatory systems. An absence of aldosterone, seen most frequently in children with **congenital adrenal hyperplasia** caused by 21-hydroxylase deficiency, causes sodium wasting (see Chapter 616).

Isolated disorders of water balance can affect volume status and Na^+ balance. Because the cell membrane is permeable to water, changes in TBW influence both the extracellular volume and the intracellular volume. In isolated water loss, as occurs in diabetes insipidus, the impact is greater on the ICS because it has a greater volume than the ECS. Thus, compared with other types of dehydration, hypernatremic dehydration has less impact on plasma volume; most of the fluid loss comes from the ICS. Yet, significant water loss eventually affects intravascular volume and will stimulate renal Na^+ retention, even if total body Na^+ content is normal. Similarly, with acute water intoxication or SIADH, there is an excess of TBW, but most is in the ICS. However, there is some effect on the intravascular volume, which causes renal excretion

of Na^+. Children with SIADH or water intoxication have high urine Na^+ concentration despite hyponatremia. This finding reinforces the concept of independent control systems for water and Na^+, but the 2 systems interact when pathophysiologic processes dictate, and control of effective intravascular volume always takes precedence over control of osmolality.

73.3 Sodium

Larry A. Greenbaum

SODIUM METABOLISM

Body Content and Physiologic Function

Sodium is the dominant cation of the ECF (see Fig. 73.3), and it is the principal determinant of extracellular osmolality. Na^+ is therefore necessary for the maintenance of intravascular volume. Less than 3% of Na^+ is intracellular. More than 40% of total body Na^+ is in bone; the remainder is in the interstitial and intravascular spaces. The low intracellular [Na^+], approximately 10 mEq/L, is maintained by Na^+,K^+-ATPase, which exchanges intracellular Na^+ for extracellular K^+.

Sodium Intake

A child's diet determines the amount of Na^+ ingested—a predominantly cultural determination in older children. An occasional child has salt craving because of an underlying salt-wasting renal disease or adrenal insufficiency. Children in the United States tend to have very high salt intakes because their diets include a large amount of "junk" food or fast food. Infants receive sodium from breast milk (approximately 7 mEq/L) and formula (7-13 mEq/L, for 20 calorie/oz formula).

Sodium is readily absorbed throughout the GI tract. Mineralocorticoids increase sodium transport into the body, although this effect has limited clinical significance. The presence of glucose enhances sodium absorption because of the presence of a co-transport system. This is the rationale for including sodium and glucose in oral rehydration solutions (see Chapter 387).

Sodium Excretion

Sodium excretion occurs in stool and sweat, but the kidney regulates Na^+ balance and is the principal site of Na^+ excretion. There is some Na^+ loss in stool, but it is minimal unless diarrhea is present. Normally, sweat has 5-40 mEq/L of sodium. Sweat [Na^+] is increased in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism. The higher sweat losses in these conditions may cause or contribute to Na^+ depletion.

Sodium is unique among electrolytes because water balance, not Na^+ balance, usually determines its concentration. When the [Na^+] increases, the resultant higher plasma osmolality causes increased thirst and increased secretion of ADH, which leads to renal conservation of water. Both these mechanisms increase the water content of the body, and the [Na^+] returns to normal. During hyponatremia, the decrease in plasma osmolality stops ADH secretion, and consequent renal water excretion leads to an increase in the [Na^+]. Even though water balance is usually regulated by osmolality, volume depletion does stimulate thirst, ADH secretion, and renal conservation of water. Volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion, even if a patient has hyponatremia.

The excretion of Na^+ by the kidney is not regulated by the plasma osmolality. The patient's effective plasma volume determines the amount of sodium in the urine. This is mediated by a variety of regulatory systems, including the renin-angiotensin-aldosterone system and intrarenal mechanisms. In hyponatremia or hypernatremia, the underlying pathophysiology determines the amount of urinary Na^+, not the serum [Na^+].

Table 73.1 Causes of Hypernatremia

EXCESSIVE SODIUM
Improperly mixed formula
Excess sodium bicarbonate
Ingestion of seawater or sodium chloride
Intentional salt poisoning (child abuse or fictitious disorder inflicted on another)
Intravenous hypertonic saline
Sodium phosphate enemas
Hyperaldosteronism
WATER DEFICIT
Nephrogenic Diabetes Insipidus

HYPERNATREMIA

Hypernatremia is a [Na^+] >145 mEq/L, although it is sometimes defined as >150 mEq/L. Mild hypernatremia is common in children, especially among infants with gastroenteritis. Hypernatremia in hospitalized patients may be iatrogenic, which is caused by inadequate water administration or, less often, by excessive Na^+ administration. Moderate or severe hypernatremia has significant morbidity because of the underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

Etiology and Pathophysiology

There are three basic mechanisms of hypernatremia (Table 73.1). *Sodium intoxication* may be iatrogenic in a hospital setting because of correction of metabolic acidosis with sodium bicarbonate. Baking soda, a putative home remedy for upset stomach, is another source of sodium bicarbonate; the hypernatremia is accompanied by a profound metabolic alkalosis. Hypernatremia may develop following sodium phosphate emesis. In hyperaldosteronism, there is renal retention of sodium and resultant hypertension; hypernatremia may not be present or is usually mild.

The classic causes of hypernatremia from a *water deficit* are **nephrogenic** and **central diabetes insipidus** (see Chapters 570 and 596). Hypernatremia develops in diabetes insipidus only if the patient does not have access to water or cannot drink adequately because of immaturity, neurologic impairment, emesis, or anorexia. Infants are at high risk because of their inability to control their own water intake. Central diabetes insipidus and the genetic forms of nephrogenic diabetes insipidus typically cause massive urinary water losses and very dilute urine. The water losses are less dramatic, and the urine often has the same osmolality as plasma when nephrogenic diabetes insipidus is secondary to intrinsic renal disease (obstructive uropathy, renal dysplasia, sickle cell disease).

The other causes of a water deficit are also secondary to an imbalance between losses and intake. Newborns, especially if premature, have high insensible water losses. Losses are further increased if the infant is placed under a radiant warmer or with the use of phototherapy for hyperbilirubinemia. The renal concentrating mechanisms are not optimal at birth, providing an additional source of water loss. Ineffective breastfeeding, often in a primiparous mother, can cause severe hypernatremic dehydration. **Adipsia**, the absence of thirst, is usually secondary to damage to the hypothalamus, such as from trauma, tumor, hydrocephalus, or histiocytosis. Primary adipsia (**essential hypernatremia**) is rare but is seen in children with central nervous system (CNS) malformations (septo-optic dysphasia, holoprosencephaly, optic nerve hypoplasia).

When hypernatremia occurs in conditions with *deficits of sodium and water,* the water deficit exceeds the sodium deficit. This occurs only if the patient is unable to ingest adequate water. Diarrhea results in depletion of both Na^+ and water. Because diarrhea is hypotonic—typical Na^+ concentration of 35-65 mEq/L—water losses exceed Na^+ losses, potentially leading to hypernatremia. Most children with gastroenteritis do not have hypernatremia because they drink enough hypotonic fluid to compensate for stool water losses (see Chapter 387). Fluids such as water, juice, and formula are more hypotonic than the stool losses, allowing correction of the water deficit and potentially even causing hyponatremia. Hypernatremia is most likely to occur in the child with diarrhea who has inadequate intake because of emesis, lack of access to water, or anorexia.

Osmotic agents, including mannitol, and glucose in diabetes mellitus, cause excessive renal losses of water and Na^+. Because the urine is hypotonic ($[Na^+]$ of approximately 50 mEq/L) during an osmotic diuresis, water loss exceeds Na^+ loss, and hypernatremia may occur if water intake is inadequate. Certain chronic kidney diseases, such as renal dysplasia and obstructive uropathy, are associated with tubular dysfunction, leading to excessive losses of water and Na^+. Many children with such diseases have disproportionate water loss and are at risk for hypernatremic dehydration, especially if gastroenteritis supervenes. Similar mechanisms occur during the polyuric phase of acute kidney injury and after relief of urinary obstruction (postobstructive diuresis). Patients with either condition may have an osmotic diuresis from urinary losses of urea and an inability to conserve water because of tubular dysfunction.

Clinical Manifestations

Most children with hypernatremia are dehydrated and show the typical clinical signs and symptoms (see Chapter 75). Children with hypernatremic dehydration tend to have better preservation of intravascular volume because of the shift of water from the ICS to the ECS. This shift maintains blood pressure and urine output and allows hypernatremic infants to be less symptomatic initially and potentially to become more dehydrated before medical attention is sought. Breastfed infants with hypernatremia are often profoundly dehydrated, with failure to thrive (malnutrition). Probably because of intracellular water loss, the pinched abdominal skin of a dehydrated, hypernatremic infant has a "doughy" feel.

Hypernatremia, even without dehydration, causes central nervous system (CNS) symptoms that tend to parallel the degree of $[Na^+]$ elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperpnea. Alert patients are very thirsty, even though nausea may be present. Hypernatremia may cause fever, although many patients have an underlying process that contributes to the fever. Hypernatremia is associated with hyperglycemia and mild hypocalcemia; the mechanisms are unknown. Beyond the sequelae of dehydration, there is no clear direct effect of hypernatremia on other organs or tissues, except the brain.

Brain hemorrhage is the most devastating consequence of *untreated* hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, leading to a decrease in brain volume. This decrease can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhages. Seizures and coma are possible sequelae of the hemorrhage, although seizures are more common during correction of hypernatremia. The cerebrospinal fluid protein is often elevated in infants with significant hypernatremia, probably because of leakage from damaged blood vessels. Neonates, especially if premature, seem especially vulnerable to hypernatremia and excessive sodium intake. There is an association between rapid or hyperosmolar sodium bicarbonate administration and the development of intraventricular hemorrhages in neonates. Even though **osmotic demyelination syndrome (ODS)**, which includes central pontine myelinolysis and extrapontine myelinolysis, is classically associated with overly rapid correction of hyponatremia, it can occur in children with hypernatremia (see "Treatment"). Thrombotic complications occur in severe hypernatremic dehydration, including stroke, dural sinus thrombosis, peripheral thrombosis, and renal vein thrombosis. This is secondary to dehydration and possibly hypercoagulability associated with hypernatremia.

Diagnosis

The etiology of hypernatremia is usually apparent from the history. Hypernatremia resulting from water loss occurs only if the patient does not have access to water or is unable to drink. In the absence of dehydration, it is important to ask about sodium intake. Children with excess salt intake do not have signs of dehydration, unless another process is present. Severe Na^+ intoxication causes signs of volume overload, such as pulmonary edema and weight gain. **Salt poisoning** is associated with an elevated fractional excretion of Na^+, whereas hypernatremic dehydration causes a low fractional excretion of Na^+. Gastric sodium concentrations are often elevated in salt poisoning. In hyperaldosteronism, hypernatremia is usually mild or absent and is associated with edema, hypertension, hypokalemia, and metabolic alkalosis.

When there is isolated water loss, the signs of volume depletion are usually less severe initially because much of the loss is from the ICS. When pure water loss causes signs of dehydration, the hypernatremia and water deficit are usually severe. In the child with renal water loss, either central or nephrogenic diabetes insipidus, the urine is inappropriately dilute and urine volume is not low. The urine is maximally concentrated and urine volume is low if the losses are extrarenal or caused by inadequate intake. With extrarenal causes of loss of water, the urine osmolality should be >1,000 mOsm/kg. When diabetes insipidus is suspected, the evaluation may include measurement of ADH and a water-deprivation test, including a trial of desmopressin acetate (synthetic ADH analog) to differentiate between nephrogenic diabetes insipidus and central

diabetes insipidus (see Chapters 570 and 596). A water-deprivation test is unnecessary if the patient has simultaneous documentation of hypernatremia and poorly concentrated urine (osmolality lower than that of plasma). In children with central diabetes insipidus, administration of desmopressin acetate increases the urine osmolality above the plasma osmolality, although maximum osmolality does not occur immediately because of the decreased osmolality of the renal medulla as a result of the chronic lack of ADH. In children with nephrogenic diabetes insipidus, there is no response to desmopressin acetate. *Hypercalcemia or hypokalemia may produce a nephrogenic diabetes insipidus–like syndrome.*

With combined Na^+ and water deficits, analysis of the urine differentiates between renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, concentrated urine, and Na^+ retention (urine $[Na^+]$ <20 mEq/L, fractional excretion of Na^+ <1%). With renal causes, the urine volume is not appropriately low, the urine is not maximally concentrated, and the urine $[Na^+]$ may be inappropriately elevated.

Treatment

As hypernatremia develops, the brain generates **idiogenic osmoles** to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum $[Na^+]$ is lowered rapidly, there is movement of water from the serum into the brain cells to equalize the osmolality in the two compartments. The resultant brain swelling may manifest as seizures or coma.

Because of the associated dangers, *chronic hypernatremia should not be corrected rapidly.* The goal is to decrease the serum $[Na^+]$, but avoid a decrease of more than 10 mEq/L every 24 hours. The most important component of correcting moderate or severe hypernatremia is frequent monitoring of the serum $[Na^+]$ value so that fluid therapy can be adjusted to provide adequate correction, neither too slow nor too fast. If a child has seizures because of brain edema secondary to rapid correction, administration of hypotonic fluid should be stopped. An infusion of 3% saline can acutely increase the serum $[Na^+]$, reversing the cerebral edema.

Chapter 75 outlines a detailed approach to the child with hypernatremic dehydration. Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly with 5% dextrose in water (D5W) because idiogenic osmoles have not had time to accumulate. This fact balances the high morbidity and mortality rates associated with hypernatremia with the dangers of overly rapid correction. When hypernatremia is severe and is caused by sodium intoxication, it may be impossible to administer enough water to correct the hypernatremia rapidly without worsening the volume overload. In this situation, dialysis allows for removal of the excess Na^+, with the precise strategy dependent on the mode of dialysis. In less severe cases, the addition of a loop diuretic increases the removal of excess Na^+ and water, decreasing the risk of volume overload. With Na^+ overload, hypernatremia is corrected with Na^+-free intravenous (IV) fluid (D5W).

Hyperglycemia from hypernatremia is not usually a problem and is not treated with insulin because the acute decrease in glucose may precipitate cerebral edema by lowering plasma osmolality. Rarely, the glucose concentration of IV fluids must be reduced (from 5% to 2.5% dextrose in water). The secondary hypocalcemia is treated as needed.

It is important to address the underlying cause of the hypernatremia, if possible. The child with central diabetes insipidus should receive desmopressin acetate. Because this treatment reduces renal excretion of water, excessive intake of water must be avoided to prevent both overly rapid correction of the hypernatremia and the development of hyponatremia. Over the long-term, reduced sodium intake and the use of medications can somewhat ameliorate the water losses in nephrogenic diabetes insipidus (see Chapter 570). The daily water intake of a child receiving tube feeding may need to be increased to compensate for high losses. The patient with significant ongoing losses, such as through diarrhea, may need supplemental water and electrolytes (see Chapter 74). Sodium intake is reduced if it contributed to the hypernatremia.

HYPONATREMIA

Hyponatremia, a very common electrolyte abnormality in hospitalized patients, is a serum sodium level <135 mEq/L. Both total body sodium and TBW determine the serum sodium concentration. Hyponatremia exists when the ratio of water to Na^+ is increased. This condition can occur with low, normal, or high levels of body Na^+. Similarly, body water can be low, normal, or high.

Etiology and Pathophysiology

Table 73.2 lists the causes of hyponatremia. **Pseudohyponatremia** is a laboratory artifact present when the plasma contains very high concentrations of protein (multiple myeloma, intravenous immune globulin [IVIG] infusion) or lipid (hypertriglyceridemia, hypercholesterolemia). It does not occur when a direct ion-selective electrode determines the $[Na^+]$ in undiluted plasma, a technique that is used by ABG analyzers or POC instruments (see Chapter 73.1). In true hyponatremia, the measured osmolality is low, whereas it is normal in pseudohyponatremia. **Hyperosmolality,** as may occur with hyperglycemia, causes a low $[Na^+]$ because water moves down its osmotic gradient from the ICS into the ECS, diluting the $[Na^+]$. However, because the manifestations of hyponatremia are a result of the low plasma osmolality, patients with hyponatremia resulting from hyperosmolality do not have symptoms of hyponatremia. When the etiology of the hyperosmolality resolves, such as hyperglycemia in diabetes mellitus, water moves back into the cells, and the $[Na^+]$ rises to its "true" value. Mannitol or sucrose, a component of IVIG preparations, may cause hyponatremia because of hyperosmolality.

Classification of hyponatremia is based on the patient's volume status. In **hypovolemic hyponatremia,** the child has lost Na^+ from the body. The water balance may be positive or negative, but Na^+ loss has been higher than water loss. The pathogenesis of the hyponatremia is usually a combination of Na^+ loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains Na^+. Most fluid that is lost has a lower $[Na^+]$ than that of plasma. Viral diarrhea fluid has an average $[Na^+]$ of 50 mEq/L. Replacing diarrhea fluid, which has $[Na^+]$ of 50 mEq/L, with formula, which has only approximately 7-10 mEq/L of Na^+, reduces the serum $[Na^+]$. Intravascular volume depletion interferes with renal water excretion, the body's usual mechanism for preventing hyponatremia. The volume depletion stimulates ADH synthesis, resulting in renal water retention. Volume depletion also decreases the GFR and enhances water resorption in the proximal tubule, thereby reducing water delivery to the collecting duct.

Diarrhea as a result of gastroenteritis is the most common cause of hypovolemic hyponatremia in children. Emesis causes hyponatremia if the patient takes in hypotonic fluid, either IV or enterally, despite the emesis. Most patients with emesis have either a normal $[Na^+]$ or hypernatremia. Burns may cause massive losses of isotonic fluid and resultant volume depletion. Hyponatremia develops if the patient receives hypotonic fluid. Losses of sodium from sweat are especially high in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism, although high losses can also occur in a hot climate. Third space losses are isotonic and can cause significant volume depletion, leading to ADH production and water retention, which can cause hyponatremia if the patient receives hypotonic fluid. In diseases that cause volume depletion through extrarenal Na^+ loss, the urine Na^+ level should be low (<10 mEq/L) as part of the renal response to maintain the intravascular volume. The only exceptions are diseases that cause both extrarenal and renal Na^+ losses: adrenal insufficiency and pseudohypoaldosteronism.

Table 73.2 Causes of Hyponatremia

PSEUDOHYPONATREMIA
Hyperlipidemia
Hyperproteinemia
HYPEROSMOLALITY
Hyperglycemia

Juvenile nephronophthisis (OMIM 256100/606966/602088/604387/611498)
Autosomal recessive polycystic kidney disease (OMIM 263200)
Tubulointerstitial nephritis
Obstructive uropathy
Cerebral salt wasting
Proximal (type II) renal tubular acidosis (OMIM 604278)*
Lack of aldosterone effect (high serum potassium):
Absence of aldosterone (e.g., 21-hydroxylase deficiency [OMIM 201910])
Pseudohypoaldosteronism type I (OMIM 264350/177735)
Urinary tract obstruction and/or infection
Addison disease
EUVOLEMIC HYPONATREMIA
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Nephrogenic syndrome of inappropriate antidiuresis (OMIM 304800)
Desmopressin acetate
Glucocorticoid deficiency
Hypothyroidism
Antidepressant medications
Water intoxication
Iatrogenic (excess hypotonic intravenous fluids)
Feeding infants excessive water products
Swimming lessons
Tap water enema
Child abuse
Psychogenic polydipsia
Diluted formula
Beer potomania
Exercise-induced hyponatremia
HYPERVOLEMIC HYPONATREMIA
Heart failure
Cirrhosis
Nephrotic syndrome
Acute, chronic kidney injury
Capillary leak caused by sepsis
Hypoalbuminemia caused by gastrointestinal disease (protein-losing enteropathy)

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.

Table 73.3 Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion

- Absence of:
  Renal, adrenal, or thyroid insufficiency
  Heart failure, nephrotic syndrome, or cirrhosis
  Diuretic ingestion
  Dehydration
- Urine osmolality >100 mOsm/kg (usually > plasma)
- Serum osmolality <280 mOsm/kg and serum sodium <135 mEq/L
- Urine sodium >30 mEq/L
- Reversal of "sodium wasting" and correction of hyponatremia with water restriction

Renal Na^+ loss may occur in a variety of situations. In some situations the urine $[Na^+]$ is >140 mEq/L; thus hyponatremia may occur without any fluid intake. In many cases, the urine Na^+ level is less than the serum $[Na^+]$; hence, the intake of hypotonic fluid is necessary for hyponatremia to develop. In diseases associated with urinary Na^+ loss, the urine Na^+ level is >20 mEq/L despite volume depletion. This may not be true if the urinary Na^+ loss is no longer occurring, as is frequently the case if diuretics are discontinued. Because loop diuretics prevent generation of a maximally hypertonic renal medulla, the patient can neither maximally dilute nor concentrate the urine. The inability to maximally retain water provides some protection against severe hyponatremia. The patient receiving thiazide diuretics can concentrate the urine and is at higher risk for severe hyponatremia. Osmotic agents, such as glucose during diabetic ketoacidosis, cause loss of both water and Na^+. Urea accumulates during kidney failure and then acts as an osmotic diuretic after relief of urinary tract obstruction and during the polyuric phase of acute tubular necrosis. Transient tubular damage in these conditions further impairs Na^+ conservation. The serum $[Na^+]$ in these conditions depends on $[Na^+]$ of the fluid used to replace the losses. Hyponatremia develops when the fluid is hypotonic relative to the urinary losses.

Renal salt wasting occurs in hereditary kidney diseases, such as juvenile nephronophthisis and autosomal recessive polycystic kidney disease. Obstructive uropathy, most often a result of posterior urethral valves, produces salt wasting, but patients with the disease may also have hypernatremia as a result of impaired ability to concentrate urine and high-water loss. Acquired tubulointerstitial nephritis, usually secondary to either medications or infections, may cause salt wasting, along with other evidence of tubular dysfunction. CNS injury may produce cerebral salt wasting, which is theoretically caused by the production of a natriuretic peptide that causes renal salt wasting. In type II **renal tubular acidosis (RTA)**, usually associated with Fanconi syndrome (see Chapter 569.1), there is increased excretion of Na^+ and bicarbonate in the urine. Patients with Fanconi syndrome also have glycosuria, aminoaciduria, and hypophosphatemia because of renal phosphate wasting.

Aldosterone is necessary for renal Na^+ retention and for the excretion of K^+ and acid. In congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the block of aldosterone production results in hyponatremia, hyperkalemia, and metabolic acidosis. Decreased aldosterone secretion may be seen in Addison disease (adrenal insufficiency). In pseudohypoaldosteronism, aldosterone levels are elevated, but there is no response because of either a defective Na^+ channel or a deficiency of aldosterone receptors. A lack of tubular response to aldosterone may occur in children with urinary tract obstruction, especially during an acute urinary tract infection.

In **hypervolemic hyponatremia,** there is an excess of TBW and Na^+, although the increase in water is greater than the increase in Na^+. In most conditions that cause hypervolemic hyponatremia, there is a decrease in the *effective blood volume*, resulting from third space fluid loss, vasodilation, or poor cardiac output. The regulatory systems sense a decrease in effective blood volume and attempt to retain water and Na^+ to correct the problem. ADH causes renal water retention, and the kidney, under the influence of aldosterone and other intrarenal mechanisms, retains sodium. The patient's

sodium concentration decreases because water intake exceeds sodium intake and ADH prevents the normal loss of excess water.

In these disorders, there is low urine [Na^+] (<10 mEq/L) and an excess of both TBW and Na^+. The only exception is in patients with kidney failure and hyponatremia. These patients have an expanded intravascular volume, and hyponatremia can therefore appropriately suppress ADH production. Water cannot be excreted because very little urine is being made. Serum Na^+ is diluted through ingestion of water. Because of renal dysfunction, the urine [Na^+] may be elevated, but urine volume is so low that urine Na^+ excretion has not kept up with Na^+ intake, leading to sodium overload. The urine [Na^+] in kidney failure varies. In patients with acute glomerulonephritis, because it does not affect the tubules, the urine Na^+ level is usually low, whereas in patients with acute tubular necrosis, it is elevated because of tubular dysfunction.

Patients with hyponatremia and no evidence of volume overload or volume depletion have **euvolemic hyponatremia.** These patients typically have an excess of TBW and a slight decrease in total body Na^+. Some of these patients have an increase in weight, implying that they are volume overloaded. Nevertheless, from a clinical standpoint, they usually appear normal or have subtle signs of fluid overload. In SIADH the secretion of ADH is not inhibited by either low serum osmolality or expanded intravascular volume (see Chapter 597). The result is that the child with SIADH is unable to excrete water. This results in dilution of the serum Na^+ and hyponatremia. The expansion of the extracellular volume because of the retained water causes a mild increase in intravascular volume. The kidney increases Na^+ excretion to decrease intravascular volume to normal; thus the patient has a mild decrease in body Na^+. SIADH typically occurs with disorders of the CNS (infection, hemorrhage, trauma, tumor, thrombosis, Guillain-Barré syndrome), but lung disease (infection, asthma, positive pressure ventilation) and malignant tumors (producing ADH) are other potential causes. A variety of medications may cause SIADH, including recreational use of 3,4 -methylenedioxymethylamphetamine (MDMA, or "Ecstasy"), opiates, antiepileptic drugs (carbamazepine, oxcarbazepine, valproate), tricyclic antidepressants, vincristine, cyclophosphamide, and selective serotonin reuptake inhibitors (SSRIs). The diagnosis of SIADH is one of exclusion, because other causes of hyponatremia must be eliminated (Table 73.3). Because SIADH is a state of intravascular volume expansion, low serum uric acid and BUN levels are supportive of the diagnosis. A rare gain-of-function pathogenic variant in the renal ADH receptor causes **nephrogenic syndrome of inappropriate antidiuresis**. Patients with this X-linked disorder appear to have SIADH but have undetectable levels of ADH.

Hyponatremia in hospitalized patients is frequently caused by inappropriate production of ADH and administration of hypotonic IV fluids (see Chapter 74). Causes of inappropriate ADH production include stress, medications such as narcotics or anesthetics, nausea, and respiratory illness. The synthetic analog of ADH, desmopressin acetate, causes water retention and may cause hyponatremia if fluid intake is not appropriately limited. The main uses of desmopressin acetate in children are for the management of central diabetes insipidus and nocturnal enuresis.

Excess water ingestion can produce hyponatremia. In these cases, [Na^+] decreases as a result of dilution. This decrease suppresses ADH secretion, and there is a marked water diuresis by the kidney. Hyponatremia develops only because the intake of water exceeds the kidney's ability to eliminate water. This condition is more likely to occur in infants because their lower GFR limits their ability to excrete water.

Hyponatremia may develop in infants <6 months of age when caregivers offer water to their infant as a supplement, during hot weather, or when they run out of formula. Hyponatremia may result in transient seizures, hypothermia, and poor tone. With cessation of water intake, the hyponatremia rapidly corrects. *Infants <6 months of age should not be given water to drink; infants 6-12 months of age should not receive >1-2 ounces. If the infant appears thirsty, the parent should offer formula or breastfeed the child.*

In some situations the water intoxication causes acute hyponatremia and is caused by a massive **acute water load**. Causes include infant swimming lessons, inappropriate use of hypotonic IV fluids, water enemas, and forced water intake as a form of child abuse. Chronic hyponatremia occurs in children who receive water but limited sodium and protein. The minimum urine osmolality is approximately 50 mOsm/kg; the kidney can excrete 1 L of water only if there is enough solute ingested to produce 50 mOsm for urinary excretion. Because Na^+ and urea (a breakdown product of protein) are the principal urinary solutes, a lack of intake of Na^+ and protein prevents adequate water excretion. This occurs with the use of diluted formula or other inappropriate diets. Subsistence on beer, a poor source of Na^+ and protein, causes hyponatremia because of the inability to excrete the high water load ("beer potomania"). **Exercise-induced hyponatremia**, reported frequently during marathons, is caused by excessive water intake, salt losses from sweat, and secretion of ADH.

The pathogenesis of the hyponatremia in glucocorticoid deficiency (adrenal insufficiency) is multifactorial and includes increased ADH secretion. In hypothyroidism there is an inappropriate retention of water by the kidney, but the precise mechanisms are not clearly elucidated.

Cerebral salt wasting, an uncommon disorder in children, may be confused with SIADH and is often associated with CNS injury or lesions. Cerebral salt wasting produces renal salt losses and hypovolemia (orthostatic hypotension and elevated hematocrit, BUN, or creatinine). Hypovolemia is not seen in SIADH.

Clinical Manifestations

Hyponatremia causes a decrease in the osmolality of the ECS. Because the ICS then has a higher osmolality, water moves from the ECS to the ICS to maintain osmotic equilibrium. The increase in intracellular water causes cells to swell. Although cell swelling is not problematic in most tissues, it is dangerous for the brain, which is confined by the skull. As brain cells swell, there is an increase in intracranial pressure (ICP), which impairs cerebral blood flow. Acute, severe hyponatremia can cause brainstem herniation and apnea; respiratory support is often necessary. Brain cell swelling is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may have hypothermia and Cheyne-Stokes respirations. Hyponatremia can cause muscle cramps and weakness; rhabdomyolysis can occur with water intoxication.

The symptoms of hyponatremia are mostly a result of the decrease in extracellular osmolality and the resulting movement of water down its osmotic gradient into the ICS. Brain swelling can be significantly obviated if the hyponatremia develops gradually, because brain cells adapt to the decreased extracellular osmolality by reducing intracellular osmolality. This reduction is achieved by extrusion of the main intracellular ions (K^+, Cl^-) and a variety of small organic molecules. This process explains why the range of symptoms in hyponatremia is related to both the serum [Na^+] and its rate of decrease. A patient with chronic hyponatremia may have only subtle neurologic abnormalities with a serum [Na^+] of 110 mEq/L, but another patient may have seizures because of an acute decline in serum [Na^+] from 140 to 125 mEq/L.

Diagnosis

The history usually points to a likely etiology of the hyponatremia. Most patients with hyponatremia have a history of volume depletion. Diarrhea and diuretic use are common causes of hyponatremia in children. A history of polyuria, perhaps with enuresis, and/or salt craving is present in children with primary kidney diseases or absence of aldosterone effect. Children may have signs or symptoms suggesting a diagnosis of hypothyroidism or adrenal insufficiency (see Chapters 603 and 615). Brain injury raises the possibility of SIADH or cerebral salt wasting, with the caveat that SIADH is much more likely. Liver disease, nephrotic syndrome, kidney failure, or congestive heart failure may be

acute or chronic. The history should include a review of the patient's intake, both IV and enteral, with careful attention to the amounts of water, Na^+, and protein.

The traditional first step in the diagnostic process is determination of the plasma osmolality. This is done because some patients with a low serum [Na^+] do not have low osmolality. The clinical effects of hyponatremia are secondary to the associated low osmolality. Without a low osmolality, there is no movement of water into the ICS.

A patient with hyponatremia can have a low, normal, or high osmolality. A normal osmolality in combination with hyponatremia occurs in pseudohyponatremia. Children with elevation of serum glucose concentration or of another effective osmole (mannitol) have a high plasma osmolality and hyponatremia. The presence of a low osmolality indicates "true" hyponatremia. Patients with low osmolality are at risk for neurologic symptoms and require further evaluation to determine the etiology of the hyponatremia.

In some situations, true hyponatremia is present despite a normal or elevated plasma osmolality. The presence of an ineffective osmole, usually urea, increases the plasma osmolality, but because urea has the same concentration in the ICS, it does not cause fluid to move into the ECS. There is no dilution of the serum Na^+ by water, and the [Na^+] remains unchanged if the ineffective osmole is eliminated. Most importantly, the ineffective osmole does not protect the brain from edema caused by hyponatremia. Therefore a patient may have symptoms of hyponatremia despite having a normal or increased osmolality because of uremia.

In patients with true hyponatremia, the next step in the diagnostic process is to clinically evaluate the volume status. Patients with hyponatremia can be hypovolemic, hypervolemic, or euvolemic. The diagnosis of volume depletion relies on the usual findings with dehydration (see Chapter 75), although subtle volume depletion may not be clinically apparent. Children with hypervolemia are edematous on physical examination. They may have ascites, pulmonary edema, pleural effusion, or hypertension.

Hypovolemic hyponatremia can have renal or nonrenal causes. The urine [Na^+] is very useful in differentiating between renal and nonrenal causes. When the losses are nonrenal and the kidney is working properly, there is renal retention of Na^+, a normal homeostatic response to volume depletion. Thus the urinary [Na^+] is low, typically <10 mEq/L, although Na^+ conservation in neonates is less avid. When the kidney is the cause of the Na^+ loss, the urine [Na^+] is >20 mEq/L, reflecting the defect in renal Na^+ retention. The interpretation of the urine Na^+ level is challenging with diuretic therapy because it is high when diuretics are being used but low after the diuretic effect is gone. This becomes an issue only when diuretic use is surreptitious. The urine [Na^+] is not useful if a metabolic alkalosis is present; the urine [Cl^-] must be used instead (see Chapter 73.7).

Differentiating among the nonrenal causes of hypovolemic hyponatremia is usually facilitated by the history. Although the renal causes are more challenging to distinguish, a high serum [K^+] is associated with disorders in which the Na^+ wasting is caused by absence of or ineffectiveness of aldosterone.

In the patient with hypervolemic hyponatremia, the urine [Na^+] is a helpful parameter. It is usually <10 mEq/L, except in the patient with kidney failure.

Treatment

The management of hyponatremia is based on the pathophysiology of the specific etiology. The management of all causes requires judicious monitoring and avoidance of an overly quick normalization of the serum [Na^+]. A patient with severe symptoms (seizures), no matter the etiology, should be given a bolus of hypertonic saline to produce a small, rapid increase in serum sodium. *Hypoxia worsens cerebral edema,* and *hyponatremia may exacerbate hypoxic cell swelling.* Therefore pulse oximetry should be monitored and hypoxia aggressively corrected.

With all causes of hyponatremia, it is important to avoid overly rapid correction, which may cause *osmotic demyelination syndrome (ODS)*, which includes central pontine myelinolysis and extrapontine myelinolysis. This syndrome, which occurs within several days of rapid correction of hyponatremia, produces neurologic symptoms, including confusion, agitation, flaccid or spastic quadriparesis, and death. There are usually characteristic pathologic and radiologic changes in the brain. Despite severe symptoms, full recovery does occur in some patients.

ODS is more common in patients who are treated for *chronic* hyponatremia than for acute hyponatremia. Presumably, this difference is based on the adaptation of brain cells to the hyponatremia. The reduced intracellular osmolality, an adaptive mechanism for chronic hyponatremia, makes brain cells susceptible to dehydration during rapid correction of the hyponatremia, which may be the mechanism of ODS. Even though ODS is rare in pediatric patients, it is advisable to avoid correcting the serum [Na^+] by >10 mEq/L/24 hr or >18 mEq/L/48 hr. Desmopressin is a potential option if the serum [Na^+] is increasing too rapidly. This guideline *does not* apply to acute hyponatremia, as may occur with water intoxication, because the hyponatremia is more often symptomatic, and the adaptive decrease in brain osmolality has not had time to occur. The consequences of brain edema in acute hyponatremia exceed the small risk of ODS.

Patients with hyponatremia can have severe neurologic symptoms, such as seizures and coma. The seizures associated with hyponatremia generally are poorly responsive to anticonvulsants. The child with hyponatremia and severe symptoms needs treatment that will quickly reduce cerebral edema. This goal is best accomplished by increasing the extracellular osmolality so that water moves down its osmolar gradient from the ICS to the ECS.

Intravenous hypertonic saline rapidly increases serum [Na^+], and the effect on serum osmolality leads to a decrease in brain edema. Each mL/kg of 3% NaCl increases the serum [Na^+] by approximately 1 mEq/L. A child with active symptoms often improves after receiving 4-6 mL/kg of 3% NaCl.

The child with **hypovolemic hyponatremia** has a deficiency in Na^+ and may have a deficiency in water. The cornerstone of therapy is to replace the Na^+ deficit and any water deficit present. The first step in treating any dehydrated patient is to restore the intravascular volume with isotonic saline. Ultimately, complete restoration of intravascular volume suppresses ADH production, thereby permitting excretion of the excess water. Chapter 75 discusses the management of hyponatremic dehydration.

The management of **hypervolemic hyponatremia** is difficult; patients have an excess of both water and Na^+. Administration of Na^+ leads to worsening volume overload and edema. In addition, patients are retaining water and Na^+ because of their ineffective intravascular volume or renal insufficiency. The cornerstone of therapy is water and Na^+ restriction, because patients have volume overload. Diuretics may help by causing excretion of both Na^+ and water. Vasopressin receptor antagonists (**vaptans**), by blocking the action of ADH and causing a water diuresis, are effective in correcting the hypervolemic hyponatremia caused by heart failure. Vaptans are contraindicated if there are moderate to severe CNS symptoms.

Hyponatremic patients with low albumin from nephrotic syndrome have a better response to diuretics after an infusion of 25% albumin; the [Na^+] often normalizes as a result of expansion of the intravascular volume. A child with heart failure may have an increase in renal water and Na^+ excretion if there is an improvement in cardiac output. This improvement will "turn off" the regulatory hormones causing renal water (ADH) and Na^+ (aldosterone) retention. The patient with kidney failure cannot respond to any of these therapies except fluid restriction. Insensible fluid losses eventually result in an increase in the [Na^+] as long as insensible and urinary losses are greater than intake. A more definitive approach in children with kidney failure is to perform dialysis, which removes water and Na^+.

In **isovolumic hyponatremia** there is usually an excess of water and a mild Na^+ deficit. Therapy is directed at eliminating the excess water. The child with acute excessive water intake loses water in the urine

because ADH production is turned off as a result of the low plasma osmolality. Children may correct their hyponatremia spontaneously over 3-6 hours. For acute, symptomatic hyponatremia as a result of water intoxication, hypertonic saline may be needed to reverse cerebral edema. For chronic hyponatremia from poor solute intake, the child needs an appropriate formula, and excess water intake should be eliminated.

Children with **iatrogenic hyponatremia** caused by the administration of hypotonic IV fluids should receive 3% saline if symptomatic. Subsequent management is dictated by the patient's volume status. The hypovolemic child should receive isotonic IV fluids. The child with nonphysiologic stimuli for ADH production should undergo fluid restriction. Prevention of this iatrogenic complication requires judicious use of IV fluids (see Chapter 74).

Specific hormone replacement is the cornerstone of therapy for the hyponatremia of hypothyroidism or cortisol deficiency. Correction of the underlying defect permits appropriate elimination of the excess water.

SIADH is a condition of excess water, with limited ability of the kidney to excrete water. The mainstay of its therapy is fluid restriction with normal sodium intake. Furosemide and NaCl supplementation are effective in the patient with SIADH and *severe* hyponatremia. Even in a patient with SIADH, furosemide causes an increase in water and Na^+ excretion. The loss of Na^+ is somewhat counterproductive, but this Na^+ can be replaced with hypertonic saline. Because the patient has a net loss of water and the urinary losses of Na^+ have been replaced, there is an increase in the $[Na^+]$, but no significant increase in blood pressure. Vaptans, which block the action of ADH and cause a water diuresis, are effective at correcting **euvolemic hyponatremia**, but overly rapid correction is a potential complication. Vaptans are not appropriate for treating symptomatic hyponatremia because it can take a few hours before the water diuresis occurs.

Treatment of chronic SIADH is challenging. Fluid restriction in children is difficult for nutritional and behavioral reasons. Other options are long-term furosemide therapy with Na^+ supplementation, an oral vaptan (tolvaptan), or oral urea.

73.4 Potassium

Larry A. Greenbaum

POTASSIUM METABOLISM

Body Content and Physiologic Function

The intracellular $[K^+]$, approximately 150 mEq/L, is much higher than the plasma $[K^+]$ (see Fig. 73.3). The majority of body K^+ is contained in muscle. As muscle mass increases, there is an increase in body K^+. Thus an increase in body K^+ occurs during puberty, and it is more significant in males. The majority of extracellular K^+ is in bone; <1% of total body K^+ is in plasma.

Because most K^+ is intracellular, the plasma concentration does not always reflect the total body K^+ content. A variety of conditions alter the distribution of K^+ between the intracellular and extracellular compartments. Na^+,K^+-ATPase maintains the high intracellular $[K^+]$ by pumping Na^+ out of the cell and K^+ into the cell. This activity balances the normal leak of K^+ out of cells via potassium channels that is driven by the favorable chemical gradient. Insulin increases K^+ movement into cells by activating Na^+,K^+-ATPase. Hyperkalemia stimulates insulin secretion, which helps mitigate the hyperkalemia. Acid-base status affects K^+ distribution, probably via K^+ channels and the Na^+,K^+-ATPase. A decrease in pH drives potassium extracellularly; an increase in pH has the opposite effect. β-Adrenergic agonists stimulate the Na^+,K^+-ATPase, increasing cellular uptake of K^+. This increase is protective, in that hyperkalemia stimulates adrenal release of catecholamines. α-Adrenergic agonists and exercise cause a net movement of K^+ out of the ICS. An increase in plasma osmolality, as with mannitol infusion, leads to water movement out of the cells, and K^+ follows as a result of solvent drag. The serum $[K^+]$ increases by approximately 0.6 mEq/L with each 10 mOsm rise in plasma osmolality.

The high intracellular concentration of K^+, the principal intracellular cation, is maintained through Na^+,K^+-ATPase. The resulting chemical gradient is used to produce the resting membrane potential of cells. K^+ is necessary for the electrical responsiveness of nerve and muscle cells and for the contractility of cardiac, skeletal, and smooth muscle. The changes in membrane polarization that occur during muscle contraction or nerve conduction make these cells susceptible to changes in serum $[K^+]$. The ratio of intracellular to extracellular K^+ determines the threshold for a cell to generate an action potential and the rate of cellular repolarization. The intracellular $[K^+]$ affects cellular enzymes. K^+ is necessary for maintaining cell volume because of its important contribution to intracellular osmolality.

Potassium Intake

Potassium is plentiful in food. Dietary consumption varies considerably, even though 1-2 mEq/kg is the recommended intake. The intestines normally absorb approximately 90% of ingested K^+. Most absorption occurs in the small intestine, whereas the colon exchanges body K^+ for luminal Na^+. Regulation of intestinal losses normally has a minimal role in maintaining potassium homeostasis, although kidney failure, aldosterone, and glucocorticoids increase colonic secretion of K^+. The increase in intestinal losses in the setting of kidney failure and hyperkalemia, which stimulates aldosterone production, is clinically significant, helping to protect against hyperkalemia.

Potassium Excretion

Some loss of K^+ occurs in sweat but is normally minimal. The colon has the ability to eliminate some K^+. In addition, after an acute K^+ load, much of the K^+ (>40%) moves intracellularly, through the actions of epinephrine and insulin, which are produced in response to hyperkalemia. This process provides transient protection from hyperkalemia, but most ingested K^+ is eventually excreted in the urine. The kidneys principally regulate long-term K^+ balance, and they alter excretion in response to a variety of signals. K^+ is freely filtered at the glomerulus, but 90% is resorbed before reaching the distal tubule and collecting duct, the principal sites of K^+ regulation that have the ability to absorb and secrete K^+. The amount of tubular secretion regulates the amount of K^+ that appears in the urine. The plasma $[K^+]$ directly influences secretion in the distal nephron. As the $[K^+]$ increases, secretion increases.

The principal hormone regulating potassium secretion is **aldosterone**, which is released by the adrenal cortex in response to increased plasma K^+. Its main site of action is the cortical collecting duct, where aldosterone stimulates Na^+ movement from the tubule into the cells. This movement creates a negative charge in the tubular lumen, facilitating K^+ excretion. In addition, the increased intracellular Na^+ stimulates the basolateral Na^+,K^+-ATPase, causing more K^+ to move into the cells lining the cortical collecting duct. Glucocorticoids, ADH, a high urinary flow rate, and high Na^+ delivery to the distal nephron also increase urinary K^+ excretion. Insulin, catecholamines, and urinary ammonia decrease K^+ excretion. Whereas ADH increases K^+ secretion, it also causes water resorption, decreasing urinary flow. The net effect is that ADH has little overall impact on K^+ balance. Alkalosis causes potassium to move into cells, including the cells lining the collecting duct. This movement increases K^+ secretion, and because acidosis has the opposite effect; acidosis decreases K^+ secretion.

The kidney can dramatically vary K^+ excretion in response to changes in intake. Normally, approximately 10–15% of the filtered load is excreted. In an adult, excretion of K^+ can vary from 5-1,000 mEq/day.

HYPERKALEMIA

Hyperkalemia—because of the potential for lethal arrhythmias—is one of the most alarming electrolyte abnormalities.

Etiology and Pathophysiology

Three basic mechanisms cause hyperkalemia including increased intake, cellular shifts, and decreased excretion; spurious lab values are also commonly seen (Table 73.4). In the individual patient, the etiology is sometimes multifactorial.

Spurious hyperkalemia or **pseudohyperkalemia** is very common in children because of the difficulties in obtaining blood specimens. This laboratory result is usually caused by hemolysis during a heelstick or phlebotomy, but it can be the result of prolonged tourniquet application or fist clenching, either of which causes local potassium release from muscle.

The serum $[K^+]$ is normally 0.4 mEq/L higher than the plasma value, secondary to K^+ release from cells during clot formation. This phenomenon is exaggerated with thrombocytosis because of K^+ release from platelets. For every 100,000/m^3 increase in the platelet count, the serum $[K^+]$ rises by approximately 0.15 mEq/L. This phenomenon also occurs with the marked white blood cell (WBC) count elevations sometimes seen with leukemia. Elevated WBC counts, typically >200,000/m^3, can cause a dramatic elevation in the measured serum $[K^+]$. Analysis of a plasma sample usually provides an accurate result. It is important to analyze the sample promptly to avoid K^+ release from cells, which occurs if the sample is stored in the cold, or cellular uptake of K^+ and spurious hypokalemia, which occurs with storage at room temperature. Pneumatic tube transport can cause pseudohyperkalemia if cell membranes are fragile (leukemia). Occasionally, heparin causes lysis of leukemic cells and a false elevation of the plasma sample; a blood gas syringe has less heparin and may provide a more accurate reading than a standard tube. There are rare genetic disorders causing in vitro leakage of K^+ from red blood cells (RBCs) that may causes familial **pseudohyperkalemia** (autosomal dominant; *ABCB6* gene).

Because of the kidney's ability to excrete K^+, it is unusual for excessive intake, by itself, to cause hyperkalemia. This condition can occur in a patient who is receiving large quantities of IV or oral K^+ for excessive losses that are no longer present. Frequent or rapid blood transfusions can acutely increase the $[K^+]$ because of the K^+ content of blood, which is variably elevated. Increased intake may precipitate hyperkalemia if there is an underlying defect in K^+ excretion.

The ICS has a very high $[K^+]$, so a shift of K^+ from the ICS to the ECS can have a significant effect on the plasma $[K^+]$. This shift occurs with metabolic acidosis, but the effect is minimal with an organic acid (lactic acidosis, ketoacidosis). A respiratory acidosis has less impact than a metabolic acidosis. Cell destruction, as seen with rhabdomyolysis, tumor lysis syndrome, tissue necrosis, or hemolysis, releases K^+ into the extracellular milieu. The K^+ released from RBCs in internal bleeding, such as hematomas, is resorbed and enters the ECS.

Normal doses of succinylcholine or β blockers and fluoride or digitalis intoxication all cause a shift of K^+ out of the intracellular compartment. *Succinylcholine should not be used during anesthesia in patients at risk for hyperkalemia.* β Blockers prevent the normal cellular uptake of K^+ mediated by binding of β-agonists to the β_2-adrenergic receptors. K^+ release from muscle cells occurs during exercise, and levels can increase by 1-2 mEq/L with high activity. With an increased plasma osmolality, water moves from the ICS, and K^+ follows. This process occurs with hyperglycemia, although in nondiabetic patients the resultant increase in insulin causes K^+ to move intracellularly. In diabetic ketoacidosis (DKA), the absence of insulin causes potassium to leave the ICS, and the problem is compounded by the hyperosmolality. The effect of hyperosmolality causes a transcellular shift of K^+ into the ECS after mannitol or hypertonic saline infusions. **Malignant hyperthermia**, which is triggered by some inhaled anesthetics, causes muscle release of potassium (see Chapter 651.2). **Hyperkalemic periodic paralysis** is an autosomal dominant disorder caused by pathogenic variants in *SCN4A*, the gene for a Na^+ channel. It results in episodic cellular release of K^+ and attacks of paralysis (see Chapter 651.1).

The kidneys excrete most of the daily K^+ intake, so a decrease in kidney function can cause hyperkalemia. Newborn infants in general, and especially premature infants, have decreased kidney function at birth; thus they are at increased risk for hyperkalemia despite an absence of intrinsic renal disease. Neonates also have decreased expression of K^+ channels, further limiting K^+ excretion.

A wide range of primary **adrenal disorders**, both hereditary and acquired, can cause decreased production of aldosterone, with secondary hyperkalemia (see Chapters 615 and 616). Patients with these disorders typically have metabolic acidosis and salt wasting with hyponatremia. Children with subtle adrenal insufficiency may have electrolyte problems only during acute illnesses. The most common form of **congenital adrenal hyperplasia**, 21-hydroxylase deficiency, typically manifests in male infants as hyperkalemia, metabolic acidosis, hyponatremia, and volume depletion. Females with this disorder usually are diagnosed as newborns because of their ambiguous genitals; treatment prevents the development of electrolyte problems.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, a result of kidney damage, can lead to decreased aldosterone production. **Hyporeninemia** occurs in many kidney diseases, with some of the more common pediatric causes listed in Table 73.4. These patients typically have hyperkalemia and a metabolic acidosis, without hyponatremia. Some of these patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in K^+ excretion is more extreme than expected for the degree of renal insufficiency.

A variety of **renal tubular disorders** impair renal excretion of K^+. Children with **pseudohypoaldosteronism type 1** have hyperkalemia, metabolic acidosis, and salt wasting (kidney, colon, sweat) leading to hyponatremia and volume depletion; aldosterone values are elevated. In the autosomal recessive variant, there is a defect in the renal Na^+ channel that is normally activated by aldosterone. Patients with this variant have severe symptoms (failure to thrive, diarrhea, recurrent respiratory infections, miliaria-rubra like rash), beginning in infancy. Patients with the autosomal dominant form have a defect in the aldosterone receptor, and the disease is milder, often remitting in adulthood. **Pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension),** also called **Gordon syndrome,** is an autosomal dominant disorder characterized by hypertension caused by salt retention and impaired excretion of K^+ and acid, leading to hyperkalemia and hyperchloremic metabolic acidosis. Pathogenic variants in at least four genes (*WNK4*, *WNK1*, *KLHL3*, *CUL3)* may cause Gordon syndrome. Patients may respond well to thiazide diuretics. In **Bartter syndrome**, caused by pathogenic variants in the potassium channel *ROMK* (type 2 Bartter syndrome), there can be transient hyperkalemia in neonates, but hypokalemia subsequently develops (see Chapter 571.1).

Acquired renal tubular dysfunction, with an impaired ability to excrete K^+, occurs in a number of conditions. These disorders, all characterized by **tubulointerstitial disease,** are often associated with impaired acid secretion and a secondary metabolic acidosis. In some affected children, the metabolic acidosis is the dominant feature, although a high K^+ intake may unmask the defect in K^+ handling. The tubular dysfunction can cause renal salt wasting, potentially leading to hyponatremia. Because of the tubulointerstitial damage, these conditions may also cause hyperkalemia as a result of hyporeninemic hypoaldosteronism.

The risk of hyperkalemia resulting from medications is greatest in patients with underlying renal insufficiency. The predominant mechanism of medication-induced hyperkalemia is impaired renal excretion, although ACE inhibitors may worsen hyperkalemia in anuric patients, probably by inhibiting GI potassium loss, which is normally upregulated in renal insufficiency. The hyperkalemia caused by trimethoprim is especially problematic at higher doses. Potassium-sparing diuretics may easily cause hyperkalemia because they are often used in patients receiving oral K^+ supplements. Oral contraceptives containing drospirenone, which blocks the action of aldosterone, may cause hyperkalemia and should not be used in patients with decreased renal function.

Clinical Manifestations

The most important effects of hyperkalemia result from the role of K^+ in membrane polarization. The cardiac conduction system is usually the dominant concern. Changes in the electrocardiogram (ECG) begin with peaking of the T waves. This is followed, as K^+ level increases, by ST-segment depression, an increased PR interval, flattening of the P wave, and widening of the QRS complex (Fig. 73.4). However, the correlation between K^+ level and ECG changes is poor. This process can eventually progress to ventricular fibrillation. Asystole may also occur. Some patients have paresthesias, fasciculations, weakness, and even an ascending paralysis, but cardiac toxicity usually precedes these clinical symptoms, emphasizing the danger of assuming that an absence of symptoms implies an absence of danger. Chronic hyperkalemia is generally better tolerated than acute hyperkalemia.

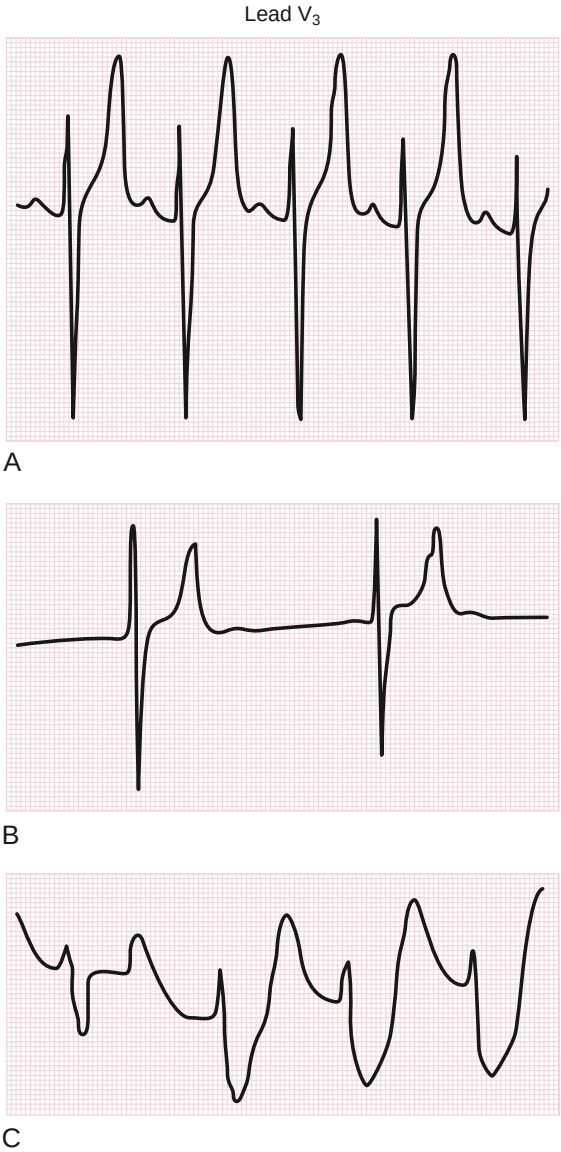

Fig. 73.4 The effects of progressive hyperkalemia on the electrocardiogram. All of the ECGs are from lead V_3. **A,** Serum potassium concentration ($[K^+]$) = 6.8 mEq/L; note the peaked T waves together with normal sinus rhythm. **B,** Serum $[K^+]$ = 8.9 mEq/L; note the peaked T waves and absent P waves. **C,** Serum $[K^+]$ >8.9 mEq/L; note the classic sine wave with absent P waves, marked prolongation of the QRS complex, and peaked T waves. *(From Goldman L, Schafer AI, eds. Goldman-Cecil Medicine. 26th ed. Elsevier; 2020. Fig. 109.2, p. 727.)*

Diagnosis

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is very common in children, so obtaining a second potassium measurement is often appropriate. If there is a significant elevation of WBC or platelet count, the second measurement should be performed on a plasma sample that is evaluated promptly. The history should initially focus on potassium intake, risk factors for transcellular shifts of K^+, medications that cause hyperkalemia, and signs of renal insufficiency, such as oliguria and edema. Initial laboratory evaluation should include creatinine, BUN, and assessment of the acid-base status. Many etiologies of hyperkalemia cause **metabolic acidosis**, which worsens hyperkalemia through the transcellular shift of K^+ out of cells. Decreased kidney function is a common cause of the combination of metabolic acidosis and hyperkalemia, also seen in diseases associated with aldosterone insufficiency or aldosterone resistance. Children with absent or ineffective aldosterone often have hyponatremia and volume depletion because of salt wasting. Genetic diseases, such as congenital adrenal hyperplasia and pseudohypoaldosteronism, usually manifest in infancy and should be strongly considered in the infant with hyperkalemia and metabolic acidosis, especially if hyponatremia is present.

It is important to consider the various etiologies of a transcellular K^+ shift. In some of these disorders, the K^+ level continues to increase, despite the elimination of all K^+ intake, especially with concurrent renal insufficiency. This increase is potentially seen in tumor lysis syndrome, hemolysis, rhabdomyolysis, and other causes of cell death. All these entities can cause concomitant hyperphosphatemia and hyperuricemia. **Rhabdomyolysis** produces an elevated creatinine phosphokinase (CPK) value and hypocalcemia, whereas children with hemolysis have hemoglobinuria and a decreasing hematocrit. For the child with diabetes, elevated blood glucose and acidosis suggest a transcellular shift of K^+.

Treatment

The plasma K^+ level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. High serum $[K^+]$ and the presence of ECG changes require vigorous treatment. An additional source of concern is the patient in whom plasma K^+ levels are rising despite minimal intake. This situation can happen if there is cellular release of K^+ (tumor lysis syndrome), especially in the setting of diminished excretion (kidney failure).

The first action in a child with a concerning elevation of plasma $[K^+]$ is to stop all sources of additional K^+ (oral, IV). Washed RBCs can be used for patients who require blood transfusions. If the $[K^+]$ is >6.5 mEq/L, an ECG should be obtained to help assess the urgency of the situation. Peaked T waves are the first sign of hyperkalemia, followed by a prolonged PR interval, and when most severe, prolonged QRS complex. Life-threatening ventricular arrhythmias may also develop. The treatment of hyperkalemia has two basic goals: (1) to stabilize the heart to prevent life-threatening arrhythmias and (2) to remove K^+ from the body. The treatments that acutely prevent arrhythmias all have the advantage of working quickly (within minutes) but do not remove K^+ from the body. **Calcium** stabilizes the cell membrane of heart cells, preventing arrhythmias; it is given IV over a few minutes, and its action is almost immediate. Calcium should be given over 30 minutes in a patient receiving digitalis because the calcium may cause arrhythmias. **Bicarbonate** causes potassium to move intracellularly, lowering the plasma $[K^+]$; it is most efficacious in a patient with a metabolic acidosis. **Insulin** causes K^+ to move intracellularly but must be given with **glucose** to avoid hypoglycemia. The combination of insulin and glucose works within 30 minutes. Nebulized **albuterol**, by stimulation of β_1-adrenergic receptors, leads to rapid intracellular movement of K^+. This has the advantage of not requiring an IV route of administration, allowing it to be given concurrently with the other measures.

It is critical to begin measures that remove K^+ from the body. In patients who are not anuric, a **loop diuretic** increases renal excretion of K^+. A high dose may be required in a patient with significant renal insufficiency. **Sodium polystyrene sulfonate** (**SPS**; Kayexalate) is an exchange resin that is given either rectally or orally. **Patiromer** and **sodium zirconium cyclosilicate** are oral exchange resins for treating hyperkalemia. Some patients require **dialysis** for acute K^+ removal. Dialysis is often necessary if the patient has either severe kidney failure or an especially high rate of endogenous K^+ release, as is sometimes present with tumor lysis syndrome or rhabdomyolysis. Hemodialysis rapidly lowers plasma $[K^+]$. Peritoneal dialysis is not nearly as quick or reliable, but it is usually adequate as long as the acute problem can be managed with medications and the endogenous release of K^+ is not high.

Long-term management of hyperkalemia includes reducing intake through dietary changes and eliminating or reducing medications that cause hyperkalemia (see Chapter 572). Some patients require medications to increase potassium excretion, such as SPS, patiromer, sodium zirconium cyclosilicate, and loop or thiazide diuretics. Some infants with chronic kidney disease may need to start dialysis to allow adequate caloric intake without hyperkalemia. It is unusual for an older child to require dialysis principally to control chronic hyperkalemia. The disorders caused by aldosterone deficiency respond to replacement therapy with fludrocortisone.

HYPOKALEMIA

Hypokalemia is common in children, with most cases related to gastroenteritis.

Etiology and Pathophysiology

There are four basic mechanisms of hypokalemia (Table 73.5). **Spurious hypokalemia** occurs in patients with leukemia and very elevated WBC counts if plasma for analysis is left at room temperature, permitting the WBCs to take up K^+ from the plasma. With a transcellular shift, there is no change in total body K^+, although there may be concomitant potassium depletion resulting from other factors. Decreased intake, extrarenal losses, and renal losses are all associated with total body K^+ depletion. In addition, seasonal pseudo-hypokalemia is seen during warm summer months as a laboratory phenomenon when blood samples are exposed to a warm environment. On immediate retesting, the potassium level is normal. This should not be confused with a pseudo-Bartter syndrome (hypokalemic, hypochloremic, alkalosis) seen in children with cystic fibrosis in a very warm environment due to excessive sweating.

Because the intracellular $[K^+]$ is much higher than the plasma level, a significant amount of K^+ can move into cells without greatly changing the intracellular $[K^+]$. **Alkalemia** is one of the more common causes of a transcellular shift. The effect is much greater with a *metabolic* alkalosis than with a respiratory alkalosis. The impact of exogenous insulin on K^+ movement into the cells is substantial in patients with DKA. Endogenous insulin may be the cause when a patient is given a bolus of glucose. Both endogenous (epinephrine in stress) and exogenous (albuterol) β-adrenergic agonists stimulate cellular uptake of K^+. Theophylline overdose, barium intoxication, administration of cesium chloride (a homeopathic cancer remedy), and toluene intoxication from paint or glue sniffing can cause a transcellular shift hypokalemia, often with severe clinical manifestations. Children with **hypokalemic periodic paralysis,** a rare autosomal dominant disorder, have acute cellular uptake of K^+ (see Chapter 651). **Thyrotoxic periodic paralysis,** which is more common in Asians, is an unusual initial manifestation of hyperthyroidism. Affected patients have dramatic hypokalemia as a result of a transcellular shift of potassium. Hypokalemia can occur during refeeding syndrome (see Chapters 63 and 385.7).

Inadequate K^+ intake occurs in **anorexia nervosa**; accompanying bulimia and laxative or diuretic abuse exacerbates the K^+ deficiency.

Table 73.5 Causes of Hypokalemia

SPURIOUS LABORATORY VALUE
High white blood cell count

TRANSCELLULAR SHIFTS
Alkalemia
Insulin
α-Adrenergic agonists
Drugs/toxins (theophylline, barium, toluene, cesium chloride, hydroxychloroquine)
Hypokalemic periodic paralysis (OMIM 170400)
Thyrotoxic period paralysis
Refeeding syndrome

DECREASED INTAKE
Anorexia nervosa

EXTRARENAL LOSSES
Diarrhea
Laxative abuse
Sweating
Sodium polystyrene sulfonate (Kayexalate) or clay ingestion

RENAL LOSSES
With Metabolic Acidosis
Distal renal tubular acidosis (OMIM 179800/602722/267300/611590)
Proximal renal tubular acidosis (OMIM 604278)*
Ureterosigmoidostomy
Diabetic ketoacidosis

Without Specific Acid-Base Disturbance
Tubular toxins: amphotericin, cisplatin, aminoglycosides
Interstitial nephritis
Diuretic phase of acute tubular necrosis
Postobstructive diuresis
Hypomagnesemia
High urine anions (e.g., penicillin or penicillin derivatives)

With Metabolic Alkalosis
Low urine chloride
- Emesis or nasogastric suction
- Chloride-losing diarrhea (OMIM 214700)
- Cystic fibrosis (OMIM 219700)
- Low-chloride formula
- Posthypercapnia
- Previous loop or thiazide diuretic use

High urine chloride and normal blood pressure
- Gitelman syndrome (OMIM 263800)
- Bartter syndrome (OMIM 241200/607364/602522/601678/300971/601198/613090)
- Autosomal dominant hypoparathyroidism (OMIM 146200)
- EAST syndrome (OMIM 612780)
- Autosomal dominant kidney hypomagnesemia due to *RRAGD* variant (OMIM not assigned)
- Loop and thiazide diuretics (current)

High urine chloride and high blood pressure
- Adrenal adenoma or hyperplasia
- Glucocorticoid-remediable aldosteronism (OMIM 103900)
- Hyperaldosteronism type II (OMIM 605635)
- Familial hyperaldosteronism type III (OMIM 613677)
- Familial hyperaldosteronism type IV (OMIM 617027)
- Renovascular disease
- Renin-secreting tumor
- 17β-Hydroxylase deficiency (OMIM 202110)
- 11β-Hydroxylase deficiency (OMIM 202010)
- Cushing syndrome
- 11β-Hydroxysteroid dehydrogenase deficiency (OMIM 218030)
- Licorice ingestion
- Liddle syndrome (OMIM 177200)
- Early-onset autosomal dominant hypertension with exacerbation in pregnancy (OMIM 605115)

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.
EAST, Epilepsy, ataxia, sensorineural hearing loss, and tubulopathy; OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

Sweat losses of K^+ can be significant during vigorous exercise in a hot climate. Associated volume depletion and hyperaldosteronism increase renal losses of K^+ (discussed later). Diarrheal fluid has a high concentration of K^+, and hypokalemia because of diarrhea is usually associated with metabolic acidosis resulting from stool losses of bicarbonate. In contrast, normal acid-base balance or mild metabolic alkalosis is seen with laxative abuse. Intake of potassium-binding resins (SPS) or ingestion of clay because of pica increases stool losses of potassium.

Urinary potassium wasting may be accompanied by a **metabolic acidosis** (proximal or distal RTA). In DKA, although it is often associated with normal plasma [K^+] from transcellular shifts, there is significant total body K^+ depletion from urinary losses because of the osmotic diuresis, and the K^+ level may decrease dramatically with insulin therapy (see Chapter 629). Both the polyuric phase of acute tubular necrosis and postobstructive diuresis cause transient, highly variable K^+ wasting and may be associated with metabolic acidosis. Tubular damage, which occurs either directly from medications or secondary to interstitial nephritis, is often accompanied by other tubular losses, including magnesium, Na^+, and water. Such tubular damage may cause a secondary RTA with metabolic acidosis. Isolated magnesium deficiency causes renal K^+ wasting. Penicillin is an anion excreted in the urine, resulting in increased K^+ excretion because the penicillin anion must be accompanied by a cation. Hypokalemia from penicillin therapy occurs only with the *sodium* salt of penicillin, not with the potassium salt.

Urinary K^+ wasting is often accompanied by a **metabolic alkalosis**. This condition is usually associated with increased aldosterone, which increases urinary K^+ and acid losses, contributing to the hypokalemia and the metabolic alkalosis. Other mechanisms often contribute to both the K^+ losses and the metabolic alkalosis. With emesis or nasogastric suction, there is gastric loss of K^+, but this is minimal given the low K^+ content of gastric fluid, approximately 10 mEq/L. More important is the gastric loss of hydrochloric acid (HCl), leading to metabolic alkalosis and a state of volume depletion. The kidney compensates for metabolic alkalosis by excreting bicarbonate in the urine, but there is obligate loss of K^+ and Na^+ with the bicarbonate. The volume depletion raises aldosterone levels, further increasing urinary K^+ losses and preventing correction of metabolic alkalosis and hypokalemia until the volume depletion is corrected.

Urinary chloride (Cl^-) is low as a response to the volume depletion. Because the volume depletion is secondary to Cl^- loss, this is a **state of Cl^- deficiency**. There were cases of Cl^- deficiency resulting from infant formula deficient in Cl^-, which caused a metabolic alkalosis with hypokalemia and low urine [Cl^-]. Current infant formula is not deficient in Cl^-. A similar mechanism occurs in cystic fibrosis because of Cl^- loss in sweat. In **congenital chloride-losing diarrhea**, an autosomal recessive

disorder, there is high stool loss of Cl^-, leading to metabolic alkalosis, an unusual sequela of diarrhea. Because of stool K^+ losses, Cl^- deficiency, and metabolic alkalosis, patients with congenital chloride-losing diarrhea have hypokalemia.

During respiratory acidosis, there is renal compensation, with retention of bicarbonate and excretion of Cl^-. After the respiratory acidosis is corrected, the patients have Cl^- deficiency and post–hypercapnic alkalosis with secondary hypokalemia. Patients with Cl^- deficiency, metabolic alkalosis, and hypokalemia have a urinary $[Cl^-]$ of <10 mEq/L. Loop and thiazide diuretics lead to hypokalemia, metabolic alkalosis, and Cl^- deficiency. During treatment, these patients have high urine chloride levels resulting from the effect of the diuretic. However, after the diuretics are discontinued, there is residual Cl^- deficiency, the urinary $[Cl^-]$ is appropriately low, and neither the hypokalemia nor the alkalosis resolves until the Cl^- deficiency is corrected.

The combination of metabolic alkalosis, hypokalemia, high urine $[Cl^-]$, and normal blood pressure is characteristic of Bartter syndrome, Gitelman syndrome, and current diuretic use. Patients with any of these conditions have high urinary losses of Cl^- despite a state of relative volume depletion with secondary hyperaldosteronism with high plasma renin. Bartter and Gitelman syndromes are autosomal recessive disorders caused by defects in tubular transporters (see Chapter 571). **Bartter syndrome** is usually associated with hypercalciuria, and often with nephrocalcinosis, whereas children with **Gitelman syndrome** have low urinary calcium losses but hypomagnesemia because of urinary magnesium losses. Some patients with Bartter syndrome have hypomagnesemia. A transient antenatal form of Bartter syndrome is associated with severe polyhydramnios and pathogenic variants in *MAGED2*.

Some patients with hypoparathyroidism and hypocalcemia caused by activating pathogenic variants of the calcium-sensing receptor (**autosomal dominant hypoparathyroidism**) have hypokalemia, hypomagnesemia, and metabolic alkalosis. The reason is that activation of the calcium-sensing receptor in the loop of Henle impairs tubular resorption of sodium and chloride, causing volume depletion and secondary hyperaldosteronism. **EAST syndrome**, an autosomal recessive disorder caused by pathologic variants in the gene for a potassium channel in the kidney, inner ear, and brain, consists of *e*pilepsy, *a*taxia, *s*ensorineural hearing loss, and *t*ubulopathy (hypokalemia, metabolic alkalosis, hypomagnesemia, and hypocalciuria).

In the presence of *high aldosterone levels*, there is urinary loss of K^+, hypokalemia, metabolic alkalosis, and elevated urinary $[Cl^-]$; renal retention of Na^+ leads to **hypertension**. Primary hyperaldosteronism caused by adenoma or hyperplasia is much less common in children than in adults (see Chapters 619 and 620). **Glucocorticoid-remediable aldosteronism**, an autosomal dominant disorder that leads to high levels of aldosterone (but low renin levels), is often diagnosed in childhood, although hypokalemia is not always present. **Familial hyperaldosteronism type II**, an autosomal dominant disorder, is due to a gain-of-function variant in *CLCN2* that causes increased aldosterone synthesis. **Familial hyperaldosteronism type III**, an autosomal dominant disorder, is due to a gain-of-function variant in *KCNJ5* that causes a dramatic increase in aldosterone synthesis and severe hypertension and hypokalemia. **Familial hyperaldosteronism type IV**, an autosomal dominant disorder, is due to a gain-of-function variant in *CACNA1H* that causes increased aldosterone synthesis.

Increased aldosterone levels may also be *secondary* to increased renin production. Renal artery stenosis leads to hypertension from increased renin and secondary hyperaldosteronism. The increased aldosterone can cause hypokalemia and metabolic alkalosis, although most patients have normal electrolyte levels. Renin-producing tumors, which are extremely rare, can cause hypokalemia.

A variety of disorders cause hypertension and hypokalemia without increased aldosterone levels. Some are a result of increased levels of mineralocorticoids other than aldosterone. Such increases occur in two forms of **congenital adrenal hyperplasia** (see Chapter 616). In **11β-hydroxylase deficiency**, which is associated with virilization, 11-deoxycorticosterone is elevated, causing variable hypertension and hypokalemia. A similar mechanism, increased 11-deoxycorticosterone, occurs in **17α-hydroxylase deficiency**, but patients with this disorder are more uniformly hypertensive and hypokalemic, and they have a defect in sex hormone production. **Cushing syndrome**, frequently associated with hypertension, less frequently causes metabolic alkalosis and hypokalemia, secondary to the mineralocorticoid activity of cortisol. In **11β-hydroxysteroid dehydrogenase deficiency**, an autosomal recessive disorder, the enzymatic defect prevents the conversion of cortisol to cortisone in the kidney. Because cortisol binds to and activates the aldosterone receptor, children with this deficiency have all the features of excessive mineralocorticoids, including hypertension, hypokalemia, and metabolic alkalosis, but low levels of aldosterone and renin. Patients with this disorder, which is also called **apparent mineralocorticoid excess**, respond to spironolactone therapy, which blocks the mineralocorticoid receptor. An acquired form of 11β-hydroxysteroid dehydrogenase deficiency occurs from the ingestion of substances that inhibit this enzyme. A classic example is glycyrrhizic acid, which is found in natural licorice. **Liddle syndrome** is an autosomal dominant disorder that results from activating pathogenic variants of the distal nephron sodium channel that is normally upregulated by aldosterone. Patients have the characteristics of hyperaldosteronism—hypertension, hypokalemia, and alkalosis—but low serum renin and aldosterone levels. These patients respond to the potassium-sparing diuretics (triamterene and amiloride) that inhibit this sodium channel (see Chapter 571.3). A pathogenic variant in the mineralocorticoid receptor causes **early-onset autosomal dominant hypertension with exacerbation in pregnancy**. Hypokalemia is usually mild but worsens during pregnancy; renin and aldosterone levels are low.

Clinical Manifestations

The heart and skeletal muscle are especially vulnerable to hypokalemia. ECG changes include a flattened T wave, a depressed ST segment, and the appearance of a U wave, which is located between the T wave (if still visible) and the P wave (Fig. 73.5). Ventricular fibrillation and torsades de pointes may occur, although usually only in the context of underlying heart disease. Hypokalemia makes the heart especially susceptible to digitalis-induced arrhythmias, such as supraventricular tachycardia, ventricular tachycardia, and heart block (see Chapter 484).

The clinical consequences of hypokalemia in skeletal muscle include muscle weakness and cramps. Paralysis is a possible complication, generally only at $[K^+]$ <2.5 mEq/L. It usually starts in the legs and moves to the arms. Respiratory paralysis may require mechanical ventilation. Some patients have rhabdomyolysis; the risk increases with exercise. Hypokalemia slows GI motility. This effect manifests as constipation; with K^+ levels <2.5 mEq/L, an ileus may occur. Hypokalemia impairs bladder function, potentially leading to urinary retention.

Hypokalemia causes **polyuria** and **polydipsia** by impairing urinary concentrating ability, which produces nephrogenic diabetes insipidus. Hypokalemia stimulates renal ammonia production, an effect that is clinically significant if hepatic failure is present, because the liver cannot metabolize the ammonia. Consequently, hypokalemia may worsen hepatic encephalopathy. Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts.

Diagnosis

Most causes of hypokalemia are readily apparent from the history. It is important to review the child's diet, GI losses, and medications. Both emesis and diuretic use can be surreptitious. The presence of **hypertension** suggests excess mineralocorticoid effects or levels. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea and distal and proximal RTA. A concurrent metabolic alkalosis is characteristic of emesis or nasogastric losses, aldosterone excess, use of diuretics, and

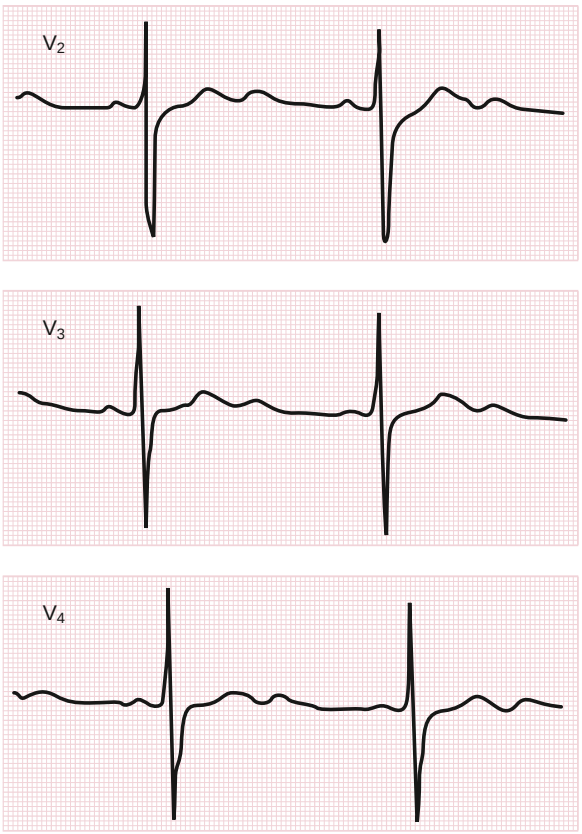

Fig. 73.5 The ECG manifestations of hypokalemia. The serum potassium concentration was 2.2 mEq/L. The ST segment is prolonged, primarily because of a U wave following the T wave, and the T wave is flattened. *(From Goldman L, Schafer AI, eds. Goldman-Cecil Medicine. 26th ed. Elsevier; 2020. Fig. 109.1, p 727.)*

Bartter and Gitelman syndromes. Figure 73.6 shows an approach to persistent hypokalemia.

If a clear etiology is not apparent, the measurement of urinary K^+ distinguishes between renal and extrarenal losses. The kidneys should conserve K^+ in the presence of extrarenal losses. Urinary K^+ losses can be assessed with a 24-hour urine collection, spot K^+:creatinine ratio, fractional excretion of K^+, or calculation of the *transtubular K^+ gradient* (TTKG), which is the most widely used approach in children:

$$\text{TTKG} = [K]_{\text{urine}} / [K]_{\text{plasma}} \times (\text{plasma osmolality} / \text{urine osmolality})$$

where $[K]_{\text{urine}}$ = urine potassium concentration and $[K]_{\text{plasma}}$ = plasma potassium concentration.

The urine osmolality must be greater than the serum osmolality for the result of this calculation to be valid. A TTKG >4 in the presence of hypokalemia suggests excessive urinary losses of K^+. The urinary K^+ excretion value can be misleading if the stimulus for renal loss, such as a diuretic, is no longer present.

Treatment

Factors that influence the treatment of hypokalemia include the K^+ level, clinical symptoms, kidney function, the presence of transcellular shifts of K^+, ongoing losses, and the patient's ability to tolerate oral K^+. Severe, symptomatic hypokalemia requires aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney's limited ability to excrete excessive K^+. The plasma potassium level does not always provide an accurate estimation of the total body K^+ deficit because there may be shifts of K^+ from the ICS to the plasma. Clinically, such shifts occur most often with metabolic acidosis and the insulin deficiency of DKA; the plasma $[K^+]$ measurement underestimates the degree of total body K^+ depletion. When these problems are corrected, K^+ moves into the ICS, so more K^+ supplementation is required to correct the hypokalemia. Likewise, the presence of a transcellular shift of K^+ into the cells indicates that the total body K^+ depletion is less severe. In an isolated transcellular shift, as in hypokalemic periodic paralysis, K^+ supplementation should be used cautiously, given the risk of hyperkalemia when the transcellular shift resolves. This caution is especially required in thyrotoxic periodic paralysis, which responds dramatically to propranolol, with correction of weakness and hypokalemia. Patients who have ongoing losses of K^+ need correction of the deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, IV K^+ should be used very cautiously. Oral K^+ is safer, but not as rapid in urgent situations. Liquid preparations are bitter tasting; microencapsulated or wax matrix formulations are less irritating than tablets to the gastric mucosa. Oral dosing is variable depending on the clinical situation. A typical starting dose is 1-2 mEq/kg/day, with a maximum of 60 mEq/day in divided doses. The dose of IV potassium is 0.5-1.0 mEq/kg, usually given over 1 hour. The adult maximum dose is 40 mEq. Conservative dosing is generally preferred. Potassium chloride is the usual choice for supplementation, although the presence of concurrent electrolyte abnormalities may dictate other options. Patients with acidosis and hypokalemia can receive potassium acetate or potassium citrate. If hypophosphatemia is present, some of the potassium deficit can be replaced with potassium phosphate. It is sometimes possible to decrease ongoing K^+ losses. For patients with excessive urinary losses, potassium-sparing diuretics are effective, but they need to be used cautiously in patients with decreased kidney function. If hypokalemia, metabolic alkalosis, and volume depletion are present (with gastric losses), restoration of intravascular volume with adequate NaCl will decrease urinary K^+ losses. Correction of concurrent hypomagnesemia is important because it may cause hypokalemia. Disease-specific therapy is effective in many of the genetic tubular disorders.

73.5 Magnesium

Larry A. Greenbaum

MAGNESIUM METABOLISM

Body Content and Physiologic Function

Magnesium is the fourth most common cation in the body and the third most common intracellular cation (see Fig. 73.3). From 50–60% of body magnesium is in bone, where it serves as a reservoir because 30% is exchangeable, allowing movement to the ECS. Most intracellular magnesium is bound to proteins; only approximately 25% is exchangeable. Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver.

The normal plasma magnesium concentration is 1.5-2.3 mg/dL (1.2-1.9 mEq/L; 0.62-0.94 mmol/L), with some variation among clinical laboratories. Infants have slightly higher plasma magnesium concentrations than older children and adults. Only 1% of body magnesium is extracellular (60% ionized, 15% complexed, 25% protein bound). In the United States, serum magnesium is reported as mg/dL (Table 73.6). Values in the left-column unit are converted into the right-column unit by multiplying the conversion factor (e.g., calcium of 10 mg/dL × 0.25 = 2.5 mmol/L). Dividing the right-column unit by the conversion factor converts to the units of the left-column unit.

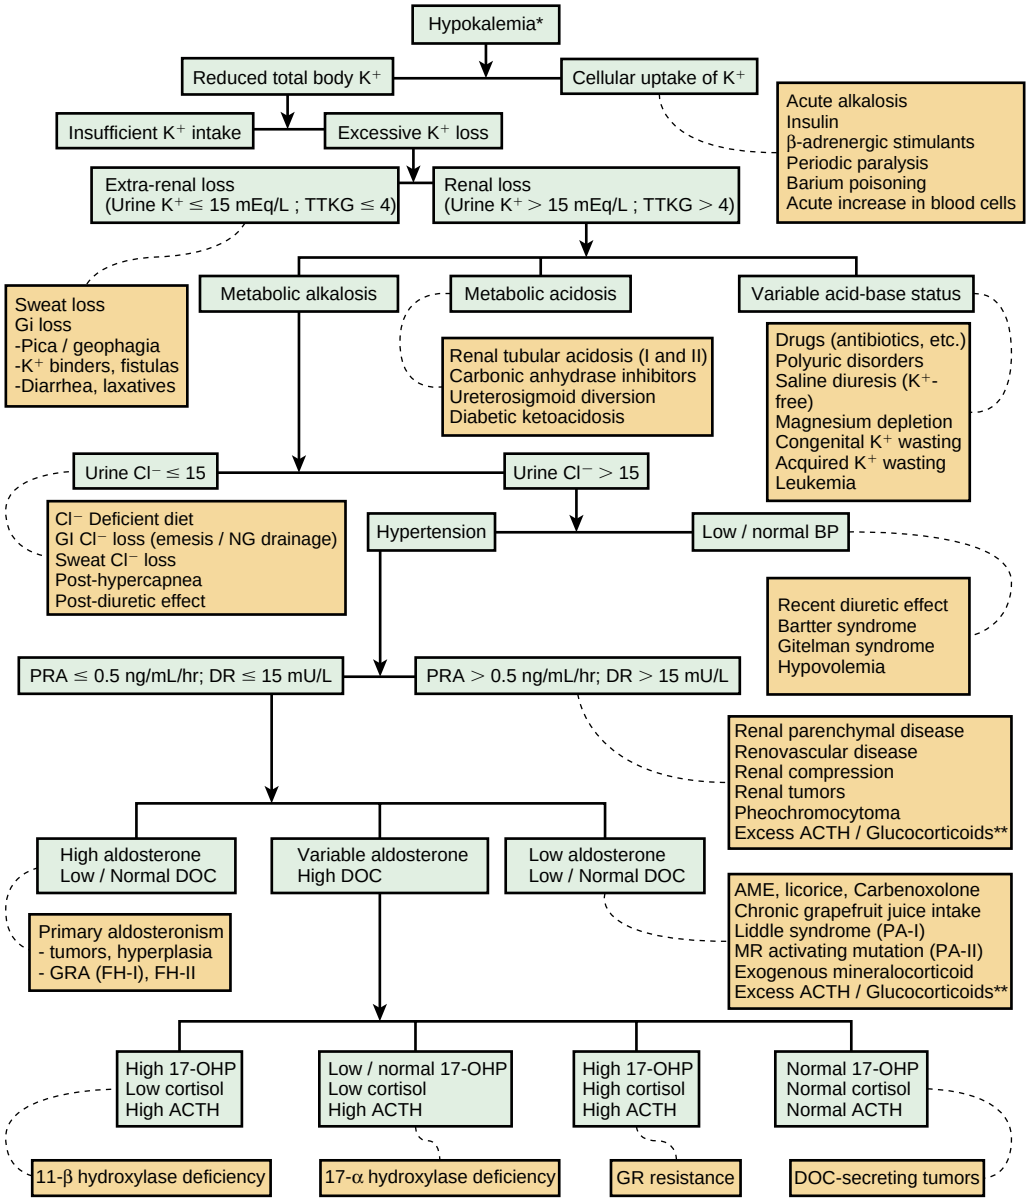

Fig. 73.6 Diagnostic algorithm to evaluate persistent hypokalemia. *Spurious hypokalemia must be excluded. **Hypokalemia is uncommon in uncomplicated edematous disorders and in conditions associated with excessive glucocorticosteroids. Conditions associated with high circulating levels of glucocorticosteroids often have normal renin activity. 17-OHP, 17-Hydroxyprogesterone; ACTH, adrenocorticotropic hormone; AME, apparent mineralocorticoid excess; BP, blood pressure; Cl^-, chloride; DOC, 11-deoxycorticosterone; DR, direct renin assay; GI, gastrointestinal; FH-II, familial hyperaldosteronism type II; GR, glucocorticoid receptor; GRA (FH-I), glucocorticoid remediable aldosteronism (familial hyperaldosteronism type I); K^+, potassium; MR, mineralocorticoid receptor; PA-I, pseudohyperaldosteronism type I; PA-II, pseudohyperaldosteronism type II; PRA, plasma renin activity; TTKG, transtubular potassium gradient. *(From Shoemaker LR, Eaton BV, Buchino JJ. A three-year-old with persistent hypokalemia. J Pediatr. 2007;151[6]:696–699.)*

Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. Adenosine triphosphate (ATP) and guanosine triphosphate need associated magnesium when they are used by ATPases, cyclases, and kinases.

Magnesium Intake

Between 30% and 50% of dietary magnesium is absorbed. Good dietary sources include green vegetables, cereals, nuts, meats, and hard water, although many foods contain magnesium. Human milk contains approximately 35 mg/L of magnesium; formula contains 40-70 mg/L. The small intestine is the major site of magnesium absorption, but the regulation of magnesium absorption is poorly understood. There is passive absorption, which permits high absorption in the presence of excessive intake. It probably occurs by a paracellular mechanism. Absorption is diminished in the presence of substances that complex with magnesium (free fatty acids, fiber, phytate, phosphate, oxalate); increased intestinal motility and calcium also decrease magnesium absorption. Vitamin D and parathyroid hormone (PTH) may enhance absorption, although this effect is limited. Intestinal absorption does increase when intake is decreased, possibly by a saturable, active transport system. If there is no oral intake of magnesium, obligatory secretory losses prevent the complete elimination of intestinal losses.

Magnesium Excretion

Renal excretion is the principal regulator of magnesium balance. There is no defined hormonal regulatory system, although PTH may increase

tubular resorption. Approximately 15% of resorption occurs in the proximal tubule and 70% in the thick ascending limb (TAL) of the loop of Henle. Proximal resorption may be higher in neonates. High serum magnesium levels inhibit resorption in the TAL, suggesting that active transport is involved. Approximately 5–10% of filtered magnesium is resorbed in the distal tubule. Hypomagnesemia increases absorption in the TAL and the distal tubule.

HYPOMAGNESEMIA

Hypomagnesemia is relatively common in hospitalized patients, although most cases are asymptomatic. Detection requires a high index of suspicion because magnesium is not measured in most basic metabolic panels.

Table 73.6 Conversion Factors for Calcium, Magnesium, and Phosphorus

	UNIT	CONVERSION FACTOR	UNIT
Calcium	mg/dL	0.25	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.5	mEq/L
Magnesium	mg/dL	0.411	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.822	mEq/L
Phosphorus	mg/dL	0.32	mmol/L

Etiology and Pathophysiology

GI and renal losses are the major causes of hypomagnesemia (Table 73.7). Diarrheal fluid contains up to 200 mg/L of magnesium; gastric contents have only approximately 15 mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss because of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses. The potassium-lowering agent patiromer binds magnesium and may cause hypomagnesemia.

Hypomagnesemia with secondary hypocalcemia, a rare autosomal recessive disorder, is caused by decreased intestinal absorption of magnesium and renal magnesium wasting. Patients with this disorder have pathogenic variants in a gene expressed in intestine and kidney; *TRPM6* codes for a transient receptor potential cation channel. The patients have seizures, tetany, tremor, or restlessness at 2-8 weeks of life because of severe hypomagnesemia (0.2-0.8 mg/dL) and secondary hypocalcemia.

Renal losses may occur because of medications that are direct tubular toxins. Amphotericin frequently causes significant magnesium wasting and is typically associated with other tubular defects (especially potassium wasting). Cisplatin produces dramatic renal magnesium losses. Diuretics affect tubular handling of magnesium. Loop diuretics cause a mild increase in magnesium excretion, and thiazide diuretics have even less effect. Chronic use of proton pump inhibitors (PPIs) may cause hypomagnesemia. Potassium-sparing diuretics reduce magnesium losses. Osmotic agents, such as mannitol, glucose in diabetes mellitus, and urea in the recovery phase of acute tubular necrosis, increase urinary magnesium losses. Epidermal growth factor (EGF) receptor inhibitors cause renal magnesium wasting. IV fluid, by expanding the intravascular volume, decreases renal resorption of

Table 73.7 Causes of Hypomagnesemia

GASTROINTESTINAL LOSSES
- Diarrhea
- Nasogastric suction or emesis
- Inflammatory bowel disease
- Celiac disease
- Cystic fibrosis
- Intestinal lymphangiectasia
- Small bowel resection or bypass
- Pancreatitis
- Protein-calorie malnutrition

- Hyperuricemia, pulmonary hypertension, renal failure in infancy and alkalosis, HUPRA syndrome (OMIM 613845)
- Transient neonatal hyperphenylalaninemia followed by hypomagnesemia and maturity onset diabetes of the young (OMIM 264070)
- Hypomagnesemia, seizures and mental retardation due to *CNNM2* pathogenic variants (OMIM 616418)
- Autosomal dominant kidney hypomagnesemia due to *RRAGD* pathogenic variants (OMIM not assigned)

MISCELLANEOUS CAUSES
- Poor intake
- Hungry bone syndrome
- Insulin administration
- Pancreatitis
- Intrauterine growth restriction
- Infants of diabetic mothers
- Exchange transfusion

*This disorder is also associated with renal magnesium wasting.
EAST, Epilepsy, ataxia, sensorineural hearing loss, and tubulopathy; OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

sodium and water, thereby impairing magnesium resorption. Hypercalcemia inhibits magnesium resorption in the loop of Henle, although this inhibition does not occur in hypercalcemia caused by familial hypercalcemic hypocalciuria or lithium.

A number of rare genetic diseases cause renal magnesium loss. Gitelman and Bartter syndromes, both autosomal recessive disorders, are the most common entities (see Chapter 571). **Gitelman syndrome**, caused by a defect in the thiazide-sensitive Na^+-Cl^- cotransporter in the distal tubule, is usually associated with hypomagnesemia. Hypomagnesemia occurs in a minority of patients with **Bartter syndrome**, which can be caused by pathogenic variants in multiple genes necessary for Na^+ and Cl^- reabsorption in the loop of Henle. In both disorders, there is hypokalemic metabolic alkalosis. Typically, hypomagnesemia is not severe and is asymptomatic, although tetany as a result of hypomagnesemia occasionally occurs.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (Michelis-Castrillo syndrome), an autosomal recessive disorder, is caused by pathogenic variants in the gene for claudin 16 (paracellin-1), located in the tight junctions of the TAL of the loop of Henle. Patients with the disease have severe renal wasting of magnesium and calcium with secondary hypomagnesemia and nephrocalcinosis; serum calcium levels are normal. Chronic kidney failure frequently occurs during childhood. Other features include kidney stones, urinary tract infections, hematuria, increased PTH levels, tetany, seizures, incomplete distal RTA, hyperuricemia, polyuria, and polydipsia. Patients with **familial hypomagnesemia with hypercalciuria, nephrocalcinosis, and severe ocular involvement** have pathogenic variants in the gene for claudin 19.

Autosomal recessive renal magnesium wasting with normocalciuria is caused by pathogenic variants in the EGF gene. Clinical manifestations include seizures, mild to moderate psychomotor retardation, and brisk tendon reflexes.

Autosomal dominant renal magnesium wasting is caused by pathogenic variants in a number of different genes. A dominant-negative pathogenic variant in the gene encoding the Na^+,K^+-ATPase γ subunit is associated with hypomagnesemia, increased urinary magnesium losses, hypocalciuria, and normocalcemia. Patients may present with seizures; most are asymptomatic, despite serum magnesium levels of 0.8-1.5 mg/dL. Pathogenic variants in *CNNM2*, which encodes a protein that mediates magnesium-sensitive sodium currents, cause isolated hypomagnesemia. A pathogenic variant in *KCNA1*, a gene that encodes a K^+ channel, also causes an autosomal dominant form of hypomagnesemia; symptoms may be severe.

Renal cysts and diabetes syndrome, which is caused by pathogenic variants in the gene for hepatocyte nuclear factor-1β, is associated with hypomagnesemia, despite the frequent presence of decreased kidney function. The hypomagnesemia is usually mild but may cause symptomatic hypocalcemia. **EAST syndrome** is caused by pathogenic variants in a potassium channel, and patients with this autosomal recessive disorder have hypokalemia, metabolic alkalosis, and hypomagnesemia. Pathogenic variants of *RRAGD* cause **autosomal dominant kidney hypomagnesemia,** and affected patients may have hypokalemia, hypomagnesemia, metabolic alkalosis, hypercalciuria, nephrocalcinosis, and a severe cardiomyopathy. **Autosomal dominant hypoparathyroidism** is caused by an activating pathogenic variant in the calcium-sensing receptor, which also senses magnesium levels in the kidney (see Chapter 611). The abnormal receptor inappropriately perceives that magnesium and calcium levels are elevated, leading to urinary wasting of both cations. Hypomagnesemia, if present, is usually mild. A pathogenic variant in a mitochondrially encoded transfer RNA is associated with hypomagnesemia, hypertension, and hypercholesterolemia. Hypomagnesemia is occasionally present in children with other mitochondrial disorders.

Poor intake is an unusual cause of hypomagnesemia, although it can be seen in children who are hospitalized and receive only IV fluids without magnesium. In **hungry bone syndrome**, which most frequently occurs after parathyroidectomy in patients with hyperparathyroidism, magnesium moves into bone as a result of accelerated bone formation. These patients usually have hypocalcemia and hypophosphatemia through the same mechanism. A similar mechanism can occur during the **refeeding phase of protein-calorie malnutrition** in children, with high magnesium use during cell growth depleting the patient's limited reserves. Insulin therapy stimulates uptake of magnesium by cells, and in DKA, in which total body magnesium is low because of osmotic losses, hypomagnesemia frequently occurs. In **pancreatitis** there is saponification of magnesium and calcium in necrotic fat, causing both hypomagnesemia and hypocalcemia.

Transient hypomagnesemia in newborns, which is sometimes idiopathic, is more common in infants of diabetic mothers, presumably as a result of maternal depletion from osmotic losses. Other maternal diseases that cause magnesium losses predispose infants to hypomagnesemia. Hypomagnesemia is more common in infants with intrauterine growth restriction. Hypomagnesemia may develop in newborn infants who require exchange transfusions because of magnesium removal by the citrate in banked blood.

Clinical Manifestations

Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting of the tissue response to PTH. Thus hypomagnesemia is part of the differential diagnosis of hypocalcemia. It usually occurs only at magnesium levels <0.7 mg/dL. The dominant manifestations of hypomagnesemia are caused by hypocalcemia: tetany, presence of Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Persistent hypocalcemia caused by hypomagnesemia is a rare cause of rickets.

Many causes of hypomagnesemia also result in hypokalemia. Hypomagnesemia may produce renal potassium wasting and hypokalemia that corrects only with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

Diagnosis

The etiology of hypomagnesemia is often readily apparent from the clinical situation. The child should be assessed for GI disease, adequate intake, and kidney disease, with close attention paid to medications that may cause renal magnesium wasting. When the diagnosis is uncertain, an evaluation of urinary magnesium losses distinguishes between renal and nonrenal causes. The *fractional excretion of magnesium* (FE_{Mg}) is calculated via the following formula:

$$FE_{Mg} = (U_{Mg} \times P_{Cr}) \,/\, ([0.7 \times P_{Mg}] \times U_{Cr}) \times 100$$

where U_{Mg} = urinary magnesium concentration, P_{Cr} = plasma creatinine concentration, P_{Mg} = plasma magnesium concentration, and U_{Cr} = urinary magnesium concentration. The plasma magnesium concentration is multiplied by 0.7 because approximately 30% is bound to albumin and not filtered at the glomerulus.

The FE_{Mg} does not vary with age, but it does change according to the serum magnesium concentration. The FE_{Mg} ranges from 1–8% in children with normal magnesium levels. In the patient with hypomagnesemia as a result of extrarenal causes, FE_{Mg} should be low because of renal conservation, typically <2%. The FE_{Mg} is inappropriately elevated in the setting of renal magnesium wasting; values are usually >4% and frequently >10%. The measurement should not be made during a magnesium infusion, because the acute increase in serum magnesium increases urinary magnesium. Other approaches for evaluating urinary magnesium losses include calculation of 24-hour urinary magnesium losses and the urine magnesium/creatinine ratio, both of which vary with age.

The genetic causes of renal magnesium loss are distinguished based on the measurement of other serum and urinary electrolytes. *Children with Gitelman or Bartter syndrome have hypokalemia and metabolic alkalosis.*

Treatment

Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulfate is given at a dose of 25-50 mg/kg (0.05-0.1 mL/kg of a 50% solution; 2.5-5.0 mg/kg of elemental magnesium). It is administered as a slow IV infusion, although it may be given intramuscularly in neonates. The rate of IV infusion should be slowed if a patient experiences diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6 hours (every 8-12 hours in neonates), for a total of 2-3 doses, before the plasma magnesium concentration is rechecked. Lower doses are used in children with decreased kidney function.

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4 mg elemental magnesium/100 mg), magnesium oxide (60 mg elemental magnesium/100 mg), and magnesium sulfate (10 mg elemental magnesium/100 mg). Sustained-release preparations include Slow-Mag (60 mg elemental magnesium/tablet) and Mag-Tab SR (84 mg elemental magnesium/tablet). Oral magnesium dosing should be divided to decrease cathartic side effects. Alternatives to oral magnesium are intramuscular injections and nighttime nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency.

HYPERMAGNESEMIA

Clinically significant hypermagnesemia is almost always secondary to excessive intake. It is unusual, except in neonates born to mothers who are receiving IV magnesium for preeclampsia or eclampsia (see Chapter 121.5).

Etiology and Pathophysiology

There is no feedback mechanism to prevent magnesium absorption from the GI tract. Magnesium is present in high amounts in certain laxatives, enemas, cathartics used to treat drug overdoses, and antacids. It is also usually present in total parenteral nutrition (TPN), and neonates may receive high amounts transplacentally if maternal levels are elevated. Usually the kidneys excrete excessive magnesium, but this ability is diminished in patients with chronic kidney disease. In addition, neonates and young infants are vulnerable to excessive magnesium ingestion because of their reduced GFR. Most pediatric cases not related to maternal hypermagnesemia occur in infants because of excessive use of antacids or laxatives. Mild hypermagnesemia may occur in chronic kidney disease, familial hypocalciuric hypercalcemia, DKA, lithium ingestion, milk-alkali syndrome, and tumor lysis syndrome. The hypermagnesemia in DKA occurs despite significant intracellular magnesium depletion because of urinary losses; hypomagnesemia often occurs after insulin treatment.

Clinical Manifestations

Symptoms usually do not appear until the plasma magnesium level is >4.5 mg/dL. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction, producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. The neuromuscular effects may be exacerbated by aminoglycoside antibiotics. Direct CNS depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium values are associated with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations from a direct effect on cardiac function. ECG changes include prolonged PR interval, QRS complex, and QT interval. Severe hypermagnesemia (>15 mg/dL) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.

Diagnosis

Except for the case of the neonate with transplacental exposure, a high index of suspicion and a good history are necessary to determine the etiology of hypermagnesemia. Prevention is essential; magnesium-containing compounds should be used judiciously in children with decreased kidney function.

Treatment

Most patients with normal kidney function rapidly clear excess magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially in patients with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, provision of fluids, monitoring of electrolyte levels, and the use of pressors for hypotension. In acute emergencies, especially in the context of severe neurologic or cardiac manifestations, 100 mg/kg of IV calcium gluconate is transiently effective.

73.6 Phosphorus

Larry A. Greenbaum

Approximately 65% of plasma phosphorus is in phospholipids, but these compounds are insoluble in acid and are not measured by clinical laboratories. It is the phosphorus content of *plasma phosphate* that is determined. The result is reported as either phosphate or phosphorus, although even when the term *phosphate* is used, it is actually the *phosphorus* concentration that is measured and reported. The result is that the terms phosphate and phosphorus are often used interchangeably. The term *phosphorus* is preferred when referring to the plasma concentration. Conversion from the units used in the United States (mg/dL) to mmol/L is straightforward (see Table 73.6).

PHOSPHORUS METABOLISM

Body Content and Physiologic Function

Most phosphorus is in bone or is intracellular, with <1% in plasma. At a physiologic pH, there are monovalent and divalent forms of phosphate because the pK_a (ionization constant of acid) of these forms is 6.8. Approximately 80% is divalent, and the remainder is monovalent at a pH of 7.4. A small percentage of plasma phosphate, approximately 15%, is protein bound. The remainder can be filtered by the glomerulus, with most existing as free phosphate and a small percentage complexed with calcium, magnesium, or sodium. Phosphate is the most plentiful intracellular anion, although the majority is part of a larger compound (ATP).

More than that of any other electrolyte, the phosphorus concentration varies with age (Table 73.8). The teleologic explanation for the high concentration during childhood is the need for phosphorus to facilitate growth. There is diurnal variation in the plasma phosphorus concentration, with the peak during sleep.

Table 73.8 Serum Phosphorus Levels During Childhood

AGE	PHOSPHORUS LEVEL (mg/dL)
0-5 day	4.8-8.2
1-3 yr	3.8-6.5
4-11 yr	3.7-5.6
12-15 yr	2.9-5.4
16-19 yr	2.7-4.7

Phosphorus, as a component of adenosine triphosphate (ATP) and other trinucleotides, is critical for cellular energy metabolism. It is necessary for cell signaling and nucleic acid synthesis, and it is a component of cell membranes and other structures. Along with calcium, phosphorus is necessary for skeletal mineralization. A net positive phosphorus balance is required during growth, with the growing skeleton especially vulnerable to deficiency.

Phosphorus Intake

Phosphorus is readily available in food. Milk and milk products are the best sources of phosphorus; high concentrations are present in meat and fish. Vegetables have more phosphorus than fruits and grains. GI absorption of phosphorus is proportional to intake, with approximately 65% of intake being absorbed, including a small amount that is secreted. Absorption, almost exclusively in the small intestine, occurs via a paracellular diffusive process and a vitamin D–regulated transcellular pathway. However, the impact of the change in phosphorus absorption caused by vitamin D is relatively small compared with the effect of variations in phosphorus intake.

Phosphorus Excretion

Despite the wide variation in phosphorus absorption dictated by oral intake, excretion matches intake, except for the needs for growth. The kidney regulates phosphorus balance, which is determined by intrarenal mechanisms and hormonal actions on the nephron.

Approximately 90% of plasma phosphate is filtered at the glomerulus, although there is some variation based on plasma phosphate and calcium concentrations. There is no significant secretion of phosphate along the nephron. Resorption of phosphate occurs mostly in the proximal tubule, although a small amount can be resorbed in the distal tubule. Normally, approximately 85% of the filtered load is resorbed. Sodium-phosphate co-transporters mediate the uptake of phosphate into the cells of the proximal tubule.

Dietary phosphorus determines the amount of phosphate resorbed by the nephron. There are both acute and chronic changes in phosphate resorption that are based on intake. Many of these changes appear to be mediated by intrarenal mechanisms that are independent of regulatory hormones. **Fibroblast growth factor-23** (**FGF-23**) inhibits renal resorption of phosphorus in the proximal tubule, and its level increases in the setting of hyperphosphatemia. FGF-23 also inhibits synthesis of 1,25-vitamin D in the kidney by decreasing 1α-hydroxylase activity.

Secreted in response to a low plasma calcium level, PTH decreases resorption of phosphate, increasing the urinary phosphate level. This process appears to have a minimal effect during normal physiologic variation in PTH levels. However, it does affect urinary phosphate in the setting of pathologic changes in PTH synthesis.

Low plasma phosphorus stimulates the 1α-hydroxylase in the kidney that converts 25-hydroxyvitamin D (25-D) to 1,25-dihydroxyvitamin D (1,25-D; calcitriol). Calcitriol increases intestinal absorption of phosphorus and is necessary for maximal renal resorption of phosphate. The effect of a change in calcitriol on urinary phosphate is significant only when the level of calcitriol was initially low, arguing against a role for calcitriol in nonpathologic conditions.

HYPOPHOSPHATEMIA

Because of the wide variation in normal plasma phosphorus levels, the definition of hypophosphatemia is age dependent (see Table 73.8). The normal range reported by a laboratory may be based on adult normal values and therefore may be misleading in children. A serum phosphorus level of 3 mg/dL, a normal value in an adult, indicates clinically significant hypophosphatemia in an infant.

The plasma phosphorus level does not always reflect the total body stores because only 1% of phosphorus is extracellular. Thus a child may have significant phosphorus deficiency despite a normal plasma phosphorus concentration when there is a shift of phosphorus from the ICS.

Etiology and Pathophysiology

A variety of mechanisms cause hypophosphatemia (Table 73.9). A transcellular shift of phosphorus into cells occurs with processes that stimulate cellular usage of phosphorus (glycolysis). Usually, this shift causes only a minor, transient decrease in plasma phosphorus, but if intracellular phosphorus deficiency is present, the plasma phosphorus level can decrease significantly, producing symptoms of acute hypophosphatemia. Glucose infusion stimulates insulin release, leading to entry of glucose and phosphorus into the cells. Phosphorus is then used during glycolysis and other metabolic processes. A similar phenomenon can occur during the treatment of DKA, and patients with DKA are typically phosphorus depleted because of urinary phosphorus losses.

Table 73.9 Causes of Hypophosphatemia

TRANSCELLULAR SHIFTS

*These are primary genetic causes of Fanconi syndrome. Fanconi syndrome may also be secondary to medications, genetic disorders (cystinosis) or systemic disease (Sjögren syndrome).

OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

Refeeding of patients with protein-calorie malnutrition causes anabolism, which leads to significant cellular demand for phosphorus (see Chapter 63). The increased phosphorus uptake for incorporation into newly synthesized compounds containing phosphorus leads to hypophosphatemia, which can be severe and symptomatic. **Refeeding hypophosphatemia** occurs frequently during treatment of severe anorexia nervosa. It can occur during treatment of children with malnutrition from any cause, such as cystic fibrosis, Crohn disease, burns, neglect, chronic infection, or famine. Hypophosphatemia usually occurs within the first 5 days of refeeding and is prevented by a gradual increase in nutrition with appropriate phosphorus supplementation. TPN without adequate phosphorus can cause hypophosphatemia.

Phosphorus moves into the ICS during a respiratory alkalosis and during recovery from a respiratory acidosis. An acute decrease in the carbon dioxide concentration, by raising the intracellular pH, stimulates glycolysis, leading to intracellular use of phosphorus and hypophosphatemia. Because a metabolic alkalosis has less effect on the intracellular pH (CO_2 diffuses across cell membranes much faster than bicarbonate), transcellular phosphorus movement is minimal with a metabolic alkalosis.

Tumors that grow rapidly, such as those associated with leukemia and lymphoma, may use large amounts of phosphorus, leading to hypophosphatemia. A similar phenomenon may occur during the hematopoietic reconstitution that follows bone marrow transplantation. In **hungry bone syndrome**, there is avid bone uptake of phosphorus, along with calcium and magnesium, which can produce plasma deficiency of all three ions. Hungry bone syndrome is most common after parathyroidectomy for hyperparathyroidism because the stimulus for bone dissolution is acutely removed, but bone synthesis continues.

Nutritional phosphorus deficiency is unusual because most foods contain phosphorus. However, infants are especially susceptible because of their high demand for phosphorus to support growth, especially of the skeleton. Very low birthweight infants have particularly rapid skeletal growth, and phosphorus deficiency and rickets may develop if they are fed human milk or formula for term infants. There is also a relative deficiency of calcium. The provision of additional calcium and phosphorus, using breast milk fortifier or special premature infant formula, prevents this complication. Phosphorus deficiency, sometimes with concomitant calcium and vitamin D deficiencies, occurs in infants who are not given enough milk or who receive a milk substitute that is nutritionally inadequate.

Antacids containing aluminum hydroxide (e.g., Maalox, Mylanta) bind dietary phosphorus and secreted phosphorus, preventing absorption. This process can cause phosphorus deficiency and rickets in growing children. A similar mechanism causes hypophosphatemia in patients who are overtreated for hyperphosphatemia with phosphorus binders. In children with kidney failure, the addition of dialysis to phosphorus binders increases the risk of iatrogenic hypophosphatemia in these normally hyperphosphatemic patients. This complication, which is more common in infants, can worsen kidney osteodystrophy.

Excessive renal losses of phosphorus occur in a variety of inherited and acquired disorders. Because PTH inhibits the resorption of phosphorus in the proximal tubule, **hyperparathyroidism** causes hypophosphatemia (see Chapter 613). The dominant clinical manifestation, however, is hypercalcemia, and the hypophosphatemia is usually asymptomatic. The phosphorus level in hyperparathyroidism is not extremely low, and there is no continued loss of phosphorus because a new steady state is achieved at the lower plasma phosphorus level. Renal excretion therefore does not exceed intake over the long term. Occasional malignancies produce PTH-related peptide, which has the same actions as PTH and causes hypophosphatemia and hypercalcemia.

A variety of diseases cause renal phosphate wasting, hypophosphatemia, and rickets resulting from excess FGF-23 (see Chapter 69). These disorders include X-linked hypophosphatemic rickets, tumor-induced osteomalacia, autosomal dominant hypophosphatemic rickets, and autosomal recessive hypophosphatemic rickets types 1-3. Ferric carboxymaltose, an IV iron preparation for correcting iron deficiency, causes hypophosphatemia via increased levels of FGF-23.

Fanconi syndrome is a generalized defect in the proximal tubule leading to urinary wasting of bicarbonate, phosphorus, amino acids, uric acid, and glucose (see Chapter 569.1). The clinical sequelae result from the metabolic acidosis and hypophosphatemia. In children, an underlying genetic disease, usually cystinosis, often causes Fanconi syndrome, but it can be secondary to a variety of toxins and acquired diseases. Some patients have incomplete Fanconi syndrome, and phosphorus wasting may be one of the manifestations.

Dent disease, an X-linked disorder, can cause renal phosphorus wasting and hypophosphatemia, although the latter is not present in most cases. Other possible manifestations of Dent disease include tubular proteinuria, hypercalciuria, nephrolithiasis, rickets, and decreased kidney function. Dent disease may be secondary to pathologic variants in a gene that encodes a chloride channel or the *OCRL1* gene, which may also cause Lowe syndrome (see Chapter 569.1). **Hypophosphatemic rickets with hypercalciuria** is a rare autosomal recessive disorder, principally described in kindreds from the Middle East (see Chapter 69). Pathologic variants in a sodium-phosphate co-transporter cause hypophosphatemia in this disorder, and complications may include nephrolithiasis and osteoporosis. Similar findings are seen in hypophosphatemic rickets with nephrolithiasis and osteoporosis types 1 and 2 (see Chapter 69).

Metabolic acidosis inhibits resorption of phosphorus in the proximal tubule. In addition, metabolic acidosis causes a transcellular shift of phosphorus out of cells because of intracellular catabolism. This released phosphorus is subsequently lost in the urine, leading to significant phosphorus depletion, even though the plasma phosphorus level may be normal. This classically occurs in DKA, in which renal phosphorus loss is further increased by the osmotic diuresis. With correction of the metabolic acidosis and the administration of insulin, both of which cause a transcellular movement of phosphorus into the cells, there is a marked decrease in the plasma phosphorus level.

Volume expansion from any cause, such as hyperaldosteronism or SIADH, inhibits resorption of phosphorus in the proximal tubule. This effect also occurs with high rates of IV fluids. Thiazide and loop diuretics can increase renal phosphorus excretion, but the increase is seldom clinically significant. Glycosuria and glucocorticoids inhibit renal conservation of phosphorus. Hypophosphatemia is common after kidney transplantation because of urinary phosphorus losses. Possible explanations include preexisting secondary hyperparathyroidism from chronic kidney disease, glucocorticoid therapy, and upregulation of FGF-23 before transplantation. The hypophosphatemia usually resolves in a few months.

Both acquired and genetic causes of **vitamin D deficiency** are associated with hypophosphatemia (see Chapter 69). The pathogenesis is multifactorial. By impairing intestinal calcium absorption, vitamin D deficiency causes secondary hyperparathyroidism that leads to increased urinary phosphorus wasting. An absence of vitamin D decreases intestinal absorption of phosphorus and directly decreases renal resorption of phosphorus. The dominant clinical manifestation is rickets, although some patients have muscle weakness that may be related to phosphorus deficiency.

Alcoholism is the most common cause of severe hypophosphatemia in adults. Fortunately, many of the risk factors that predispose alcoholic adults to hypophosphatemia are not usually present in adolescents (malnutrition, antacid abuse, recurrent DKA episodes). Hypophosphatemia often occurs in sepsis, but the mechanism is not clear. Aggressive, protracted hemodialysis, as might be used for

the treatment of methanol or ethylene glycol ingestion, can cause hypophosphatemia.

Clinical Manifestations

There are acute and chronic manifestations of hypophosphatemia. **Rickets** occurs in children with long-term phosphorus deficiency. The clinical features of rickets are described in Chapter 69.

Severe hypophosphatemia, typically at levels <1.0-1.5 mg/dL, may affect every organ in the body because phosphorus has a critical role in maintaining adequate cellular energy. Phosphorus is a component of ATP and is necessary for glycolysis. With inadequate phosphorus, 2,3-diphosphoglycerate levels in RBCs decrease, impairing release of oxygen to the tissues. Severe hypophosphatemia can cause hemolysis and dysfunction of WBCs. Chronic hypophosphatemia causes proximal muscle weakness and atrophy. In the intensive care unit, phosphorus deficiency may slow weaning from mechanical ventilation or cause acute respiratory failure. **Rhabdomyolysis** is the most common complication of acute hypophosphatemia, usually in the setting of an acute transcellular shift of phosphorus into cells in a child with chronic phosphorus depletion (anorexia nervosa). The rhabdomyolysis is actually somewhat protective, in that cellular release of phosphorus occurs. Other manifestations of severe hypophosphatemia include cardiac dysfunction and neurologic symptoms, such as tremor, paresthesia, ataxia, seizures, delirium, and coma.

Diagnosis

The history and basic laboratory evaluation often suggest the etiology of hypophosphatemia. The history should investigate nutrition, medications, and familial disease. Hypophosphatemia and rickets in an otherwise healthy young child suggest a genetic defect in renal phosphorus conservation, Fanconi syndrome, inappropriate use of antacids, poor nutrition, vitamin D deficiency, or a genetic defect in vitamin D metabolism. The patient with Fanconi syndrome usually has metabolic acidosis, glycosuria, aminoaciduria, and a low plasma uric acid level. Measurement of 25-D and 1,25-D, calcium, and PTH differentiates among the various vitamin D deficiency disorders and primary renal phosphate wasting (see Chapter 69). Hyperparathyroidism is easily distinguished by the presence of elevated plasma PTH and calcium values.

Treatment

The plasma phosphorus level, the presence of symptoms, the likelihood of chronic depletion, and the presence of ongoing losses dictate the approach to therapy. Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or that losses are ongoing. Oral phosphorus can cause diarrhea, so the doses should be divided. IV therapy is effective in patients who have severe deficiency or who cannot tolerate oral medications. IV phosphorus is available as either sodium phosphate or potassium phosphate, with the choice usually based on the patient's plasma potassium level. Starting doses are 0.08-0.16 mmol/kg over 6 hours. The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load, whereas supplemental potassium may be helpful in some diseases, such as Fanconi syndrome and malnutrition. Oral maintenance dosages are 2-3 mmol/kg/day in divided doses, although the maintenance dose varies considerably between patients.

Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually from dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require specific therapy (see Chapter 69). Specifically, X-linked hypophosphatemia responds to burosumab, a monoclonal antibody targeting FGF-23.

HYPERPHOSPHATEMIA

Etiology and Pathophysiology

Renal insufficiency is the most common cause of hyperphosphatemia, with the severity proportional to the degree of kidney impairment (see Chapter 572). This occurs because GI absorption of the large dietary intake of phosphorus is unregulated, and the kidneys normally excrete this phosphorus. As kidney function deteriorates, increased excretion of phosphorus is able to compensate. When kidney function is <30% of normal, hyperphosphatemia usually develops, although this varies considerably depending on dietary intake. Many of the other causes of hyperphosphatemia are more likely to develop in the setting of decreased kidney function (Table 73.10).

Cellular content of phosphorus is high relative to plasma phosphorus, and cell lysis can release substantial phosphorus. This is the etiology of hyperphosphatemia in **tumor lysis syndrome**, **rhabdomyolysis**, and **acute hemolysis**. These disorders cause concomitant potassium release and the risk of hyperkalemia. Additional features of tumor lysis and rhabdomyolysis are hyperuricemia and hypocalcemia, whereas indirect hyperbilirubinemia and elevated lactate dehydrogenase (LDH) values are often present with hemolysis. An elevated CPK level is suggestive of rhabdomyolysis. During lactic acidosis or DKA, use of phosphorus by cells decreases, and phosphorus shifts into the ECS. This problem reverses when the underlying problem is corrected, and especially with DKA, patients subsequently become hypophosphatemic because of previous renal phosphorus loss.

Excessive intake of phosphorus is especially dangerous in children with decreased kidney function. Neonates are at risk because kidney function is normally reduced during the first few months of life. In addition, they may erroneously be given doses of phosphorus that are meant for an older child or adult. In infants fed cow's milk, which has higher phosphorus content than breast milk or formula, hyperphosphatemia may develop. **Fleet Enema** has a high amount of phosphorus that can be absorbed, especially in the patient with an ileus; infants and children with Hirschsprung disease are especially vulnerable. There is often associated hypernatremia from sodium absorption and water loss from diarrhea. Sodium phosphorus laxatives may cause hyperphosphatemia if the dose is excessive or if renal insufficiency is present. Hyperphosphatemia occurs in children who receive overaggressive treatment for hypophosphatemia. **Vitamin D intoxication** causes excessive GI absorption of both calcium and phosphorus, and the suppression of PTH by hypercalcemia decreases renal phosphorus excretion.

The absence of PTH in **hypoparathyroidism** or PTH responsiveness in **pseudohypoparathyroidism** causes hyperphosphatemia because of increased resorption of phosphorus in the proximal tubule of the kidney (see Chapters 611 and 612). The associated hypocalcemia is responsible for the clinical symptoms. The hyperphosphatemia in hyperthyroidism or acromegaly is usually mild. It is secondary to increased resorption of phosphorus in the proximal tubule from the actions of thyroxine or growth hormone. Excessive thyroxine can also cause bone resorption, which may contribute to the hyperphosphatemia and cause hypercalcemia. Patients with **familial tumoral calcinosis** (three types), a rare autosomal recessive disorder, have hyperphosphatemia because of decreased renal phosphate excretion and heterotopic calcifications. The disease may be secondary to pathologic variants in the genes for a glycosyltransferase (most common etiology), FGF-23, or klotho, which encodes the co-receptor for FGF-23. Autoimmune hyperphosphatemic tumoral calcinosis occurs with antibodies producing FGF-23 resistance.

Clinical Manifestations

The principal clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. The hypocalcemia is probably caused by tissue deposition of calcium-phosphorus salt, inhibition of 1,25-D production, and decreased bone resorption. Symptomatic hypocalcemia is most likely to occur when the phosphorus level increases rapidly or when diseases predisposing to hypocalcemia are present (chronic kidney disease, rhabdomyolysis). Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. Clinically, this condition is often apparent in the conjunctiva, where it manifests as a foreign body feeling, erythema, and injection. More ominous manifestations are hypoxia from pulmonary calcification and kidney failure from nephrocalcinosis.

Diagnosis

Plasma creatinine and BUN levels should be assessed in any patient with hyperphosphatemia. The history should focus on intake of phosphorus and the presence of chronic diseases that may cause hyperphosphatemia. Measurement of K^+, uric acid, calcium, LDH, bilirubin, hemoglobin, and CPK may be indicated if rhabdomyolysis, tumor lysis, or hemolysis is suspected. With mild hyperphosphatemia and significant hypocalcemia, measurement of the serum PTH level distinguishes between hypoparathyroidism and pseudohypoparathyroidism.

Treatment

The treatment of acute hyperphosphatemia depends on its severity and etiology. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; the resolution can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, IV fluids can enhance renal phosphorus excretion. For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding what is normally secreted and absorbed by the GI tract. Phosphorus binders are most effective when given with food. Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective alternative and may be preferred if there is a need to treat concomitant hypocalcemia. Preservation of renal function, as with high urine flow in rhabdomyolysis or tumor lysis, is an important adjunct because it will permit continued excretion of phosphorus. If the hyperphosphatemia is not responding to conservative management, especially if acute kidney injury is supervening, dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow, given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism and mild chronic kidney disease. For more problematic hyperphosphatemia, such as with moderate chronic kidney disease and end-stage kidney disease, phosphorus binders are usually necessary. They include calcium carbonate, calcium acetate, sevelamer, ferric citrate, sucroferric oxyhydroxide, and lanthanum. Aluminum-containing phosphorus binders are no longer used in patients with **chronic kidney disease** because of the risk of aluminum toxicity. Dialysis directly removes phosphorus from the blood in patients with end-stage kidney disease, but it is only an adjunct to dietary restriction and phosphorus binders; removal by dialysis does not keep up with normal dietary intake.

73.7 Acid-Base Balance

Larry A. Greenbaum

ACID-BASE PHYSIOLOGY

Terminology

Chronic, mild derangements in acid-base status may interfere with normal growth and development, whereas acute, severe changes in pH can be fatal. Control of acid-base balance depends on the kidneys, the lungs, and intracellular and extracellular buffers.

A normal pH is 7.35-7.45. There is an inverse relationship between the pH and the hydrogen ion concentration([H^+]). At a pH of 7.40, [H^+] is 40 nmol/L. A normal serum sodium concentration, 140 mEq/L, is 1 million times higher. Maintaining a normal pH is necessary because hydrogen ions are highly reactive and are especially likely to combine with proteins, altering their function.

An **acid** is a substance that releases ("donates") a hydrogen ion (H^+). A **base** is a substance that accepts a hydrogen ion. An acid (HA) can dissociate into a hydrogen ion and a conjugate base (A^-), as follows:

$$HA \leftrightarrow H^+ + A^-$$

A strong acid is highly dissociated, so in this reaction, there is little HA. A weak acid is poorly dissociated; not all the hydrogen ions are released from HA. A^- acts as a base when the reaction moves to the left. These reactions are in equilibrium. When HA is added to the system, there is dissociation of some HA until the concentrations of H^+ and A^- increase enough that a new equilibrium is reached. Addition of hydrogen ions causes a decrease in A^- and an increase in HA. Addition of A^- causes a decrease in hydrogen ions and an increase in HA.

Buffers are substances that attenuate the change in pH that occurs when acids or bases are added to the body. Given the extremely low [H^+] in the body at physiologic pH, without buffers a small amount of hydrogen ions could cause a dramatic decline in the pH. Buffers prevent the decrease in pH by binding the added hydrogen ions, as follows:

$$A^- + H^+ \rightarrow HA$$

The increase in [H^+] drives this reaction to the right. Similarly, when base is added to the body, buffers prevent the pH from increasing by releasing hydrogen ions, as follows:

$$HA \rightarrow A^- + H^+$$

The best buffers are weak acids and bases. This is because a buffer works best when it is 50% dissociated (half HA and half A^-). The pH at which a buffer is 50% dissociated is its pK_a (ionization constant

of acid). The best physiologic buffers have a pK_a close to 7.40. The concentration of a buffer and its pK_a determine the buffer's effectiveness (buffering capacity). When the pH is lower than the pK_a of a buffer, there is more HA than A^-. When the pH is higher than the pK_a, there is more A^- than HA.

Physiologic Buffers

The bicarbonate and nonbicarbonate buffers protect the body against major changes in pH. The **bicarbonate buffer system** is routinely monitored clinically and is based on the relationship between carbon dioxide (CO_2) and bicarbonate (HCO_3^-):

$$CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$$

CO_2 acts as an acid in that, after combining with water, it releases an H^+; bicarbonate acts as its conjugate base in that it accepts an H^+. The pK_a of this reaction is 6.1. The **Henderson-Hasselbalch equation** expresses the relationship among pH, pK_a, and the concentrations of an acid and its conjugate base. This relationship is valid for any buffer. The Henderson-Hasselbalch equation for bicarbonate and CO_2 is as follows:

$$pH = 6.1 + \log [HCO_3^-] \; / \; [CO_2]$$

The **Henderson-Hasselbalch equation** for the bicarbonate buffer system has three variables: pH, bicarbonate concentration ($[HCO_3^-]$), and carbon dioxide concentration ($[CO_2]$). Thus, if any two of these variables are known, it is possible to calculate the third. When one is using the Henderson-Hasselbalch equation, it is important that CO_2 and bicarbonate have the same units. CO_2 is reported clinically as mm Hg and must be multiplied by its solubility constant, 0.03 mmol/L/mm Hg, before the equation can be used. Mathematical manipulation of the Henderson-Hasselbalch equation produces the following relationship:

$$\left[H^+\right] = 24 \times PCO_2 / \left[HCO_3^-\right]$$

At a normal $[H^+]$ of 40 nmol (pH 7.40), the partial pressure of carbon dioxide (P_{CO_2}), which is expressed as mm Hg in this equation, is 40 when the $[HCO_3^-]$ is 24 mEq/L. This equation emphasizes that $[H^+]$, and thus pH, can be determined by the ratio of P_{CO_2} and $[HCO_3^-]$.

The bicarbonate buffer system is very effective because of the high concentration of bicarbonate in the body (24 mEq/L) and because it is an open system. The remaining body buffers are in a closed system. The bicarbonate buffer system is an open system because the lungs increase CO_2 excretion when the blood CO_2 concentration increases. When acid is added to the body, the following reaction occurs:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

In a closed system, the CO_2 would increase. The higher CO_2 concentration would lead to an increase in the reverse reaction:

$$CO_2 + H_2O \rightarrow H^+ + HCO_3^-$$

This would increase $[H^+]$, limiting the buffering capacity of bicarbonate. However, because the lungs excrete the excess CO_2, the reverse reaction does not increase; this fact enhances the buffering capacity of bicarbonate. The same principle holds with the addition of base, because the lungs decrease CO_2 excretion and prevent the CO_2 level from falling. The lack of change in $[CO_2]$ dramatically increases the buffering capacity of bicarbonate.

The **nonbicarbonate buffers** include proteins, phosphate, and bone. Protein buffers consist of extracellular proteins, mostly albumin and intracellular proteins, including hemoglobin. Proteins are effective buffers, largely because of the presence of the amino acid *histidine,* which has a side chain that can bind or release H^+. The pK_a of histidine varies slightly, depending on its position in the protein molecule, but its average pK_a is approximately 6.5. This is close enough to a normal pH (7.4) to make histidine an effective buffer. Hemoglobin and albumin have 34 and 16 histidine molecules, respectively.

Phosphate can bind up to three hydrogen molecules, so it can exist as PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^{1-}$, or H_3PO_4. However, at a physiologic pH, most phosphate exists as either HPO_4^{2-} or $H_2PO_4^{1-}$. $H_2PO_4^{1-}$ is an acid, and HPO_4^{2-} is its conjugate base:

$$H_2PO_4^{1-} \leftrightarrow H^+ + HPO_4^{2-}$$

The pK_a of this reaction is 6.8, making phosphate an effective buffer. The concentration of phosphate in the ECS is relatively low, limiting the overall buffering capacity of phosphate; it is less important than albumin. However, phosphate is found at a much higher concentration in the urine, where it is an important buffer. In the ICS, most phosphate is covalently bound to organic molecules (ATP), but it still serves as an effective buffer.

Bone is an important buffer. Bone is *basic*—it is composed of compounds such as sodium bicarbonate and calcium carbonate—and thus dissolution of bone releases base. This release can buffer an acid load, although at the expense of bone density, if it occurs over an extended period. In contrast, bone formation, by consuming base, helps buffer excess base.

Clinically, we measure the extracellular pH, but it is the intracellular pH that affects cell function. Measurement of the intracellular pH is unnecessary because changes in the intracellular pH parallel the changes in the extracellular pH. However, the change in the intracellular pH tends to be less than the change in the extracellular pH because of the greater buffering capacity in the ICS.

NORMAL ACID-BASE BALANCE

The lungs and kidneys maintain a normal acid-base balance. Carbon dioxide generated during normal metabolism is a weak acid. The lungs prevent an increase in the P_{CO_2} in the blood by excreting the CO_2 that the body produces. CO_2 production varies according to the body's metabolic needs, increasing with physical activity. The rapid pulmonary response to changes in the CO_2 concentration occurs via central sensing of the P_{CO_2} and a subsequent increase or decrease in ventilation to maintain a normal P_{CO_2} (35-45 mm Hg). An increase in ventilation decreases the P_{CO_2}, and a decrease in ventilation increases the P_{CO_2}.

The kidneys excrete endogenous acid. An adult normally produces approximately 1-2 mEq/kg/24 hr of H^+. Children normally produce 2-3 mEq/kg/24 hr of H^+. The three principal sources of H^+ are dietary protein metabolism, incomplete metabolism of carbohydrates and fat, and stool losses of bicarbonate. Because metabolism of protein generates H^+, endogenous acid production varies with protein intake. The complete oxidation of carbohydrates or fats to CO_2 and water does not generate H^+; the lungs remove the CO_2. However, incomplete metabolism of carbohydrates or fats produces H^+. Incomplete glucose metabolism can produce lactic acid, and incomplete triglyceride metabolism can produce ketoacids, such as β-hydroxybutyric acid and acetoacetic acid. There is always some baseline incomplete metabolism that contributes to endogenous acid production. This factor increases in pathologic conditions, such as **lactic acidosis** and diabetic ketoacidosis (DKA). Stool loss of bicarbonate is the third major source of endogenous acid production. The stomach secretes H^+, but most of the remainder of the GI tract secretes bicarbonate, and the net effect is a loss of bicarbonate from the body. To secrete bicarbonate, the cells of the intestine produce hydrogen ions that are released into the bloodstream. For each bicarbonate molecule lost in the stool, the body gains one H^+. This source of endogenous acid production is normally minimal but may increase dramatically in a patient with diarrhea.

The hydrogen ions formed from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to decrease. The kidneys regenerate this bicarbonate by secreting H^+. The lungs cannot regenerate bicarbonate, even though loss of CO_2 lowers the $[H^+]$, as shown in the following reaction:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

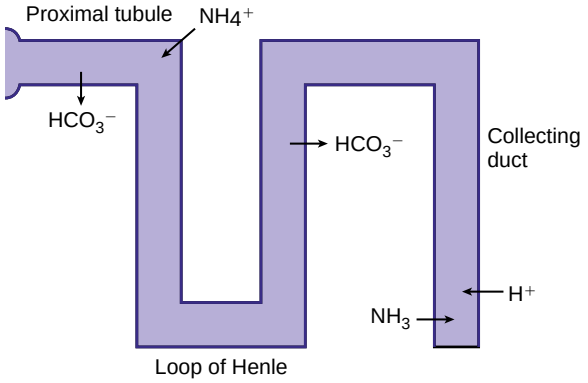

Fig. 73.7 Tubular sites involved in acid-base balance. The proximal tubule is the site where most filtered bicarbonate is reclaimed, even though other sites along the nephron, especially the thick ascending limb of the loop of Henle, resorb some of the filtered bicarbonate. The collecting duct is the principal location for the hydrogen ion secretion that acidifies the urine. The proximal tubule generates the ammonia that serves as a urinary buffer in the collecting duct.

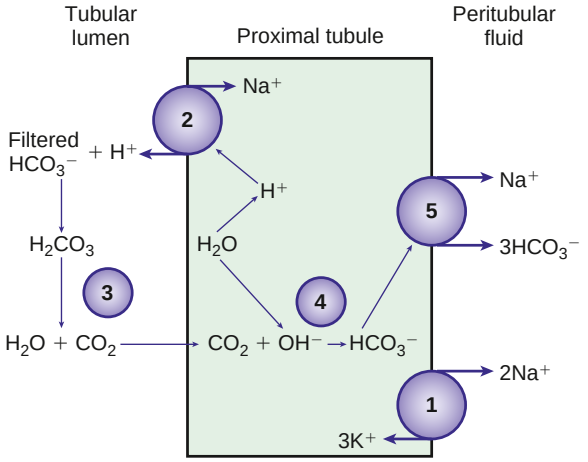

Fig. 73.8 Resorption of filtered bicarbonate in the proximal tubule. The Na^+,K^+-ATPase *(1)* excretes sodium across the basolateral cell membrane, maintaining a low intracellular sodium concentration. The low intracellular sodium concentration provides the energy for the Na^+,H^+ antiporter *(2)*, which exchanges sodium from the tubular lumen for intracellular hydrogen ions. The hydrogen ions that are secreted into the tubular lumen then combine with filtered bicarbonate to generate carbonic acid. CO_2 and water are produced from carbonic acid (H_2CO_3). This reaction is catalyzed by luminal carbonic anhydrase *(3)*. CO_2 diffuses into the cell and combines with OH^- ions to generate bicarbonate. This reaction is catalyzed by an intracellular carbonic anhydrase *(4)*. The dissociation of water generates an OH^- ion and an H^+ ion. The Na^+,H^+ antiporter *(2)* secretes the hydrogen ions. Bicarbonate ions cross the basolateral membrane and enter the blood via the $3HCO_3^-/1Na^+$ co-transporter *(5)*. The energy for the $3HCO_3^-/1Na^+$ co-transporter comes from the negatively charged cell interior, which makes it electrically favorable to transport a net negative charge (i.e., 3 bicarbonates and only 1 sodium) out of the cell.

A decrease in $[CO_2]$ causes the reaction to move to the right, which decreases $[H^+]$, but it also lowers $[HCO_3^-]$. During a metabolic acidosis, hyperventilation can lower $[CO_2]$, decrease $[H^+]$, and thus increase pH. The underlying metabolic acidosis is still present. Similarly, the kidneys cannot correct an abnormally high $[CO_2]$, as shown in the following reaction:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

An increase in $[HCO_3^-]$ also causes the reaction to move to the right, which increases $[CO_2]$ while simultaneously decreasing $[H^+]$. During a respiratory acidosis, increased renal generation of bicarbonate can decrease $[H^+]$ and increase pH but cannot repair the respiratory acidosis. Both the lungs and the kidneys can affect $[H^+]$ and thus pH. However, only the lungs can regulate $[CO_2]$, and only the kidneys can regulate $[HCO_3^-]$.

Renal Mechanisms

The kidneys regulate the serum bicarbonate concentration by modifying acid excretion in the urine. This requires a two-step process. First, the renal tubules resorb the bicarbonate that is filtered at the glomerulus. Second, there is tubular secretion of H^+. The urinary excretion of H^+ generates bicarbonate that neutralizes endogenous acid production. The tubular actions necessary for renal acid excretion occur throughout the nephron (Fig. 73.7).

The resorption of filtered bicarbonate is a necessary first step in renal regulation of the acid-base balance. A normal adult has a GFR of approximately 180 L/24 hr. This fluid enters Bowman's space with $[HCO_3^-]$ that is essentially identical to the plasma concentration, normally 24 mEq/L. Multiplying 180 L by 24 mEq/L indicates that >4,000 mEq of bicarbonate enters Bowman's space each day. This bicarbonate, if not reclaimed along the nephron, would be lost in the urine and would cause a profound metabolic acidosis.

The proximal tubule reclaims approximately 85% of the filtered bicarbonate (Fig. 73.8). The final 15% is reclaimed beyond the proximal tubule, mostly in the ascending limb of the loop of Henle. Bicarbonate molecules are not transported from the tubular fluid into the cells of the proximal tubule. Rather, hydrogen ions are secreted into the tubular fluid, leading to conversion of filtered bicarbonate into CO_2 and water. The secretion of H^+ by the cells of the proximal tubule is coupled to generation of intracellular bicarbonate, which is transported across the basolateral membrane of the proximal tubule cell and enters the capillaries. The bicarbonate produced in the cell replaces the bicarbonate filtered at the glomerulus.

Increased bicarbonate resorption by the cells of the proximal tubule—the result of increased H^+ secretion—occurs in a variety of clinical situations. Volume depletion increases bicarbonate resorption. This is partially mediated by activation of the renin-angiotensin system; angiotensin II increases bicarbonate resorption. Increased bicarbonate resorption in the proximal tubule is one of the mechanisms that accounts for the metabolic alkalosis that may occur in some patients with volume depletion. Other stimuli that increase bicarbonate resorption include hypokalemia and an increased P_{CO_2}. This partially explains the observations that hypokalemia causes a metabolic alkalosis, and that a respiratory acidosis leads to a compensatory increase in serum $[HCO_3^-]$.

Stimuli that decrease bicarbonate resorption in the proximal tubule may cause a decrease in the serum $[HCO_3^-]$. A decrease in the P_{CO_2} (respiratory alkalosis) decreases proximal tubule bicarbonate resorption, partially mediating the decrease in serum $[HCO_3^-]$ that compensates for a respiratory alkalosis. PTH decreases proximal tubule bicarbonate resorption; hyperparathyroidism may cause a mild metabolic acidosis. A variety of medications and diseases cause a metabolic acidosis by impairing bicarbonate resorption in the proximal tubule. Examples are the medication acetazolamide, which directly inhibits carbonic anhydrase, and the many disorders that cause proximal RTA (see Chapter 569.1).

After reclaiming filtered bicarbonate, the kidneys perform the second step in renal acid-base handling, the excretion of the acid created by endogenous acid production. Excretion of acid occurs mostly in the collecting duct, with a small role for the distal tubule.

Along with secretion of H^+ by the tubular cells lining the collecting duct, adequate excretion of endogenous acid requires the presence of urinary buffers. The hydrogen pumps in the collecting duct cannot lower the urine pH below 4.5. The $[H^+]$ at pH 4.5 is <0.04 mEq/L; it would require >25 L of water with a pH of 4.5 to excrete one mEq of H^+. A 10-kg child, with an endogenous acid production of 20 mEq H^+ each day, would need to have a daily urinary output of >500 L without the presence of urinary buffers. As in the blood, buffers in the urine attenuate the decrease in pH that occurs with the addition of H^+. The two principal urinary buffers are phosphate and ammonia.

Urinary **phosphate** is proportional to dietary intake. Whereas most of the phosphate filtered at the glomerulus is resorbed in the proximal tubule, the urinary phosphate concentration is usually much greater than the serum phosphate concentration. This arrangement allows phosphate to serve as an effective buffer through the following reaction:

$$H^+ + HPO_4^{2-} \rightarrow H_2PO_4^{1-}$$

The pK_a of this reaction is 6.8, making phosphate an effective buffer as the urinary pH decreases from 7.0 to 5.0 within the collecting duct. Although phosphate is an effective buffer, its buffering capacity is limited by its concentration; there is no mechanism for increasing urinary phosphate excretion in response to changes in acid-base status.

In contrast, **ammonia** production can be modified, allowing for regulation of acid excretion. The buffering capacity of ammonia (NH_3) is based on the reaction of ammonia with hydrogen ions to form ammonium:

$$NH_3 + H^+ \rightarrow NH_4^+$$

The cells of the proximal tubule are the source of the excreted ammonia, mostly through metabolism of glutamine through the following reactions:

$$\text{Glutamine} \rightarrow NH_4^+ + \text{glutamate}^-$$

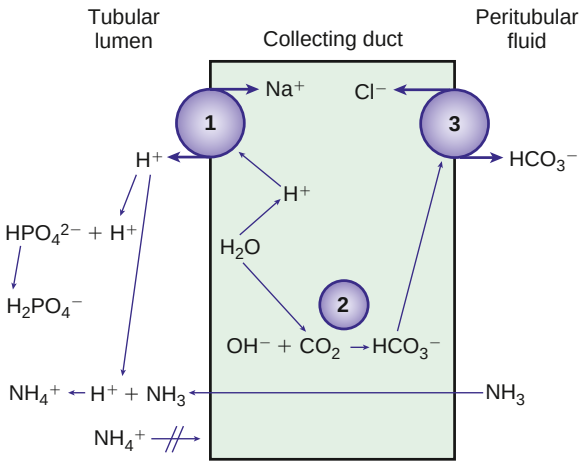

Fig. 73.9 Secretion of hydrogen ions in the collecting duct. The dissociation of water generates an OH^- ion and an H^+ ion. The H^+-ATPase *(1)* secretes hydrogen ions into the tubular lumen. Bicarbonate is formed when an OH^- ion combines with CO_2 in a reaction mediated by carbonic anhydrase *(2)*. Bicarbonate ions cross the basolateral membrane and enter the blood via the HCO_3^-/Cl^- exchanger *(3)*. The hydrogen ions in the tubular lumen are buffered by phosphate and ammonia (NH_3). NH_3 can diffuse from the peritubular fluid into the tubular lumen, but ammonium (NH_4^+) cannot pass through the cells of the collecting duct.

$$\text{Glutamate}^- \rightarrow NH_4^+ + \alpha - \text{ketoglutarate}^{3-}$$

The metabolism of glutamine generates two ammonium ions. In addition, the metabolism of α-ketoglutarate generates two bicarbonate molecules. The ammonium ions are secreted into the lumen of the proximal tubule, whereas the bicarbonate molecules exit the proximal tubule cells via the basolateral $Na^+,3HCO_3^-$ co-transporter (see Fig. 73.8). This arrangement would seem to accomplish the goal of excreting H^+ (as NH_4^+) and regenerating bicarbonate molecules. However, the ammonium ions secreted in the proximal tubule do not remain within the tubular lumen. Cells of the TAL of the loop of Henle resorb the ammonium ions. The result is that there is a high medullary interstitial concentration of ammonia, but the tubular fluid entering the collecting duct does not have significant amounts of ammonium ions. Moreover, the hydrogen ions that were secreted with ammonia (as ammonium ions) in the proximal tubule enter the bloodstream, canceling the effect of the bicarbonate generated in the proximal tubule. The excretion of ammonium ions, and thus of hydrogen ions, depends on the cells of the collecting duct.

The cells of the collecting duct secrete H^+ and regenerate bicarbonate, which is returned to the bloodstream (Fig. 73.9). This bicarbonate neutralizes endogenous acid production. Phosphate and ammonia buffer the H^+ secreted by the collecting duct. Ammonia is an effective buffer because of the high concentrations in the medullary interstitium and because the cells of the collecting duct are permeable to ammonia but not to ammonium. As ammonia diffuses into the lumen of the collecting duct, the low urine pH causes almost all the ammonia to be converted into ammonium. This process maintains a low luminal ammonia concentration. Because the luminal pH is lower than the pH in the medullary interstitium, there is a higher concentration of ammonia within the medullary interstitium than in the tubular lumen, favoring movement of ammonia into the tubular lumen. Even though the concentration of ammonium in the tubular lumen is higher than in the interstitium, the cells of the collecting duct are impermeable to ammonium, preventing back-diffusion of ammonium out of the tubular lumen and permitting ammonia to be an effective buffer.

The kidneys adjust H^+ excretion according to physiologic needs. There is variation in endogenous acid production, largely a result of diet and pathophysiologic stresses, such as diarrheal losses of bicarbonate, which increase the need for acid excretion. H^+ excretion is increased by upregulation of H^+ secretion in the collecting duct, causing the pH of the urine to decrease. This response is prompt, occurring within hours of an acid load, but it is limited by the buffering capacity of the urine; the hydrogen pumps in the collecting duct cannot lower the pH to <4.5. A more significant increase in acid excretion requires upregulation of ammonia production by the proximal tubule so that more ammonia is available to serve as a buffer in the tubular lumen of the collecting duct. This response to a low serum pH reaches its maximum within 5-6 days; ammonia excretion can increase approximately 10-fold over the baseline value.

Acid excretion by the collecting duct increases in a number of different clinical situations. The extracellular pH is the most important regulator of renal acid excretion. A decrease in the extracellular pH from either a respiratory or a metabolic acidosis causes an increase in renal acid excretion. Aldosterone stimulates H^+ excretion in the collecting duct, causing an increase in the serum bicarbonate concentration. This explains the metabolic alkalosis that occurs with primary hyperaldosteronism or secondary hyperaldosteronism caused by volume depletion. Hypokalemia increases acid secretion, by both stimulating ammonia production in the proximal tubule and increasing H^+ secretion in the collecting duct. Hypokalemia therefore tends to produce a metabolic alkalosis. Hyperkalemia has the opposite effects, which may cause a metabolic acidosis.

In patients with an increased pH, the kidney has two principal mechanisms for correcting the problem. First, less bicarbonate is resorbed in the proximal tubule, leading to an increase in urinary bicarbonate losses. Second, in a limited number of specialized cells, the process for

secretion of H^+ by the collecting duct can be reversed (see Fig. 73.9), leading to secretion of bicarbonate into the tubular lumen and secretion of hydrogen ions into the peritubular fluid, where they enter the bloodstream.

CLINICAL ASSESSMENT OF ACID-BASE DISORDERS

The following rearrangement of the Henderson-Hasselbalch equation emphasizes the relationship among P_{CO_2}, bicarbonate concentration, and hydrogen ion concentration:

$$[H^+] = 24 \times PCO_2 [HCO_3^-]$$

An increase in the P_{CO_2} or a decrease in $[HCO_3^-]$ increases $[H^+]$; the pH decreases. A decrease in the P_{CO_2} or an increase in $[HCO_3^-]$ decreases $[H^+]$; the pH increases.

Terminology

Acidemia is a pH below normal (<7.35), and **alkalemia** is a pH above normal (>7.45). An **acidosis** is a pathologic process that causes an increase in $[H^+]$, and an **alkalosis** is a pathologic process that causes a decrease in $[H^+]$. Whereas acidemia is always accompanied by an acidosis, a patient can have an acidosis and a low, normal, or high pH. For example, a patient may have a mild metabolic acidosis but a simultaneous, severe respiratory alkalosis; the net result may be alkalemia. Acidemia and alkalemia indicate the pH abnormality; acidosis and alkalosis indicate the pathologic process that is taking place.

A **simple acid-base disorder** is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation. With a metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in P_{CO_2}. The decrease in the $[CO_2]$ leads to an increase in the pH. This appropriate respiratory compensation is expected with a primary metabolic acidosis. Despite the decrease in $[CO_2]$, appropriate respiratory compensation is not a respiratory alkalosis, even though it is sometimes erroneously called a "compensatory" respiratory alkalosis. A low P_{CO_2} can result either from a primary respiratory alkalosis or from appropriate respiratory compensation for a metabolic acidosis. Appropriate respiratory compensation also occurs with a primary metabolic alkalosis, although in this case $[CO_2]$ increases to attenuate the increase in the pH. The respiratory compensation for a metabolic process happens quickly and is complete within 12-24 hours; it cannot overcompensate for or normalize the pH.

During a primary respiratory process, there is metabolic compensation, mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing H^+ excretion, thereby increasing bicarbonate generation and raising the serum $[HCO_3^-]$. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; $[HCO_3^-]$ decreases. Unlike respiratory compensation, which occurs rapidly, it takes 3-4 days for the kidneys to complete appropriate metabolic compensation. There is, however, a small and rapid compensatory change in $[HCO_3^-]$ during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder depends on whether the process is acute or chronic.

A **mixed acid-base disorder** is present when there is more than one primary acid-base disturbance. An infant with bronchopulmonary dysplasia may have a respiratory acidosis from chronic lung disease and a metabolic alkalosis from the furosemide used to treat the chronic lung disease. More dramatically, a child with pneumonia and sepsis may have severe acidemia because of a combined metabolic acidosis caused by lactic acid and respiratory acidosis caused by ventilatory failure.

There are formulas for calculating the appropriate metabolic or respiratory compensation for the six primary simple acid-base disorders (Table 73.11). The appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have the appropriate compensation, a mixed acid-base disorder is present. For example, if a patient has a primary metabolic acidosis with a serum $[HCO_3^-]$ of 10 mEq/L, the expected respiratory compensation is $[CO_2]$ of 23 mm Hg ± 2 ($1.5 \times 10 + 8 \pm 2 = 23 \pm 2$; see Table 73.11). If the patient's $[CO_2]$ is >25 mm Hg, a concurrent respiratory acidosis is present; $[CO_2]$ is higher than expected. A patient may have a respiratory acidosis despite a CO_2 level below the "normal" value of 35-45 mm Hg. In this example, $[CO_2]$ <21 mm Hg indicates a concurrent respiratory alkalosis; $[CO_2]$ is lower than exp ected.

Table 73.11 Appropriate Compensation During Simple Acid-Base Disorders

DISORDER	EXPECTED COMPENSATION
Metabolic acidosis	$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$
Metabolic alkalosis	P_{CO_2} increases by 7 mm Hg for each 10 mEq/L increase in serum $[HCO_3^-]$
Respiratory Acidosis	
Acute	$[HCO_3^-]$ increases by 1 for each 10 mm Hg increase in P_{CO_2}
Chronic	$[HCO_3^-]$ increases by 3.5 for each 10 mm Hg increase in P_{CO_2}
Respiratory Alkalosis	
Acute	$[HCO_3^-]$ falls by 2 for each 10 mm Hg decrease in P_{CO_2}
Chronic	$[HCO_3^-]$ falls by 4 for each 10 mm Hg decrease in P_{CO_2}

Table 73.12 Normal Values of Arterial Blood Gases

pH	7.35-7.45
$[HCO_3^-]$	20-28 mEq/L
P_{CO_2}	35-45 mm Hg

Diagnosis

A systematic evaluation of an arterial blood gas (ABG) sample, combined with the clinical history, can usually explain the patient's acid-base disturbance. Assessment of an ABG sample requires knowledge of normal values (Table 73.12). In most cases, this is accomplished through a three-step process (Fig. 73.10):

1. Determine whether acidemia or alkalemia is present.
2. Determine a cause of the acidemia or alkalemia.
3. Determine whether a mixed disorder is present.

Most patients with an acid-base disturbance have an abnormal pH, although there are two exceptions. One exception is in the patient with a mixed disorder in which the two processes have opposite effects on pH (a metabolic acidosis and a respiratory alkalosis) and cause changes in $[H^+]$ that are comparable in magnitude, although opposite. The other exception is in the patient with a simple chronic respiratory alkalosis; in some cases, the appropriate metabolic compensation is enough to normalize the pH. In both situations, the presence of an acid-base disturbance is deduced because of the abnormal CO_2 and bicarbonate levels. Determining the acid-base disturbance in these patients requires proceeding to the third step of the process.

The second step requires inspection of the serum $[HCO_3^-]$ and P_{CO_2} to determine a cause of the abnormal pH (see Fig. 73.10). In most cases, there is only one obvious explanation for the abnormal pH. In some mixed disorders, however, there may be two possibilities (e.g., a high P_{CO_2} and a low $[HCO_3^-]$ in a patient with acidemia). In such cases, the patient has two causes for abnormal pH—a metabolic acidosis and a respiratory acidosis, in this instance—and it is unnecessary to proceed to the third step.

The third step requires determining whether the patient's compensation is appropriate. It is assumed that the primary disorder was

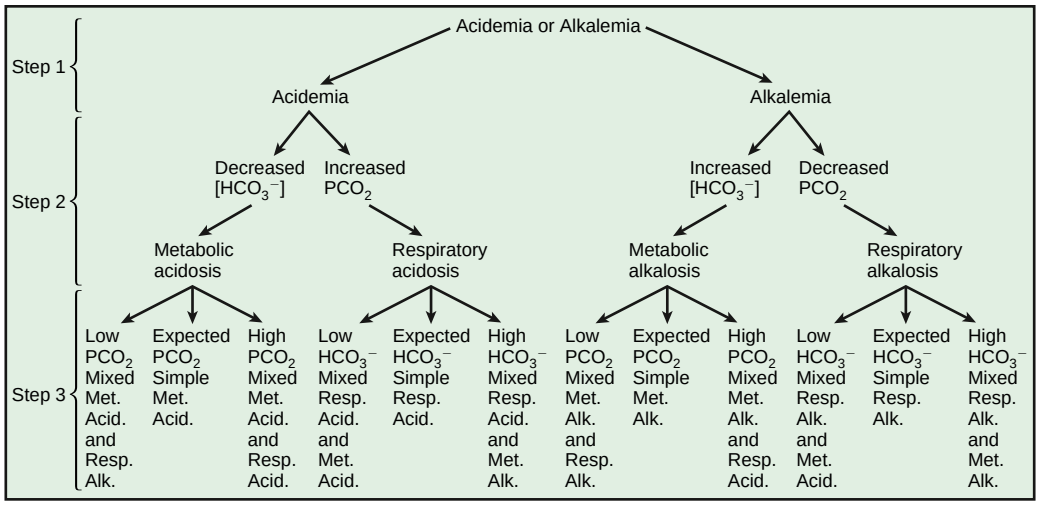

Fig. 73.10 Three-step process for interpreting acid-base disturbances. In step 1, determine whether the pH is low (acidemia) or high (alkalemia). In step 2, establish an explanation for the acidemia or alkalemia. In step 3, calculate the expected compensation (see Table 73.11) and determine whether a mixed disturbance is present. Met. Acid., metabolic acidosis; Met. Alk., metabolic alkalosis; Resp. Acid., respiratory acidosis; Resp. Alk., respiratory alkalosis.

diagnosed in the second step, and the expected compensation is calculated (see Table 73.11). If the compensation is appropriate, a simple acid-base disorder is present. If the compensation is not appropriate, a mixed disorder is present. The identity of the second disorder is determined by deciding whether the compensation is too little or too much compared with what was expected (see Fig. 73.10).

The history is always useful in evaluating and diagnosing patients with acid-base disturbances. It is especially helpful in a respiratory process. The expected metabolic compensation for a respiratory process changes according to whether the process is **acute** or **chronic**, which can be deduced only from the history. The metabolic compensation for an acute respiratory acidosis is less than that for a chronic respiratory acidosis. In a patient with a respiratory acidosis, a small increase in $[HCO_3^-]$ would be consistent with a simple acute respiratory acidosis or a mixed disorder (a chronic respiratory acidosis and a metabolic acidosis). Only the history can differentiate among the possibilities. Knowledge of the length of the respiratory process and the presence or absence of a risk factor for a metabolic acidosis (diarrhea) allows the correct conclusion to be reached.

An alternative to the **physiologic** approach just described (which includes calculation of the anion gap; see later) is the **physiochemical** approach, often called the **Stewart method**. Some view this approach as superior to the physiologic approach, but it requires multiple calculations and additional laboratory values and is thus more challenging to use in the clinical setting. The physiochemical approach requires measurement of the blood pH and P_{CO_2} and calculation of the apparent strong ion difference (SIDa), the effective strong ion difference (SIDe), the strong ion gap (SIG), and the total concentration of weak acids (A_{TOT}).

METABOLIC ACIDOSIS

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common etiology. For a patient with an unknown medical problem, the presence of a metabolic acidosis is often helpful diagnostically, because it suggests a relatively narrow differential diagnosis.

Patients with a metabolic acidosis have a low serum $[HCO_3^-]$, although not every patient with a low serum $[HCO_3^-]$ has a metabolic acidosis. The exception is the patient with a respiratory alkalosis, which causes a decrease in the serum $[HCO_3^-]$ as part of appropriate renal compensation. In a patient with an isolated metabolic acidosis, there is a predictable decrease in the blood $[CO_2]$, as follows:

$$PCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$$

A mixed acid-base disturbance is present if the respiratory compensation is not appropriate. If the P_{CO_2} is greater than predicted, the patient has a concurrent respiratory acidosis. A lower P_{CO_2} than predicted indicates a concurrent respiratory alkalosis or, less frequently, an isolated respiratory alkalosis. Because the appropriate respiratory compensation for a metabolic acidosis never normalizes the patient's pH, the presence of a normal pH and a low $[HCO_3^-]$ occurs only if some degree of respiratory alkalosis is present. In this situation, distinguishing an isolated chronic respiratory alkalosis from a mixed metabolic acidosis and acute respiratory alkalosis may be possible only clinically. In contrast, the combination of a low serum pH and a low $[HCO_3^-]$ occurs only if a metabolic acidosis is present.

Etiology and Pathophysiology

There are many causes of a metabolic acidosis (Table 73.13), resulting from three basic mechanisms:

1. Loss of bicarbonate from the body
2. Impaired ability to excrete acid by the kidney
3. Addition of acid to the body (exogenous or endogenous)

Diarrhea, the most common cause of metabolic acidosis in children, causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and $[HCO_3^-]$ of the stool, which tends to increase with more severe diarrhea. The kidneys attempt to balance the losses by increasing acid secretion, but metabolic acidosis occurs when this compensation is inadequate. Diarrhea often causes volume depletion because of losses of sodium and water, potentially exacerbating the acidosis by causing shock and a lactic acidosis. In addition, diarrheal losses of potassium lead to hypokalemia. Moreover, the volume depletion causes increased production of aldosterone. This increase stimulates renal retention of sodium, helping to maintain intravascular volume, but also leads to increased urinary losses of potassium, exacerbating the hypokalemia.

There are four forms of renal tubular acidosis (RTA): distal (type I), proximal (type II), mixed (type III), and hyperkalemic (type IV) (see Chapter 569). In **distal** RTA, children may have accompanying hypokalemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis. Failure

*Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.
†Most cases of proximal RTA are not caused by this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies.
‡Hyperkalemic RTA can be secondary to a genetic disorder (some of the more common are listed) or other etiologies.
OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim); RTA, renal tubular acidosis.

to thrive because of chronic metabolic acidosis is the most common presenting complaint. Patients with distal RTA cannot acidify their urine and thus have a urine pH >5.5 despite a metabolic acidosis.

Proximal RTA is rarely present in isolation. In most patients, proximal RTA is part of **Fanconi syndrome**, a generalized dysfunction of the proximal tubule. The dysfunction leads to glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The presence of a low serum uric acid level, glycosuria, and aminoaciduria is helpful diagnostically. Chronic hypophosphatemia leads to rickets in children (see Chapter 69). Rickets and/or failure to thrive may be the presenting complaint. The ability to acidify the urine is intact in proximal RTA; thus untreated patients have a urine pH <5.5. However, bicarbonate therapy increases bicarbonate losses in the urine, and the urine pH increases. A mixed RTA (combined distal and proximal) occurs in patients with autosomal recessive osteopetrosis caused by pathologic variants in the gene for carbonic anhydrase II.

In **hyperkalemic** RTA, renal excretion of acid and potassium is impaired. Hyperkalemic RTA is the result of hyperkalemia, absence of aldosterone, or inability of the kidney to respond to aldosterone. In severe **aldosterone deficiency**, as occurs with congenital adrenal hyperplasia because of 21α-hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia. Patients may have aldosterone deficiency caused by decreased renin production by the kidney; renin normally stimulates aldosterone synthesis. Children with hyporeninemic hypoaldosteronism usually have either isolated hyperkalemia or hyperkalemic RTA. The manifestations of aldosterone resistance depend on the severity of the resistance. In the autosomal recessive form of **pseudohypoaldosteronism** type I, which is the result of an absence of the sodium channel that normally responds to aldosterone, there is often severe salt wasting and hyponatremia. In contrast, the aldosterone resistance in kidney transplant recipients usually produces either isolated hyperkalemia or hyperkalemic RTA; hyponatremia is unusual. Similarly, the medications that cause hyperkalemic RTA do not cause hyponatremia. Pseudohypoaldosteronism type II, an autosomal dominant disorder also known as **Gordon syndrome**, is a unique cause of hyperkalemic RTA because the genetic defect causes volume expansion and hypertension.

Children with abnormal urinary tracts, usually secondary to congenital malformations, may require diversion of urine through intestinal segments. Ureterosigmoidostomy, anastomosis of a ureter to the sigmoid colon, almost always produces a metabolic acidosis and hypokalemia. Consequently, ileal conduits are the more commonly used procedure, although there is still a risk of a metabolic acidosis.

The appropriate metabolic compensation for a chronic respiratory alkalosis is a decrease in renal acid excretion. The resultant decrease in the serum [HCO_3^-] lessens the alkalemia caused by the respiratory alkalosis. If the respiratory alkalosis resolves quickly, the patient continues to have a decreased serum [HCO_3^-], causing acidemia as the result of a metabolic acidosis. This resolves over 1-2 days through increased acid excretion by the kidneys.

Lactic acidosis (L-lactic) typically occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to shock, severe anemia, or hypoxemia. When the underlying cause of the lactic acidosis is alleviated, the liver is able to metabolize the accumulated lactate into bicarbonate, correcting the metabolic acidosis. There is normally some tissue production of lactate metabolized by the liver. In children with severe liver dysfunction, impairment of lactate metabolism may produce a lactic acidosis. Rarely, a metabolically active malignancy grows so fast that its blood supply becomes inadequate, with resultant anaerobic metabolism and lactic acidosis. Patients who have **short bowel syndrome** resulting from small bowel resection can have bacterial overgrowth. In these patients, excessive intestinal bacterial metabolism of glucose into *D-lactic acid* can cause a lactic acidosis. Lactic acidosis occurs in a variety of **inborn errors of metabolism**, especially those affecting mitochondrial oxidation (see Chapters 107.4 and 108). **Medications** also can cause lactic acidosis. Nucleoside reverse transcriptase inhibitors that are used to treat HIV infection inhibit mitochondrial replication; lactic acidosis is a rare complication, although elevated serum lactate concentrations without acidosis are quite common. Metformin, used to treat type 2 diabetes mellitus, is most likely to cause a lactic acidosis in patients with chronic kidney disease. High dosages and prolonged use of propofol can cause lactic acidosis. Propylene glycol is a diluent in a variety of oral and IV medications; excessive intake causes a lactic acidosis, principally from accumulation of D-lactic acid. Linezolid is another medication that may cause a lactic acidosis

In **insulin-dependent diabetes mellitus**, inadequate insulin leads to hyperglycemia and DKA (see Chapter 629). Production of acetoacetic acid and β-hydroxybutyric acid causes the metabolic acidosis. Administration of insulin corrects the underlying metabolic problem and permits conversion of acetoacetate and β-hydroxybutyrate into bicarbonate, which helps correct the metabolic acidosis. However, in some patients, urinary losses of acetoacetate and β-hydroxybutyrate may be substantial, preventing rapid regeneration of bicarbonate. In these patients, full correction of the metabolic acidosis requires renal regeneration of bicarbonate, a slower process. The hyperglycemia causes an osmotic diuresis, usually producing volume depletion, along with substantial losses of potassium, sodium, and phosphate.

In **starvation ketoacidosis** the lack of glucose leads to ketoacid production, which in turn can produce a metabolic acidosis, although it is usually mild as a result of increased acid secretion by the kidney. In **alcoholic ketoacidosis**, which is much less common in children than in adults, the acidosis usually follows a combination of an alcoholic binge with vomiting and poor intake of food. The acidosis is potentially more severe than with isolated starvation, and the blood glucose level may be low, normal, or high. Hypoglycemia and acidosis also suggest an inborn error of metabolism.

Kidney failure causes a metabolic acidosis because of the need for the kidneys to excrete the acid produced by normal metabolism. With mild or moderate chronic kidney disease, the remaining nephrons are usually able to compensate by increasing acid excretion. When the GFR is <20–30% of normal, the compensation is inadequate, and a metabolic acidosis develops. In some children, especially those with chronic kidney disease because of tubular damage, the acidosis develops at a higher GFR because of a concurrent defect in acid secretion by the distal tubule (distal RTA).

A variety of **toxic ingestions** can cause a metabolic acidosis (see Chapter 94). **Salicylate** intoxication is now much less common because aspirin is no longer recommended for fever control in children. Acute salicylate intoxication occurs after a large overdose. Chronic salicylate intoxication is possible with gradual buildup of the drug. Especially in adults, respiratory alkalosis may be the dominant acid-base disturbance. In children, the metabolic acidosis is usually the more significant finding. Other symptoms of salicylate intoxication are fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication.

Ethylene glycol, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause kidney failure. The toxicity of **methanol** ingestion also depends on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and CNS. Symptoms may include nausea, emesis, visual impairment, and altered mental status. **Toluene** inhalation and **paraldehyde** ingestion are other potential causes of a metabolic acidosis.

Many **inborn errors of metabolism** cause a metabolic acidosis (see Chapters 104-107). The metabolic acidosis may be the result of excessive production of ketoacids, lactic acid, and other organic anions. Some patients have accompanying hypoglycemia or hyperammonemia. In most patients, the acidosis occurs episodically during acute decompensations, which may be precipitated by ingestion of specific dietary substrates, the stress of a mild illness, or poor compliance with dietary or medical therapy. In a few inborn errors of metabolism, patients have a chronic metabolic acidosis.

Clinical Manifestations

The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than those with a concomitant respiratory acidosis. At a serum pH <7.2, there may be impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia, there may be a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in newborn infants with **persistent pulmonary hypertension** (see Chapter 130).

The normal respiratory response to metabolic acidosis—compensatory hyperventilation— may be subtle with mild metabolic acidosis, but it causes discernible increased respiratory effort with worsening acidemia. The acute metabolic effects of acidemia include insulin resistance, increased protein degradation, and reduced ATP synthesis. Chronic metabolic acidosis causes failure to thrive in children. Acidemia causes potassium to move from the ICS to the ECS, thereby increasing the serum [K^+]. Severe acidemia impairs brain metabolism, eventually resulting in lethargy and coma.

Diagnosis

The etiology of a metabolic acidosis is often apparent from the history and physical examination. Acutely, diarrhea and shock are common causes of a metabolic acidosis. Shock, which causes a lactic acidosis, is usually apparent on physical examination and can be secondary to dehydration, acute blood loss, sepsis, or heart disease. Failure to thrive suggests a chronic metabolic acidosis, as with renal insufficiency or RTA. New onset of polyuria occurs in children with undiagnosed diabetes mellitus and DKA. Metabolic acidosis with seizures and/or a depressed sensorium, especially in an infant, warrants consideration of an inborn error of metabolism. Meningitis and sepsis with lactic acidosis are more common explanations for metabolic acidosis with neurologic signs and symptoms. Identification of a toxic ingestion (e.g., ethylene glycol, methanol) is especially important because of the potentially excellent response to specific therapy. A variety of medications can cause a metabolic acidosis, whether prescribed or accidentally ingested. Hepatomegaly and metabolic acidosis may occur in children with sepsis, congenital or acquired heart disease, hepatic failure, or inborn errors of metabolism.

Basic laboratory tests in a child with a metabolic acidosis should include measurements of BUN, serum creatinine, serum glucose, urinalysis, and serum electrolytes. Metabolic acidosis, hyperglycemia, glycosuria, and ketonuria support a diagnosis of DKA. Starvation causes ketosis, but the metabolic acidosis, if present, is usually mild (HCO_3^- >18 mEq/L). Most children with ketosis from poor intake and metabolic acidosis have a concomitant disorder, such as gastroenteritis with diarrhea, that explains the metabolic acidosis. Alternatively, metabolic acidosis with or without ketosis occurs in inborn errors of metabolism; patients with these disorders may have hyperglycemia, normoglycemia, or hypoglycemia. Adrenal insufficiency may cause metabolic acidosis and hypoglycemia. Metabolic acidosis with hypoglycemia also occurs with liver failure. Metabolic acidosis, normoglycemia, and glycosuria occur in children when type II RTA is part of Fanconi syndrome; the defect in resorption of glucose by the proximal tubule of the kidney causes the glycosuria.

The serum [K^+] is often abnormal in children with a metabolic acidosis. Even though a metabolic acidosis causes potassium to move from the ICS to the ECS, many patients with a metabolic acidosis have a low serum [K^+] because of excessive body losses of K^+. With diarrhea, there are high stool losses of K^+ and, often, secondary renal losses of K^+, whereas in type I or type II RTA, there are increased urinary losses of K^+. In DKA, urinary losses of K^+ are high, but the shift of K^+ out of cells because of a lack of insulin and metabolic acidosis is especially significant. Consequently, the initial serum [K^+] can be low, normal, or high, even though total body K^+ is almost always decreased. The serum [K^+] is usually increased in patients with acidosis caused

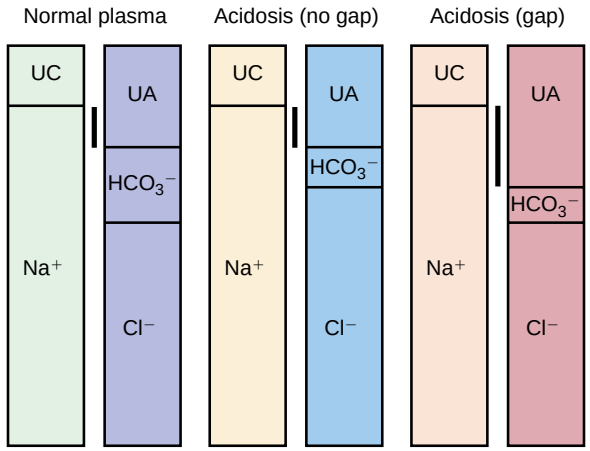

Fig. 73.11 Anion gap. The anion gap is the difference between the sodium concentration and the combined concentrations of chloride and bicarbonate *(vertical black bars)*. In both a gap and a nongap metabolic acidosis, there is a decrease in the bicarbonate concentration. There is an increase in unmeasured anions (UA) in patients with a gap metabolic acidosis. In a nongap metabolic acidosis, there is an increase in the serum chloride concentration. UC, Unmeasured cations.

by renal insufficiency; urinary K^+ excretion is impaired. The combination of metabolic acidosis, hyperkalemia, and hyponatremia occurs in patients with severe aldosterone deficiency (adrenogenital syndrome) or aldosterone resistance. Patients with less severe, type IV RTA often have only hyperkalemia and metabolic acidosis. Very ill children with metabolic acidosis may have an elevated serum K^+ because of a combination of renal insufficiency, tissue breakdown, and a shift of K^+ from the ICS to the ECS secondary to the metabolic acidosis.

The **plasma anion gap** is useful for evaluating patients with a metabolic acidosis. It divides patients into two diagnostic groups, those with normal anion gap and those with increased anion gap. The following formula determines the anion gap:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

A normal anion gap is 4-11, although there is variation among laboratories. Approximately 11 mEq of the anion gap is normally secondary to albumin. A 1 g/dL decrease in the albumin concentration decreases the anion gap by approximately 2.5 mEq/L. Thus, if the albumin is not close to 4 g/dL, the anion gap should be corrected for the albumin concentration:

$$\text{Anion gap (corrected for albumin)} = [Na^+] - ([Cl^-] + [HCO_3^-]) + [2.5 \times (4 - \text{observed albumin})]$$

The number of serum anions must equal the number of serum cations to maintain electrical neutrality (Fig. 73.11). The anion gap is the difference between the measured cation (Na^+) and the measured anions (Cl^- + bicarbonate). The anion gap is also the difference between the unmeasured cations (K^+, magnesium, calcium) and the unmeasured anions (albumin, phosphate, urate, sulfate). An increased anion gap occurs when there is an increase in unmeasured anions. With a lactic acidosis, there is endogenous production of lactic acid, which is composed of positively charged hydrogen ions and negatively charged lactate anions. The hydrogen ions are largely buffered by serum bicarbonate, resulting in a decrease in $[HCO_3^-]$. The hydrogen ions that are not buffered by bicarbonate cause the serum pH to decrease. The lactate anions remain, causing the increase in the anion gap.

An increase in unmeasured anions, along with H^+ generation, is present in all causes of an increased gap metabolic acidosis (see Table 73.13). In DKA, the ketoacids β-hydroxybutyrate and acetoacetate are the unmeasured anions. In kidney failure there is retention of unmeasured anions, including phosphate, urate, and sulfate. The increase in unmeasured anions in kidney failure is usually less than the decrease in $[HCO_3^-]$. Kidney failure is thus a mix of an increased-gap and a normal-gap metabolic acidosis. The normal-gap metabolic acidosis is especially prominent in children with kidney failure because of tubular damage, as occurs with renal dysplasia or obstructive uropathy, because these patients have a concurrent RTA. The unmeasured anions in toxic ingestions vary: formate in methanol intoxication, glycolate in ethylene glycol intoxication, and lactate and ketoacids in salicylate intoxication. In inborn errors of metabolism, the unmeasured anions depend on the specific etiology and may include ketoacids, lactate, and other organic anions. In a few inborn errors of metabolism, the acidosis occurs without generation of unmeasured anions; thus the anion gap is normal.

A **normal–anion gap metabolic acidosis** occurs when there is a decrease in $[HCO_3^-]$ without an increase in the unmeasured anions. With diarrhea, there is a loss of bicarbonate in the stool, causing a decrease in the serum pH and $[HCO_3^-]$; the serum $[Cl^-]$ increases to maintain electrical neutrality (see Fig. 73.11). **Hyperchloremic metabolic acidosis** is an alternative term for a normal–anion gap metabolic acidosis. Calculation of the anion gap is more precise than using $[Cl^-]$ to differentiate between a normal-gap and an increased-gap metabolic acidosis, in that the anion gap directly determines the presence of unmeasured anions. Electrical neutrality dictates that the $[Cl^-]$ increases or decreases according to the serum $[Na^+]$, making $[Cl^-]$ a less reliable predictor of unmeasured anions than the more direct measure, calculation of the anion gap.

An increase in unmeasured cations, such as calcium, potassium, and magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap, and other variables, the presence of a normal or an increased anion gap is not always reliable in differentiating among the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. In some patients, there is more than one explanation for the metabolic acidosis, such as the child with diarrhea and lactic acidosis as a result of poor perfusion. The anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility.

Treatment

The most effective therapeutic approach for patients with a metabolic acidosis is repair of the underlying disorder, if possible. The administration of insulin in DKA and the restoration of adequate perfusion with IV fluids in lactic acidosis because of hypovolemia or shock eventually result in normalization of the acid-base balance. In other diseases, the use of bicarbonate therapy is indicated because the underlying disorder is irreparable. Children with metabolic acidosis caused by RTA or chronic kidney disease require long-term base therapy. Patients with acute kidney injury and metabolic acidosis may need base therapy until their kidneys' ability to excrete hydrogen normalizes. In other disorders the cause of the metabolic acidosis eventually resolves, but base therapy may be necessary during the acute illness. In salicylate poisoning, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings (ethylene glycol, methanol) and inborn errors of metabolism (pyruvate carboxylase deficiency, propionic acidemia). Some inborn errors of metabolism require long-term base therapy.

The use of base therapy in DKA with lactic acidosis is controversial; *there is little evidence that it improves patient outcome, and it has a variety of potential side effects.* The risks of giving sodium bicarbonate

include the possibility of causing hypernatremia or volume overload. Furthermore, the patient may have overcorrection of the metabolic acidosis once the underlying disorder resolves, because metabolism of lactate or ketoacids generates bicarbonate. The rapid change from acidemia to alkalemia can cause a variety of problems, including hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of CO_2, which can accumulate in patients with respiratory failure. Because CO_2 readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Base therapy is usually reserved for children with severe acute lactic acidosis and severe DKA.

Oral base therapy is given to children with chronic metabolic acidosis. Sodium bicarbonate tablets are available for older children. Younger children generally take citrate solutions; the liver generates bicarbonate from citrate. Citrate solutions are available as sodium citrate, potassium citrate, and a 1:1 mix of sodium citrate and potassium citrate. The patient's potassium needs dictate the choice. Children with type I or type II RTA may have hypokalemia and benefit from potassium supplements, but most children with chronic kidney failure cannot tolerate additional potassium.

Oral or IV base can be used in acute metabolic acidosis; IV therapy is generally used when a rapid response is necessary. Sodium bicarbonate may be given as a bolus, usually at a dose of 1 mEq/kg, in an emergency situation. Another approach is to add sodium bicarbonate or sodium acetate to the patient's IV fluids, remembering to remove an equal amount of sodium chloride from the solution to avoid giving an excessive sodium load. Careful monitoring is mandatory so that the dose of base can be titrated appropriately. Tris(hydroxymethyl) aminomethane (**tromethamine, THAM**) is an option in patients with a metabolic acidosis and a respiratory acidosis, because it neutralizes acids without releasing CO_2. THAM also diffuses into cells and therefore provides intracellular buffering.

Hemodialysis is another option for correcting a metabolic acidosis, and it is an appropriate choice in patients with renal insufficiency, especially if significant uremia or hyperkalemia is also present. Hemodialysis is advantageous for correcting the metabolic acidosis caused by methanol or ethylene glycol intoxication, because hemodialysis efficiently removes the offending toxin. In addition, these patients often have a severe metabolic acidosis that does not respond easily to IV bicarbonate therapy. Peritoneal dialysis is another option for correcting the metabolic acidosis due to chronic kidney disease.

Many causes of metabolic acidosis require specific therapy. Administration of a glucocorticoid and a mineralocorticoid is necessary in patients with adrenal insufficiency. Patients with DKA require insulin therapy, whereas patients with lactic acidosis respond to measures that alleviate tissue hypoxia. Along with correction of acidosis, patients with methanol or ethylene glycol ingestion should receive an agent that prevents the breakdown of the toxic substance to its toxic metabolites. Fomepizole has supplanted ethanol as the treatment of choice. These agents work by inhibiting alcohol dehydrogenase, the enzyme that performs the first step in the metabolism of ethylene glycol or methanol. There are a variety of disease-specific therapies for patients with a metabolic acidosis resulting from an inborn error of metabolism.

METABOLIC ALKALOSIS

Metabolic alkalosis in children is most often secondary to emesis or diuretic use. The serum bicarbonate concentration is increased with a metabolic alkalosis, although a respiratory acidosis also leads to a compensatory elevation of the serum [HCO_3^-]. With a simple metabolic alkalosis, however, the pH is elevated; alkalemia is present. Patients with a respiratory acidosis are acidemic. Decreasing ventilation causes appropriate respiratory compensation for a metabolic alkalosis. P_{CO_2} increases by 7 mm Hg for each 10 mEq/L increase in the serum [HCO_3^-]. Appropriate respiratory compensation never exceeds a P_{CO_2} of 55-60 mm Hg. The patient has a concurrent respiratory alkalosis if the P_{CO_2} is lower than the expected compensation. A greater than expected P_{CO_2} occurs with a concurrent respiratory acidosis.

Etiology and Pathophysiology

The kidneys normally respond promptly to a metabolic alkalosis by increasing base excretion. Two processes are therefore usually present to produce a metabolic alkalosis: (1) the generation of the metabolic alkalosis, which requires the addition of base to the body, and (2) the maintenance of the metabolic alkalosis, which requires impairment in the kidney's ability to excrete base.

The etiologies of a metabolic alkalosis are divided into two categories based on the urinary chloride level (Table 73.14). The alkalosis in patients with a low urinary [Cl^-] is maintained by **volume depletion**; thus volume repletion is necessary for correction of the alkalosis. The volume depletion in these patients is caused by losses of Na^+ and K^+, but the loss of Cl^- is usually greater than the losses of Na^+ and K^+ combined. Because Cl^- losses are the dominant cause of the volume depletion, these patients require Cl^- to correct the volume depletion and metabolic alkalosis; they are said to have **Cl^--responsive metabolic alkalosis.** In contrast, the alkalosis in a patient with an elevated urinary [Cl^-] does not respond to volume repletion and so is termed **Cl^--resistant metabolic alkalosis.**

Emesis or nasogastric suction results in **loss of gastric fluid**, which has a high content of HCl. Generation of H^+ by the gastric mucosa causes simultaneous release of bicarbonate into the bloodstream. Normally, the hydrogen ions in gastric fluid are reclaimed in the small intestine (by neutralizing secreted bicarbonate); thus there is no net loss of acid. With loss of gastric fluid, this does not occur, and a metabolic alkalosis develops. This period is the *generation phase* of the metabolic alkalosis.

The *maintenance phase* of the metabolic alkalosis from gastric losses is caused by the volume depletion ("chloride depletion" from gastric loss of HCl). Volume depletion interferes with urinary loss of bicarbonate, the normal renal response to a metabolic alkalosis. During volume depletion, several mechanisms prevent renal bicarbonate loss. First, there is a reduction in the GFR, so less bicarbonate is filtered. Second, volume depletion increases resorption of sodium and bicarbonate in the proximal tubule, limiting the amount of bicarbonate that can be excreted in the urine. This effect is mediated by angiotensin II and adrenergic stimulation of the kidney, both of which are increased in response to volume depletion. Third, the increase in aldosterone during volume depletion increases bicarbonate resorption and H^+ secretion in the collecting duct.

In addition to volume depletion, gastric losses are usually associated with hypokalemia as a result of both gastric loss of K^+ and, most importantly, increased urinary K^+ losses. The increased urinary losses of K^+ are mediated by aldosterone, through volume depletion, and by the increase in intracellular K^+ secondary to the metabolic alkalosis, which causes K^+ to move into the cells of the kidney, causing increased K^+ excretion. Hypokalemia contributes to the maintenance of the metabolic alkalosis by decreasing bicarbonate loss. Hypokalemia increases H^+ secretion in the distal nephron and stimulates ammonia production in the proximal tubule. Ammonia production enhances renal excretion of H^+.

A metabolic alkalosis can develop in patients receiving **loop** or **thiazide diuretics.** Diuretic use leads to volume depletion, which increases angiotensin II, aldosterone, and adrenergic stimulation of the kidney. Diuretics increase the delivery of sodium to the distal nephron, further enhancing acid excretion. Moreover, these diuretics cause hypokalemia, which increases acid excretion by the kidney. The increase in renal acid excretion generates the metabolic alkalosis, and the decrease in bicarbonate loss maintains it. In addition, patients who are receiving diuretics have a "contraction alkalosis." Diuretic use causes fluid loss without bicarbonate; thus the remaining body bicarbonate is contained in a smaller total body fluid compartment. The $[HCO_3^-]$ increases, helping to generate the metabolic alkalosis.

Diuretics are often used in patients with edema, such as those with nephrotic syndrome, heart failure, or liver failure. In many of these patients, metabolic alkalosis resulting from diuretic use develops despite the continued presence of edema. This is because the effective intravascular volume is low, and it is the effective intravascular volume that stimulates the compensatory mechanisms that cause and maintain a metabolic alkalosis. Many of these patients have a decreased effective intravascular volume before they begin diuretic therapy, increasing the likelihood of diuretic-induced metabolic alkalosis.

Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urine $[Cl^-]$ is typically high (>20 mEq/L). After the diuretic effect has worn off, the urinary $[Cl^-]$ is low (<15 mEq/L) because of appropriate renal Cl^- retention in response to volume depletion. Thus categorization of diuretics because of urinary $[Cl^-]$ depends on the timing of the measurement. However, the metabolic alkalosis from diuretics is Cl^- responsive; it is corrected after adequate volume repletion. This is the rationale for including this process among the chloride-responsive causes of a metabolic alkalosis.

Most patients with diarrhea have a metabolic acidosis because of stool losses of bicarbonate. In **chloride-losing diarrhea**, an autosomal recessive disorder, there is a defect in the normal intestinal exchange of bicarbonate for chloride, causing excessive stool losses of chloride (see Chapter 385). In addition, stool losses of H^+ and K^+ cause metabolic alkalosis and hypokalemia, both of which are exacerbated by increased renal H^+ and K^+ losses from volume depletion. Treatment is with oral supplements of K^+ and NaCl. Use of a gastric proton pump inhibitor (PPI), by decreasing gastric HCl production, reduces both the volume of diarrhea and the need for electrolyte supplementation.

Formulas with extremely low Cl^- content have led to Cl^- deficiency and volume depletion. There is secondary metabolic alkalosis and hypokalemia. **Cystic fibrosis** can rarely cause metabolic alkalosis, hypokalemia, and hyponatremia because of excessive NaCl losses in sweat (see Chapter 454). The volume depletion causes the metabolic alkalosis and hypokalemia through increased urinary losses, whereas the hyponatremia, a less common finding, is secondary to Na^+ loss combined with renal water conservation in an effort to protect the intravascular volume ("appropriate" ADH production).

A **posthypercapnic metabolic alkalosis** occurs after the correction of a chronic respiratory acidosis. This is typically seen in patients with chronic lung disease who are started on mechanical ventilation. During chronic respiratory acidosis, appropriate renal compensation leads to an increase in the serum $[HCO_3^-]$. Because it is still present after acute correction of the respiratory acidosis, the elevated $[HCO_3^-]$ causes a metabolic alkalosis. The metabolic alkalosis persists because the patient with a chronic respiratory acidosis is intravascularly depleted because of the Cl^- loss that occurred during the initial metabolic compensation for the primary respiratory acidosis. In addition, many children with a chronic respiratory acidosis receive diuretics, which further decrease the intravascular volume. The metabolic alkalosis responds to correction of the intravascular volume deficit.

The **chloride-resistant** causes of metabolic alkalosis can be subdivided according to blood pressure status. Patients with **hypertension** either have increased aldosterone levels or act as if they do. Aldosterone levels are elevated in children with adrenal adenomas or hyperplasia. Aldosterone causes renal retention of sodium, with resultant hypertension. Metabolic alkalosis and hypokalemia result from aldosterone-mediated renal excretion of H^+ and K^+. The urinary Cl^- level is not low because these patients are volume overloaded, not volume depleted. The volume expansion and hypertension allow normal excretion of Na^+ and Cl^- despite the presence of aldosterone. This is known as the *mineralocorticoid escape phenomenon.*

In **glucocorticoid-remediable aldosteronism**, an autosomal dominant disorder, excess production of aldosterone results from the presence of an aldosterone synthase gene regulated by adrenocorticotropic hormone (ACTH) (see Chapter 616.8). Glucocorticoids effectively treat this disorder by inhibiting ACTH production by the pituitary, downregulating the inappropriate aldosterone production. Familial hyperaldosteronism type II, which causes elevated aldosterone levels, responds to spironolactone. Familial hyperaldosteronism type III typically requires bilateral adrenalectomy due to the severity of the hyperaldosteronism. Renovascular disease and renin-secreting tumors both cause excessive renin, leading to an increase in aldosterone, although hypokalemia and metabolic alkalosis are less common findings than hypertension. In two forms of **congenital adrenal hyperplasia**, 11β-hydroxylase deficiency and 17α-hydroxylase deficiency, there is excessive production of the mineralocorticoid 11-deoxycorticosterone (see Chapters 616.2 and 616.4). Hypertension, hypokalemia, and metabolic alkalosis are more likely in 17α-hydroxylase deficiency than in 11β-hydroxylase deficiency. These disorders respond to glucocorticoids because the excess production of 11-deoxycorticosterone is under the control of ACTH.

Cushing syndrome frequently causes hypertension. Cortisol has *some* mineralocorticoid activity, and high levels can produce hypokalemia and metabolic alkalosis in patients with Cushing syndrome.

Cortisol can bind to the mineralocorticoid receptors in the kidney and function as a mineralocorticoid. This binding normally does not occur because 11β-hydroxysteroid dehydrogenase in the kidney converts cortisol to cortisone, which does not bind to the mineralocorticoid receptor. In the autosomal recessive disorder 11β-hydroxysteroid dehydrogenase deficiency, also called **apparent mineralocorticoid excess**, cortisol is not converted in the kidney to cortisone. Cortisol is therefore available to bind to the mineralocorticoid receptor in the kidney and act as a mineralocorticoid. Patients with this deficiency, despite low levels of aldosterone, are hypertensive and hypokalemic, and they have a metabolic alkalosis. The same phenomenon can occur with excessive intake of natural licorice, a component of which, glycyrrhizic acid, inhibits 11β-hydroxysteroid dehydrogenase. The autosomal dominant disorder **Liddle syndrome** is secondary to an activating variant in the gene for the sodium channel in the distal nephron (see Chapter 571.3). Upregulation of this sodium channel is one of the principal actions of aldosterone. Because this Na^+ channel is continuously open, children with Liddle syndrome have the features of hyperaldosteronism, including hypertension, hypokalemia, and metabolic alkalosis, but low serum levels of aldosterone.

Bartter and Gitelman syndromes are autosomal recessive disorders associated with normal blood pressure, elevated urinary Cl^-, metabolic alkalosis, and hypokalemia (see Chapter 571). In **Bartter syndrome**, patients have a defect in Na^+ and Cl^- resorption in the loop of Henle. This leads to excessive urinary losses of Na^+ and Cl^-, and as in patients receiving loop diuretics, volume depletion and secondary hyperaldosteronism occur, causing hypokalemia and metabolic alkalosis. **Gitelman syndrome** is usually milder than Bartter syndrome. Patients have renal Na^+ and Cl^- wasting with volume depletion caused by variants in the gene encoding the thiazide-sensitive Na^+-Cl^- transporter in the distal tubule. As in patients receiving a thiazide diuretic, affected patients have volume depletion and secondary hyperaldosteronism with hypokalemia and metabolic alkalosis. Children with Gitelman syndrome have hypocalciuria and hypomagnesemia. Some patients with autosomal dominant hypoparathyroidism have hypokalemia and metabolic alkalosis from impaired Na^+ and Cl^- resorption in the loop of Henle. **EAST syndrome** causes hypokalemia, metabolic alkalosis, and hypomagnesemia.

Excessive base intake can cause a metabolic alkalosis. Affected patients do not have low urine $[Cl^-]$, unless there is associated volume depletion. In the absence of volume depletion, excess base is rapidly corrected via renal excretion of bicarbonate. Rarely, massive base intake can cause a metabolic alkalosis by overwhelming the kidney's ability to excrete bicarbonate. This may occur in infants who are given baking soda as a "home remedy" for colic or stomach upset. Each teaspoon of baking soda has 42 mEq of sodium bicarbonate. Infants have increased vulnerability because of a lower GFR, limiting the rate of compensatory renal bicarbonate excretion. A metabolic alkalosis may also occur in patients who receive a large amount of sodium bicarbonate during cardiopulmonary resuscitation. Blood products are anticoagulated with citrate, which is converted into bicarbonate by the liver. Patients who receive large amounts of blood products may have a metabolic alkalosis. Iatrogenic metabolic alkalosis can occur because of acetate in TPN. Aggressive use of bicarbonate therapy in a child with a lactic acidosis or DKA may cause a metabolic alkalosis. This is especially likely in a patient in whom the underlying cause of the lactic acidosis is successfully corrected (restoration of intravascular volume in a patient with severe dehydration). Once the cause of the lactic acidosis resolves, lactate can be converted by the liver into bicarbonate, which when combined with infused bicarbonate can create a metabolic alkalosis. A similar phenomenon can occur in a child with DKA because the administration of insulin allows ketoacids to be metabolized, producing bicarbonate. However, this phenomenon rarely occurs because of judicious use of bicarbonate therapy in DKA and because there are usually significant pretreatment losses of ketoacids in the urine, preventing massive regeneration of bicarbonate. Base administration is most likely to cause a metabolic alkalosis in patients who have an impaired ability to excrete bicarbonate in the urine. This impairment occurs in patients with concurrent volume depletion or renal insufficiency.

Clinical Manifestations

The symptoms in patients with a metabolic alkalosis are often related to the underlying disease and associated electrolyte disturbances. Children with Cl^--responsive causes of metabolic alkalosis often have symptoms related to volume depletion, such as thirst and lethargy. In contrast, children with Cl^--unresponsive causes may have symptoms related to hypertension.

Alkalemia causes potassium to shift into the ICS, producing a decrease in the extracellular $[K^+]$. Alkalemia leads to increased urinary losses of K^+. Increased K^+ losses are present in many of the conditions that cause a metabolic alkalosis. Therefore most patients with a metabolic alkalosis have hypokalemia, and their symptoms may be related to the hypokalemia (see Chapter 73.4).

The symptoms of a metabolic alkalosis are caused by the associated alkalemia. The magnitude of the alkalemia is related to the severity of the metabolic alkalosis and the presence of concurrent respiratory acid-base disturbances. During alkalemia, the ionized calcium concentration decreases because of increased binding of calcium to albumin. The decrease in the ionized calcium concentration may cause symptoms of **tetany** (**carpopedal spasm**).

Arrhythmias are a potential complication of a metabolic alkalosis, and the risk for arrhythmia increases if there is concomitant hypokalemia. Alkalemia increases the risk of digoxin toxicity, and antiarrhythmic medications are less effective in the presence of alkalemia. In addition, alkalemia may decrease cardiac output. A metabolic alkalosis causes a compensatory increase in the P_{CO_2} by decreasing ventilation. The decrease in ventilatory drive can cause hypoxia.

Diagnosis

Measurement of the urine $[Cl^-]$ is the most helpful test in differentiating among the causes of a metabolic alkalosis. The urine $[Cl^-]$ is low in patients with a metabolic alkalosis resulting from volume depletion, unless there is a defect in renal handling of Cl^-. The urine $[Cl^-]$ is superior to the urine $[Na^+]$ in assessment of volume status in patients with a metabolic alkalosis because the normal renal response to a metabolic alkalosis is to excrete bicarbonate. Because bicarbonate is negatively charged, it can only be excreted with cations, usually Na^+ and K^+. Therefore a patient with a metabolic alkalosis may excrete Na^+ in the urine despite the presence of volume depletion, which normally causes avid Na^+ retention. The urine $[Cl^-]$ is usually a good indicator of volume status, and it differentiates Cl^--resistant and Cl^--responsive causes of a metabolic alkalosis.

Diuretics and gastric losses are the most common causes of metabolic alkalosis and are usually apparent from the patient history. Occasionally, metabolic alkalosis, usually with hypokalemia, may be a clue to the presence of bulimia or surreptitious diuretic use (see Chapter 41). Patients with bulimia have a low urine Cl^- level, indicating that they have volume depletion because of an extrarenal etiology, but there is no alternative explanation for their volume depletion. Surreptitious diuretic use may be diagnosed by obtaining a urine toxicology screen for diuretics. The urine $[Cl^-]$ is increased while a patient is using diuretics but is low when the patient stops taking them. *Rarely, children with mild Bartter or Gitelman syndrome are misdiagnosed as having bulimia or abusing diuretics.* The

urine [Cl^-] is always elevated in Bartter and Gitelman syndromes, and the urine toxicology screen for diuretics has a negative result. Metabolic alkalosis with hypokalemia is occasionally the initial manifestation of cystic fibrosis. An elevated sweat Cl^- finding is diagnostic.

Patients with a metabolic alkalosis and a high urinary [Cl^-] are subdivided according to blood pressure status. Children with normal blood pressure may have Bartter or Gitelman syndrome. Excess base administration is another diagnostic possibility, but it is usually apparent from the history. In patients with sodium bicarbonate ingestion (baking soda), which may be unreported by the parent, the metabolic alkalosis usually occurs with significant hypernatremia. In addition, unless volume depletion is superimposed, the metabolic alkalosis from base ingestion resolves itself once the source of base is eliminated.

Measuring serum concentrations of renin and aldosterone differentiates children with a metabolic alkalosis, a high urinary [Cl^-], and elevated blood pressure. Both renin and aldosterone are elevated in children with either renovascular disease or a renin-secreting tumor. Aldosterone is high and renin is low in patients with adrenal adenomas or hyperplasia and glucocorticoid-remediable aldosteronism. Renin and aldosterone are low in children with Cushing syndrome, Liddle syndrome, licorice ingestion, and 17α-hydroxylase, 11β-hydroxylase, and 11β-hydroxysteroid dehydrogenase deficiencies. An elevated 24-hour urine cortisol value is diagnostic of Cushing syndrome, which is suspected from the presence of the other classic features of this disease (see Chapter 619). Elevations of 11-deoxycorticosterone values are seen in 17α-hydroxylase and 11β-hydroxylase deficiency.

Treatment

The approach to treatment of metabolic alkalosis depends on the severity of the alkalosis and the underlying etiology. In children with a mild metabolic alkalosis ([HCO_3^-] <32 mEq/L), intervention is often unnecessary, although this depends on the specific circumstances. In a child with congenital heart disease who is receiving a stable dose of a loop diuretic, a mild alkalosis does not require treatment. In contrast, intervention may be appropriate in a child with a worsening mild metabolic alkalosis because of nasogastric suction. The presence of a concurrent respiratory acid-base disturbance also influences therapeutic decision-making. A patient with a concurrent respiratory acidosis should have some increase in bicarbonate from metabolic compensation; thus the severity of the pH elevation is more important than [HCO_3^-]. In contrast, a patient with respiratory alkalosis and a metabolic alkalosis is at risk for severe alkalemia; treatment may be indicated, even if the increase in bicarbonate value is only mild.

Intervention is usually necessary in children with moderate or severe metabolic alkalosis. The most effective approach is to address the underlying etiology. In some children, nasogastric suction may be decreased or discontinued. Alternatively, the addition of a gastric PPI reduces gastric secretion and losses of HCl. Diuretics are an important cause of metabolic alkalosis, and if a change is tolerated, they should be eliminated or the dose reduced. Adequate potassium supplementation or the addition of a potassium-sparing diuretic is also helpful in a child with a metabolic alkalosis from diuretics. Potassium-sparing diuretics not only decrease renal K^+ losses but, by blocking the action of aldosterone, also decrease H^+ secretion in the distal nephron, increasing urinary bicarbonate excretion. Many children cannot tolerate discontinuation of diuretic therapy; hence, potassium supplementation and potassium-sparing diuretics are the principal therapeutic approach. Arginine HCl may also be used to treat chloride-responsive metabolic acidosis if sodium or potassium salts are not appropriate. Arginine HCl may raise the serum K^+ levels during administration. Rarely, in cases of severe metabolic alkalosis, acetazolamide is an option. A carbonic anhydrase inhibitor, acetazolamide decreases resorption of bicarbonate in the proximal tubule, causing significant bicarbonate loss in the urine. The patient receiving this drug must be monitored closely, because acetazolamide produces major losses of potassium in the urine and increases fluid losses, potentially necessitating a reduction in dosage of other diuretics.

Most children with a metabolic alkalosis have one of the **chloride-responsive** etiologies. In these situations, administration of sufficient sodium chloride and potassium chloride to correct the volume deficit and the potassium deficit is necessary to correct the metabolic alkalosis. This approach may not be an option in the child who has volume depletion due to diuretics, because volume repletion may be contraindicated. Adequate replacement of gastric losses of sodium and potassium in a child with a nasogastric tube can minimize or prevent the development of the metabolic alkalosis. With adequate intravascular volume and a normal serum [K^+], the kidney excretes the excess bicarbonate within 2 days.

In children with the **chloride-resistant** causes of a metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it would exacerbate the hypertension and would not repair the metabolic alkalosis. Ideally, treatment focuses on eliminating the excess aldosterone effect. Adrenal adenomas can be resected, licorice intake can be eliminated, and renovascular disease can be repaired. Glucocorticoid-remediable aldosteronism, 17α-hydroxylase deficiency, and 11β-hydroxylase deficiency respond to the administration of glucocorticoids. The mineralocorticoid effect of cortisol in 11β-hydroxysteroid dehydrogenase deficiency can be decreased with the use of spironolactone, which blocks the mineralocorticoid receptor. In contrast, the metabolic alkalosis in children with Liddle syndrome does not respond to spironolactone; however, either triamterene or amiloride is effective therapy because both agents block the sodium channel that is constitutively active in Liddle syndrome.

In children with Bartter or Gitelman syndrome, therapy includes oral potassium and sodium supplementation; potassium-sparing diuretics may be helpful in select cases. Children with Gitelman syndrome often require magnesium supplementation, whereas children with severe Bartter syndrome often benefit from indomethacin.

RESPIRATORY ACIDOSIS

A respiratory acidosis is an inappropriate increase in blood carbon dioxide tension (P_{CO_2}). CO_2 is a by-product of metabolism and is removed from the body by the lungs. During a respiratory acidosis, the effectiveness of CO_2 removal by the lungs is decreased. A respiratory acidosis is secondary to either pulmonary disease, such as severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose (see Chapter 86). Even though body production of CO_2 can vary, normal lungs are able to accommodate this variation; excess production of CO_2 is not an isolated cause of a respiratory acidosis. With impairment of alveolar ventilation, the rate of body production of CO_2 may affect the severity of the respiratory acidosis, but this is usually not a significant factor.

A respiratory acidosis causes a decrease in the blood pH, but there is normally a metabolic response that partially compensates, minimizing the severity of the acidemia. The acute metabolic response to a respiratory alkalosis occurs within minutes. The metabolic compensation for an *acute* respiratory acidosis is secondary to titration of acid by nonbicarbonate buffers. This buffering of H^+ causes a predictable increase in the serum [HCO_3^-]: Plasma bicarbonate increases by 1 for each 10 mm Hg increase in the P_{CO_2} (acute compensation).

With a *chronic* respiratory acidosis, there is more significant metabolic compensation and thus less severe acidemia than in an acute respiratory acidosis with the same increase in P_{CO_2}. During a chronic respiratory acidosis, the kidneys increase acid excretion. This response occurs over 3-4 days and causes a predictable increase in the serum [HCO_3^-]: Plasma bicarbonate increases by 3.5 for each 10 mm Hg increase in the P_{CO_2} (chronic compensation).

The increase of serum [HCO_3^-] during a chronic respiratory acidosis is associated with a decrease in body chloride. After acute correction of a chronic respiratory acidosis, the plasma bicarbonate continues to

Table 73.15 Causes of Respiratory Acidosis

CENTRAL NERVOUS SYSTEM DEPRESSION
- Encephalitis
- Head trauma
- Brain tumor
- Central sleep apnea
- Primary pulmonary hypoventilation (Ondine curse)
- Stroke
- Hypoxic brain damage
- Obesity-hypoventilation (Pickwickian) syndrome
- Increased intracranial pressure

UPPER AIRWAY DISEASE
- Aspiration
- Laryngospasm
- Angioedema
- Obstructive sleep apnea
- Tonsillar hypertrophy
- Vocal cord paralysis
- Extrinsic tumor
- Extrinsic or intrinsic hemangioma

MISCELLANEOUS
- Flail chest
- Cardiac arrest
- Kyphoscoliosis
- Decreased diaphragmatic movement due to ascites or peritoneal dialysis

be increased, and the patient has a metabolic alkalosis. Because of the Cl^- deficit, this is a chloride-responsive metabolic alkalosis; it corrects once the patient's Cl^- deficit is replaced.

A **mixed disorder** is present if the metabolic compensation is inappropriate. A higher than expected bicarbonate value occurs in the setting of a concurrent metabolic alkalosis, and a lower than expected bicarbonate value occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory acidosis requires clinical knowledge of the acuity of the process, because the expected compensation is different, depending on whether the process is acute or chronic.

The P_{CO_2} cannot be interpreted in isolation to determine whether a patient has a respiratory acidosis. A respiratory acidosis is always present if a patient has acidemia and an elevated P_{CO_2}. However, an elevated P_{CO_2} also occurs as appropriate respiratory compensation for a simple metabolic alkalosis. The patient is *alkalemic*; this is not a respiratory acidosis. During a mixed disturbance, a patient can have a respiratory acidosis and a normal or even low P_{CO_2}. This condition may occur in a patient with a metabolic acidosis. A respiratory acidosis is present if the patient does not have appropriate respiratory compensation (the P_{CO_2} is higher than expected from the severity of the metabolic acidosis).

Etiology and Pathophysiology

The causes of a respiratory acidosis are either pulmonary or nonpulmonary (Table 73.15). CNS disorders can decrease the activity of the central respiratory center, reducing ventilatory drive. A variety of medications and illicit drugs suppress the respiratory center. The signals from the respiratory center need to be transmitted to the respiratory muscles via the nervous system. Respiratory muscle failure can be secondary to disruption of the signal from the CNS in the spinal cord, the phrenic nerve, or the neuromuscular junction. Disorders directly affecting the muscles of respiration can prevent adequate ventilation, causing a respiratory acidosis.

Mild or moderate lung disease often causes a respiratory alkalosis as a result of hyperventilation secondary to hypoxia or stimulation of lung mechanoreceptors or chemoreceptors. Only more severe lung disease causes a respiratory acidosis. Upper airway diseases, by impairing air entry into the lungs, may decrease ventilation, producing a respiratory acidosis.

Increased production of CO_2 is never the sole cause of a respiratory acidosis, but it can increase the severity of the disease in a patient with decreased ventilation of CO_2. Increased production of CO_2 occurs in patients with fever, hyperthyroidism, excess caloric intake, and high levels of physical activity. Increased respiratory muscle work also increases CO_2 production.

Clinical Manifestations

Patients with a respiratory acidosis are often tachypneic in an effort to correct the inadequate ventilation. Exceptions include patients with a respiratory acidosis resulting from CNS depression and patients who are on the verge of complete respiratory failure secondary to fatigue of the respiratory muscles.

The symptoms of respiratory acidosis are related to the severity of the **hypercarbia**. Acute respiratory acidosis is usually more symptomatic than chronic respiratory acidosis. Symptoms are also increased by concurrent hypoxia or metabolic acidosis. In a patient breathing room air, hypoxia is always present if a respiratory acidosis is present. The potential CNS manifestations of respiratory acidosis include anxiety, dizziness, headache, confusion, asterixis, myoclonic jerks, hallucinations, psychosis, coma, and seizures.

Acidemia, no matter the etiology, affects the cardiovascular system. An arterial pH <7.2 impairs cardiac contractility and the normal response to catecholamines in both the heart and the peripheral vasculature. Hypercapnia causes vasodilation, most dramatically in the cerebral vasculature, but hypercapnia produces vasoconstriction of the pulmonary circulation. Respiratory acidosis increases the risk of cardiac **arrhythmias**, especially in a child with underlying cardiac disease.

Diagnosis

The history and physical findings often point to a clear etiology. For the obtunded patient with poor respiratory effort, evaluation of the CNS is often indicated. This may include imaging studies (CT or MRI) and, potentially, a lumbar puncture for cerebrospinal fluid analysis. A toxicology screen for illicit drugs may also be appropriate. A response to naloxone is both diagnostic and therapeutic. In many of the diseases affecting the respiratory muscles, there is evidence of weakness in other muscles. Stridor is a clue that the child may have upper airway disease. Along with a physical examination, a chest radiograph is often helpful in diagnosing pulmonary disease.

In many patients, respiratory acidosis may be multifactorial. A child with bronchopulmonary dysplasia, an intrinsic lung disease, may worsen because of respiratory muscle dysfunction caused by severe hypokalemia resulting from long-term diuretic therapy. Conversely, a child with muscular dystrophy, a muscle disease, may worsen because of aspiration pneumonia.

For a patient with respiratory acidosis, calculation of the gradient between the alveolar oxygen concentration and the arterial oxygen concentration, the A-a O_2 gradient, is useful for distinguishing between poor respiratory effort and intrinsic lung disease. The A-a O_2 gradient is increased if the hypoxemia is caused by intrinsic lung disease (see Chapter 421).

Treatment

Respiratory acidosis is best managed by treatment of the underlying etiology. In some patients, the response is very rapid, such as after the administration of naloxone to a patient with a narcotic overdose. In contrast, in the child with pneumonia, a number of days of antibiotic therapy may be required before the respiratory status improves. In many children with a chronic respiratory acidosis, there is no curative therapy, although an acute respiratory illness superimposed on a chronic respiratory condition is usually reversible.

All patients with an *acute* respiratory acidosis are hypoxic and therefore need to receive supplemental oxygen. Mechanical ventilation is necessary in some children with respiratory acidosis. Children with significant respiratory acidosis caused by CNS disease usually require mechanical ventilation because such a disorder is unlikely to respond quickly to therapy. In addition, hypercarbia causes cerebral vasodilation, and the increase in ICP can be dangerous in a child with an underlying CNS disease. Readily reversible CNS depression, as from a narcotic overdose, may not require mechanical ventilation. Decisions on mechanical ventilation for other patients depend on a number of factors. Patients with severe hypercarbia (P_{CO_2} >75 mm Hg) usually require mechanical ventilation (see Chapter 86.1). The threshold for intubation is lower if there is concomitant metabolic acidosis, a slowly responsive underlying disease, or hypoxia that responds poorly to oxygen, or if the patient appears to be tiring and respiratory arrest seems likely.

In patients with a *chronic* respiratory acidosis, the respiratory drive is often less responsive to hypercarbia and more responsive to hypoxia. Thus, with chronic respiratory acidosis, excessive use of oxygen can blunt the respiratory drive and therefore increase the P_{CO_2}. In these patients, oxygen must be used cautiously.

When possible, it is best to avoid mechanical ventilation in a patient with chronic respiratory acidosis because extubation is often difficult. However, an acute illness may necessitate mechanical ventilation in a child with a chronic respiratory acidosis. When intubation is necessary, the P_{CO_2} should be lowered only to the patient's normal baseline, and this should be done gradually. These patients normally have an elevated serum [HCO_3^-] as a result of metabolic compensation for their respiratory acidosis. A rapid lowering of the P_{CO_2} can cause a severe metabolic alkalosis, potentially leading to complications, including cardiac arrhythmias, decreased cardiac output, and decreased cerebral blood flow. In addition, prolonged mechanical ventilation at a normal P_{CO_2} causes the metabolic compensation to resolve. When the patient is subsequently extubated, the patient will no longer benefit from metabolic compensation, causing a more severe acidemia because of the respiratory acidosis.

RESPIRATORY ALKALOSIS

A respiratory alkalosis is an inappropriate reduction in the blood CO_2 concentration. This is usually secondary to hyperventilation, initially causing removal of CO_2 to surpass production. Eventually, a new steady state is achieved, with removal equaling production, although at a lower CO_2 tension (P_{CO_2}). A respiratory alkalosis that is not the result of hyperventilation may occur in children receiving extracorporeal membrane oxygenation, with CO_2 lost directly from the blood in the extracorporeal circuit.

With a simple respiratory alkalosis, the pH increases, but there is a normal metabolic response that attenuates some of the change in the blood pH. A metabolic response to an acute respiratory alkalosis occurs within minutes, mediated by hydrogen ion release from nonbicarbonate buffers. The metabolic response to an acute respiratory alkalosis is predictable: Plasma bicarbonate falls by 2 for each 10 mm Hg decrease in the P_{CO_2} (acute compensation).

A chronic respiratory alkalosis leads to more significant metabolic compensation because of the actions of the kidneys, which decrease acid secretion, producing a decrease in the serum [HCO_3^-]. Both the proximal and distal tubules decrease acid secretion. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2-3 days to produce the full effect: Plasma bicarbonate falls by 4 for each 10 mm Hg decrease in the P_{CO_2} (chronic compensation).

A chronic respiratory alkalosis is the only acid-base disturbance in which appropriate compensation may *normalize the pH,* although >7.4.

A **mixed disorder** is present if the metabolic compensation is inappropriate. A higher than expected HCO_3^- level occurs in the setting of a concurrent metabolic alkalosis, and a lower than expected HCO_3^- level occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory alkalosis requires clinical knowledge of the acuity of the process, because the expected compensation differs according to whether the process is acute or chronic.

A low P_{CO_2} value does not always indicate a respiratory alkalosis. The P_{CO_2} also decreases as part of the appropriate respiratory compensation for a metabolic acidosis; this is not a respiratory alkalosis.

Table 73.16 Causes of Respiratory Alkalosis

HYPOXEMIA OR TISSUE HYPOXIA
Pneumonia
Pulmonary edema
Cyanotic heart disease
Congestive heart failure
Asthma
Severe anemia
High altitude
Laryngospasm
Aspiration
Carbon monoxide poisoning
Pulmonary embolism
Interstitial lung disease
Hypotension
LUNG RECEPTOR STIMULATION
Pneumonia
Pulmonary edema
Asthma
Pulmonary embolism
Hemothorax
Pneumothorax
Respiratory distress syndrome (adult or infant)
CENTRAL STIMULATION
Central nervous system disease
Subarachnoid hemorrhage
Encephalitis or meningitis
Trauma
Brain tumor
Stroke
Fever
Pain
Anxiety (panic attack)
Psychogenic hyperventilation or anxiety
Liver failure
Sepsis
Pregnancy
Mechanical ventilation
Hyperammonemia
Extracorporeal membrane oxygenation or hemodialysis
Medications
Salicylate intoxication
Theophylline
Progesterone
Exogenous catecholamines
Caffeine

A metabolic acidosis is the dominant acid-base disturbance in a patient with acidemia and a low P_{CO_2}, even though there could still be a concurrent respiratory alkalosis. In contrast, a respiratory alkalosis is always present in a patient with alkalemia and a low P_{CO_2}. Even a normal P_{CO_2} value may be consistent with a respiratory alkalosis in a patient with a metabolic alkalosis, because an elevated P_{CO_2} is expected as part of appropriate respiratory compensation for the metabolic alkalosis.

Etiology and Pathophysiology

A variety of stimuli can increase the ventilatory drive and cause a respiratory alkalosis (Table 73.16). Arterial hypoxemia or tissue **hypoxia** stimulates peripheral chemoreceptors to signal the central respiratory center in the medulla to increase ventilation. The resultant greater respiratory effort increases the oxygen content of the blood (P_{O_2}) but depresses the P_{CO_2}. The effect of hypoxemia on ventilation begins when the arterial oxygen saturation (Sa_{O_2}) decreases to approximately 90% (P_{O_2} = 60 mm Hg), and hyperventilation increases as hypoxemia worsens. Acute hypoxia is a more potent stimulus for hyperventilation than chronic hypoxia; thus chronic hypoxia, as occurs in cyanotic heart disease, causes a much less severe respiratory alkalosis than an equivalent degree of acute hypoxia. The many causes of hypoxemia or tissue hypoxia include primary lung disease, severe anemia, and carbon monoxide (CO) poisoning.

The lungs contain chemoreceptors and mechanoreceptors that respond to irritants and stretching and send signals to the respiratory center to increase ventilation. Aspiration or pneumonia may stimulate the chemoreceptors, whereas pulmonary edema may stimulate the mechanoreceptors. Most of the diseases that activate these receptors may also cause hypoxemia and can therefore potentially lead to hyperventilation by two mechanisms. Patients with primary lung disease may initially have a respiratory alkalosis, but worsening of the disease, combined with respiratory muscle fatigue, often causes respiratory failure and the development of a respiratory acidosis.

Hyperventilation in the absence of lung disease occurs with direct stimulation of the central respiratory center. This occurs with CNS diseases such as meningitis, hemorrhage, and trauma. Central hyperventilation caused by lesions, such as infarcts or tumors near the central respiratory center in the midbrain, increases the rate and depth of the respiratory effort. This respiratory pattern portends a poor prognosis because these midbrain lesions are frequently fatal. Systemic processes may cause centrally mediated hyperventilation. Although the exact mechanisms are not clear, liver disease causes a respiratory alkalosis that is usually proportional to the degree of liver failure. **Pregnancy** causes a chronic respiratory alkalosis, probably mediated by progesterone acting on the respiratory centers. **Salicylates**, although often causing a concurrent metabolic acidosis, directly stimulate the respiratory center to produce a respiratory alkalosis. The respiratory alkalosis during sepsis is probably caused by cytokine release.

Hyperventilation may be secondary to an underlying disease that causes pain, stress, or anxiety. In psychogenic hyperventilation or in **panic attacks**, there is no disease process accounting for the hyperventilation. This disorder may occur in a child who has had an emotionally stressful experience. Alternatively, it may be part of a panic disorder, especially if there are repeated episodes of hyperventilation. In such a patient, the symptoms of acute alkalemia increase anxiety, potentially perpetuating the hyperventilation.

A respiratory alkalosis is quite common in children receiving mechanical ventilation because the respiratory center is not controlling ventilation. In addition, these children may have a decreased metabolic rate and thus less CO_2 production because of sedation and paralytic medications. Normally, decreased CO_2 production and the resultant hypocapnia decrease ventilation, but this physiologic response cannot occur in a child who cannot reduce ventilatory effort.

Clinical Manifestations

The disease process causing the respiratory alkalosis is usually more concerning than the clinical manifestations. Chronic respiratory alkalosis is usually asymptomatic because metabolic compensation decreases the magnitude of the alkalemia.

Acute respiratory alkalosis may cause chest tightness, palpitations, lightheadedness, circumoral numbness, and paresthesias of the extremities. Less common manifestations include tetany, seizures, muscle cramps, and syncope. The lightheadedness and syncope probably result from the reduction in cerebral blood flow caused by hypocapnia. The reduction in cerebral blood flow is the rationale for using hyperventilation to treat children with increased intracranial pressure (ICP). The paresthesias, tetany, and seizures may be partially related to the reduction in ionized calcium that occurs because alkalemia causes more calcium to bind to albumin. A respiratory alkalosis also causes a mild reduction in the serum potassium level. Patients with psychogenic hyperventilation tend to be symptomatic because of the respiratory alkalosis, and these symptoms, along with a sensation of breathlessness, exacerbate the hyperventilation.

Diagnosis

In many patients, hyperventilation producing a respiratory alkalosis is not clinically detectable, even with careful observation of the patient's

respiratory effort. Metabolic compensation for a respiratory alkalosis causes a low serum [HCO_3^-]. When hyperventilation is not appreciated and only serum electrolytes are evaluated, there is often a presumptive diagnosis of a metabolic acidosis. If a respiratory alkalosis is suspected, only ABG determination can make the diagnosis.

Hyperventilation does not always indicate a primary respiratory disorder. In some patients, the hyperventilation is appropriate respiratory compensation for a metabolic acidosis. With a primary metabolic acidosis, acidemia is present, and the serum HCO_3^- level is usually quite low if there is clinically detectable hyperventilation. In contrast, the serum HCO_3^- level never goes below 17 mEq/L as part of the metabolic compensation for acute respiratory alkalosis, and simple acute respiratory alkalosis causes alkalemia.

The etiology of a respiratory alkalosis is often apparent from the physical examination or history, and it may consist of lung disease, neurologic disease, or cyanotic heart disease. **Hypoxemia** is a common cause of hyperventilation, and it is important to diagnose because it suggests a significant underlying disease that requires expeditious treatment. Hypoxemia may be detected on physical examination (cyanosis) or by pulse oximetry. However, normal pulse oximetry values do not eliminate hypoxemia as the etiology of the hyperventilation. There are two reasons why pulse oximetry is not adequate for eliminating hypoxemia as a cause of a respiratory alkalosis. First, pulse oximetry is not very sensitive at detecting a mildly low arterial P_{O_2} (Pa_{O_2}). Second, the hyperventilation during a respiratory alkalosis causes Pa_{O_2} to increase, possibly to a level that is not identified as abnormal by pulse oximetry. Only ABG measurement can eliminate hypoxia as an explanation for a respiratory alkalosis. Along with hypoxemia, it is important to consider processes that cause **tissue hypoxia without necessarily causing hypoxemia**. Examples are CO or cyanide poisoning, severe anemia, and heart failure.

Lung disease without hypoxemia may cause hyperventilation. Although lung disease is often apparent by history or physical examination, a chest radiograph may detect more subtle disease. The patient with a pulmonary embolism may have benign chest radiograph findings, normal Pa_{O_2}, and isolated respiratory alkalosis, although hypoxia may eventually occur. Diagnosis of a pulmonary embolism requires a high index of suspicion and should be considered in children without another explanation for respiratory alkalosis, especially if risk factors are present, such as prolonged bed rest and a hypercoagulable state (e.g., nephrotic syndrome, lupus anticoagulant).

Treatment

There is seldom a need for specific treatment of respiratory alkalosis. Rather, treatment focuses on the underlying disease. Mechanical ventilator settings are adjusted to correct **iatrogenic** respiratory alkalosis, unless the hyperventilation has a therapeutic purpose (e.g., treatment of increased ICP).

For the patient with hyperventilation secondary to anxiety, efforts should be undertaken to reassure the child, usually enlisting the parents. Along with reassurance, patients with **psychogenic hyperventilation** may benefit from benzodiazepines. During an acute episode of psychogenic hyperventilation, rebreathing into a paper bag increases the patient's P_{CO_2}. Using a paper bag instead of a plastic bag allows adequate oxygenation but permits [CO_2] in the bag to increase. The resultant increase in the patient's P_{CO_2} decreases the symptoms of the respiratory alkalosis that tend to perpetuate the hyperventilation. Rebreathing should be performed only when other causes of hyperventilation have been eliminated; pulse oximetry during the rebreathing is prudent.

Chapter 74

Maintenance and Replacement Therapy

Larry A. Greenbaum

Maintenance intravenous (IV) fluids are used in a child who cannot be fed enterally. Along with maintenance fluids, children may require concurrent **replacement fluids** if they have continued excessive losses, as may occur with drainage from a nasogastric (NG) tube or with high urine output because of nephrogenic diabetes insipidus. If dehydration is present, the patient also needs to receive **deficit** replacement (see Chapter 75). A child awaiting surgery may need only maintenance fluids, whereas a child with diarrheal dehydration needs maintenance and deficit therapy and also may require replacement fluids if significant diarrhea continues.

MAINTENANCE THERAPY

Children normally have large variations in their daily intake of water and electrolytes. The only exceptions are patients who receive fixed dietary regimens orally, via a gastric tube, or as IV total parenteral nutrition (TPN). Healthy children can tolerate significant variations in intake because of the many homeostatic mechanisms that can adjust absorption and excretion of water and electrolytes (see Chapter 73). The calculated water and electrolyte need that form the basis of maintenance therapy are not absolute requirements. Rather, these calculations provide reasonable guidelines for a *starting point to estimate IV therapy*. Children do not need to be started on IV fluids simply because their intake is being monitored in a hospital and they are not taking "maintenance fluids" orally, unless there is a pathologic process present that necessitates high fluid intake.

Maintenance fluids are most often necessary in preoperative and postoperative surgical patients; many nonsurgical patients also require maintenance fluids. It is important to recognize when it is necessary to begin maintenance fluids. A normal teenager who is given nothing by mouth (NPO) overnight for a morning procedure does not require maintenance fluids because a healthy adolescent can easily tolerate 12-18 hours without oral intake. In contrast, a 6-month-old child waiting for surgery should begin receiving IV fluids within 8 hours of the last feeding. Infants become dehydrated more quickly than older patients. A child with obligatory high urine output from nephrogenic diabetes insipidus should begin receiving IV fluids soon after being classified as NPO.

Maintenance fluids are composed of a solution of water, glucose, sodium (Na^+), and potassium (K^+). This solution has the advantages of simplicity, long shelf life, low cost, and compatibility with peripheral IV administration. Such a solution accomplishes the major objectives of maintenance fluids (Table 74.1). Patients lose water, Na^+, and K^+ in their urine and stool; water is also lost from the skin and lungs. Maintenance fluids replace these losses, thereby avoiding the development of dehydration and Na^+ or K^+ deficiency.

Table 74.1 Goals of Maintenance Fluids

- Prevent dehydration
- Prevent electrolyte disorders
- Prevent ketoacidosis
- Prevent protein degradation

The glucose in maintenance fluids provides approximately 20% of the normal caloric needs of the patient, prevents the development of starvation ketoacidosis, and diminishes the protein degradation that would occur if the patient received no calories. Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. This fact is typically not problematic for a patient receiving IV fluids for a few days. A patient receiving maintenance IV fluids is receiving inadequate calories and will lose 0.5–1% of weight each day. It is imperative that patients not remain on maintenance therapy indefinitely; TPN should be used for children who cannot be fed enterally for more than a few days, especially patients with underlying malnutrition.

Prototypical maintenance fluid therapy does not provide electrolytes such as calcium, phosphorus, magnesium, and bicarbonate. For most patients, this lack is not problematic for a few days, although there are patients who will not tolerate this omission, usually because of excessive losses. A child with proximal renal tubular acidosis wastes bicarbonate in urine. Such a patient will rapidly become acidemic unless bicarbonate (or another base) is added to the maintenance fluids. It is important to remember the limitations of maintenance fluid therapy.

MAINTENANCE WATER

Water is a crucial component of maintenance fluid therapy because of the obligatory daily water losses. These losses are both measurable (urine, stool) and not measurable (**insensible losses** from the skin and lungs). Failure to replace these losses leads to a child who is thirsty, uncomfortable, and ultimately dehydrated.

The goal of maintenance water is to provide enough water to replace these losses. Although urinary losses are approximately 60% of the total, the normal kidney can greatly modify water losses, with daily urine volume potentially varying by more than a factor of 20. Maintenance water is designed to provide enough water so that the kidney does not need to significantly dilute or concentrate the urine. It also provides a margin of safety so that normal homeostatic mechanisms can adjust urinary water losses to prevent overhydration and dehydration. This adaptability obviates the need for absolute precision in determining water requirements. This fact is important, given the absence of absolute accuracy in the formulas for calculation of water needs.

Table 74.2 provides a system for calculating maintenance water on the basis of the patient's weight and emphasizes the high water needs of smaller, less mature patients. This approach is reliable, although calculations based on weight do overestimate the water needs of an overweight child, in whom it is better to base the calculations on the lean body weight, which can be estimated by using the 50th percentile of body weight for the child's height. It is also important to remember that there is an upper limit of 2.4 L/24 hr in adult-sized patients. IV fluids are written as an hourly rate. The formulas in Table 74.3 enable rapid calculation of the rate of maintenance fluids.

Table 74.2 Body Weight Method for Calculating Daily Maintenance Fluid Volume

BODY WEIGHT	FLUID PER DAY
0-10 kg	100 mL/kg
11-20 kg	1,000 mL + 50 mL/kg for each kg >10 kg
>20 kg	1,500 mL + 20 mL/kg for each kg >20 kg*

*The maximum total fluid per day is normally 2,400 mL.

Table 74.3 Hourly Maintenance Water Rate

For body weight 0-10 kg: 4 mL/kg/hr
For body weight 10-20 kg: 40 mL/hr + 2 mL/kg/hr × (wt − 10 kg)
For body weight >20 kg: 60 mL/hr + 1 mL/kg/hr × (wt − 20 kg)*

*The maximum fluid rate is normally 100 mL/hr.

INTRAVENOUS SOLUTIONS

The components of available solutions are shown in Table 74.4. These solutions are available with 5% dextrose (D5), 10% dextrose (D10), or without dextrose. Except for Ringer lactate (lactated Ringer, LR), they are also available with added potassium (10 or 20 mEq/L). A *balanced IV fluid* contains a base (lactate or acetate), a more physiologic chloride concentration than normal saline (NS), and additional physiologic concentrations of electrolytes such as potassium, calcium, and magnesium. Examples include LR and Plasma-Lyte, and there is evidence suggesting benefit versus NS in some but not all clinical situations. A hospital pharmacy can also prepare custom-made solutions with different concentrations of sodium or potassium. In addition, other electrolytes, such as calcium, magnesium, phosphate, acetate, and bicarbonate, can be added to IV solutions. Custom-made solutions take time to prepare and are much more expensive than commercial solutions. The use of custom-made solutions is necessary only for patients who have underlying disorders that cause significant electrolyte imbalances. The use of commercial solutions saves time and expense.

A normal plasma osmolality is 285-295 mOsm/kg. Infusing an IV solution peripherally with a much lower osmolality can cause water to move into red blood cells, leading to hemolysis. Thus IV fluids are generally designed to have an osmolality that is either close to 285 or greater (fluids with moderately higher osmolality do not cause problems). Thus 0.2NS (osmolality = 68) should not be administered peripherally, but D5 0.2NS (osmolality = 346) or D5 1/2NS + 20 mEq/L potassium chloride (KCl) with an osmolality of 472 can be administered.

Hypotonic fluids seem more physiologic given the low Na^+ content of breast milk and formula (~7 mEq/L). However, hospitalized children often have impaired water excretion because of volume depletion or nonosmotic stimuli for antidiuretic hormone (ADH) production, such as respiratory disease, central nervous system disease, stress, pain, nausea, and medications (e.g., narcotics). Hypotonic fluids increase the risk of hyponatremia, which may have serious sequelae; *hence, isotonic fluids with D5 are recommended as standard maintenance fluid except in neonates <28 days of age.*

GLUCOSE

Maintenance fluids usually contain D5, which provides 17 calories/100 mL and nearly 20% of the daily caloric needs. This level is enough to prevent ketone production and helps minimize protein degradation, but the child will lose weight on this regimen. Maintenance fluids are also lacking in such crucial nutrients as protein, fat, vitamins, and minerals. Hence, a patient needs to be started on TPN after a few days of maintenance fluids if enteral feedings are still not possible.

SELECTION OF MAINTENANCE FLUIDS

An isotonic fluid (NS, LR, Plasma-Lyte) with D5 and KCl (10-20 mEq/L is usually added to NS) is recommended for maintenance IV fluids. Surgical patients typically receive isotonic fluids (NS, LR) during surgery and in the recovery room for 6-8 hours postoperatively; the rate is typically approximately two thirds the calculated maintenance rate, with dextrose added if clinically indicated. Subsequent maintenance fluids have the addition of D5 and 10-20 mEq/L KCl based on the serum K^+ and the clinical setting. Electrolytes should be measured at least daily in all children receiving >50% of maintenance fluids intravenously unless the child is receiving prolonged IV fluids (TPN).

These guidelines assume that no disease process is present that would require an adjustment in either the volume or the electrolyte composition of maintenance fluids. Neonates, and especially premature infants, are outside the scope of these guidelines given their unique physiology. Children with renal insufficiency may be hyperkalemic or unable to excrete K^+ and may not tolerate 10 or 20 mEq/L of potassium. Patients with persistent ADH production because of an underlying disease process (syndrome of inappropriate ADH secretion, congestive heart failure, nephrotic syndrome, liver disease) should receive less

Table 74.4 Composition of Intravenous Solutions*

FLUID	[NA^+]	[CL^-]	[K^+]	[CA^{2+}]	[$LACTATE^-$]
Normal saline (0.9% NaCl)	154	154	—	—	—
Half-normal saline (0.45% NaCl)	77	77	—	—	—
0.2 normal saline (0.2% NaCl)	34	34	—	—	—
Ringer lactate	130	109	4	3	28

*Electrolyte concentrations in mEq/L.

than maintenance fluids. Children with meningitis are fluid restricted unless intravascular volume depletion is present (see Chapter 643.1). Treatment is individualized, and careful monitoring is critical.

In children with complicated pathophysiologic derangements, it may be necessary to adjust empirically the electrolyte composition and rate of maintenance fluids on the basis of electrolyte measurements and assessment of fluid balance. In all children it is critical to monitor weight, urine output, and electrolytes carefully to identify overhydration or underhydration, hyponatremia, and other electrolyte disturbances, and then adjust the rate or composition of the IV solution accordingly.

VARIATIONS IN MAINTENANCE WATER AND ELECTROLYTES

The calculation of maintenance water is based on standard assumptions regarding water losses. In some patients, however, these assumptions are incorrect. To identify such situations, it is helpful to understand the source and magnitude of normal water losses. Table 74.5 lists the three sources of normal water loss.

Urine is the most important contributor to normal water loss. Insensible losses represent approximately one third of total maintenance water (40% in infants; 25% in adolescents and adults). Insensible losses are composed of evaporative losses from the skin and lungs that cannot be quantitated. The evaporative losses from the skin *do not* include sweat, which would be considered an additional (sensible) source of water loss. Stool normally represents a minor source of water loss.

Maintenance water and electrolyte needs may be increased or decreased, depending on the clinical situation. This may be obvious, as in the infant with profuse diarrhea, or subtle, as in the patient who has decreased insensible losses while receiving mechanical ventilation. It is helpful to consider the sources of normal water and electrolyte losses and to determine whether any of these sources is being modified in a specific patient. It is then necessary to adjust maintenance water and electrolyte calculations.

Table 74.6 lists a variety of clinical situations that modify normal water and electrolyte losses. The skin can be a source of very significant water loss, particularly in neonates, especially premature infants, who are under radiant warmers or are receiving phototherapy. Very low birthweight infants can have insensible losses of 100-200 mL/kg/24 hr. Burns can result in massive losses of water and electrolytes, and there are specific guidelines for fluid management in children with burns (see Chapter 89). Sweat losses of water and electrolytes, especially in a warm climate, can also be significant. Children with cystic fibrosis and some children with pseudohypoaldosteronism have increased sodium losses from the skin.

Fever increases evaporative losses from the skin. These losses are somewhat predictable, leading to a 10–15% increase in maintenance water needs for each 1°C (1.8°F) increase in temperature above 38°C (100.4°F). These guidelines are for a patient with a persistent fever; a 1-hour fever spike does not cause an appreciable increase in water needs.

Tachypnea or a tracheostomy increases evaporative losses from the lungs. A humidified system (nasal cannula, mask, ventilator) causes a decrease in insensible losses from the lungs and can even lead to water absorption via the lungs; a ventilated patient has a decrease in maintenance water requirements. It may be difficult to quantify the changes that take place in the individual patient in these situations.

Table 74.5 Sources of Water Loss

- Urine: 60%
- Insensible losses: ≈35% (skin and lungs)
- Stool: 5%

REPLACEMENT FLUIDS

The gastrointestinal (GI) tract is potentially a source of considerable water loss. GI water losses are accompanied by electrolytes and thus may cause disturbances in intravascular volume and electrolyte concentrations. GI losses are often associated with loss of potassium, leading to hypokalemia. Because of the high bicarbonate concentration in stool, children with diarrhea usually have a **metabolic acidosis**, which may be accentuated if volume depletion causes hypoperfusion and a concurrent lactic acidosis. Emesis or losses from an NG tube can cause a **metabolic alkalosis** (see Chapter 73).

In the absence of vomiting, diarrhea, or NG drainage, GI losses of water and electrolytes are usually quite small. All GI losses are considered excessive, and the increase in the water requirement is equal to the volume of fluid losses. Because GI water and electrolyte losses can be precisely measured, an appropriate replacement solution can be used.

It is impossible to predict the losses for the next 24 hours; it is better to replace excessive GI losses as they occur. The child should receive an appropriate maintenance fluid that does not consider the GI losses. The losses should then be replaced after they occur, with use of a solution with a similar electrolyte concentration as the GI fluid. The losses are usually replaced every 1-6 hours, depending on the rate of loss, with very rapid losses being replaced more frequently.

Diarrhea is a common cause of fluid loss in children and can result in dehydration and electrolyte disorders. In the unusual patient with significant diarrhea and a limited ability to take oral fluid, it is important to have a plan for replacing excessive stool losses. The volume of stool should be measured, and an equal volume of replacement solution should be given. Data are available on the average electrolyte composition of diarrhea in children (see Table 74.7). With this information, an appropriate replacement solution can be designed. The solution shown in Table 74.7 replaces stool losses of Na^+, K^+, chloride (Cl^-), and bicarbonate. Each 1 mL of stool should be replaced by 1 mL of this solution. The average electrolyte composition of diarrhea is just an average, and there may be considerable variation. It is therefore advisable to consider measuring the electrolyte composition of a patient's diarrhea if the amount is especially excessive or if the patient's serum electrolyte levels are problematic.

Loss of gastric fluid, through emesis or NG suction, is also likely to cause dehydration, in that most patients with either condition have impaired oral intake of fluids. Electrolyte disturbances, particularly hypokalemia and metabolic alkalosis, are also common. These complications can be avoided by judicious use of a replacement solution. The composition of gastric fluid shown in Table 74.8 is the basis for designing a replacement solution.

Table 74.6 Adjustments in Maintenance Water

SOURCE	CAUSES OF INCREASED WATER NEEDS	CAUSES OF DECREASED WATER NEEDS
Skin	Radiant warmer	Incubator (premature infant)
	Phototherapy	
	Fever	
	Sweat	
	Burns	
Lungs	Tachypnea	Humidified system (nasal cannula, mask, ventilator)
	Tracheostomy	
Gastrointestinal tract	Diarrhea	—
	Emesis	
	Nasogastric suction	
Renal	Polyuria	Oliguria/anuria
Miscellaneous	Surgical drain	—
	Third spacing	

Table 74.7 Replacement Fluid for Diarrhea

AVERAGE COMPOSITION OF DIARRHEA
Sodium: 55 mEq/L
Potassium: 25 mEq/L
Bicarbonate: 15 mEq/L
APPROACH TO REPLACEMENT OF ONGOING LOSSES
Solution: D5 1/2NS + 30 mEq/L sodium bicarbonate + 20 mEq/L KCl
Replace stool mL/mL every 1-6 hr

D5, 5% dextrose; NS, normal saline.

Table 74.8 Replacement Fluid for Emesis or Nasogastric Losses

AVERAGE COMPOSITION OF GASTRIC FLUID
Sodium: 60 mEq/L
Potassium: 10 mEq/L
Chloride: 90 mEq/L
APPROACH TO REPLACEMENT OF ONGOING LOSSES
Solution: normal saline + 10 mEq/L KCl
Replace output mL/mL every 1-6 hr

Patients with gastric losses frequently have hypokalemia, although the K^+ concentration of gastric fluid is relatively low. The associated urinary K^+ loss is an important cause of hypokalemia in this situation (see Chapter 73). These patients may need additional potassium either in their maintenance fluids or in their replacement fluids to compensate for prior or ongoing urinary losses. Restoration of the patient's intravascular volume, by decreasing aldosterone synthesis, lessens the urinary K^+ losses.

Urine output is normally the largest cause of water loss. Diseases such as renal failure and syndrome of inappropriate ADH secretion can lead to a decrease in urine volume. The patient with oliguria or anuria has a decreased need for water and electrolytes; continuation of maintenance fluids produces fluid overload. In contrast, postobstructive diuresis, the polyuric phase of acute tubular necrosis, diabetes mellitus, and diabetes insipidus increase urine production. To prevent dehydration, the patient must receive more than standard maintenance fluids when urine output is excessive. The electrolyte losses in patients with polyuria are variable. In diabetes insipidus, the urine electrolyte concentration is usually low, whereas children with diseases such as juvenile nephronophthisis and obstructive uropathy usually have increased losses of both water and sodium.

Table 74.9 Adjusting Fluid Therapy for Altered Renal Output

OLIGURIA/ANURIA
Replacement of insensible fluid losses (25–40% of maintenance) with D5 1/2NS
Replace urine output mL/mL with D5 1/2NS ± KCl
POLYURIA
Replacement of insensible fluid losses (25–40% of maintenance) with D5 1/2NS ± KCl
Measure urine electrolytes
Replace urine output mL/mL with solution based on measured urine electrolytes

D5, 5% dextrose; NS, normal saline.

The approach to decreased or increased urine output is similar (Table 74.9). The patient receives fluids at a rate to replace insensible losses. This is accomplished by a rate of fluid administration that is 25–40% of the normal maintenance rate, depending on the patient's age. Replacing insensible losses in the anuric child will theoretically maintain an even fluid balance, with the caveat that 25–40% of the normal maintenance rate is only an estimate of insensible losses. In the individual patient, this rate is adjusted on the basis of monitoring of the patient's weight and volume status. Most children with renal insufficiency receive little or no potassium because the kidney is the principal site of K^+ excretion.

For the **oliguric** child, it is important to add a urine replacement solution to prevent dehydration. This issue is especially important in the patient with acute kidney injury, in whom output may increase, potentially leading to volume depletion and worsening of kidney injury if the patient remains on only insensible fluids. A replacement solution of D5 1/2NS is usually appropriate initially, although its composition may have to be adjusted if urine output increases significantly.

Most children with **polyuria** (except in diabetes mellitus; see Chapter 629) should be started on replacement of insensible fluid plus urine losses. This approach avoids the need to attempt to calculate the volume of urine output that is "normal" so that the patient can be given

replacement fluid for the excess. In these patients, urine output is, by definition, excessive, and it is often helpful to measure Na^+ and K^+ concentrations of the urine to help in formulating the urine replacement solution.

Surgical drains and chest tubes can produce measurable fluid output. These fluid losses should be replaced when they are significant. They can be measured and replaced with an appropriate solution. **Third space losses**, which manifest as edema and ascites, are caused by a shift of fluid from the intravascular space into the interstitial space. Although these losses cannot be quantitated easily, third space losses can be large and may lead to intravascular volume depletion, despite the patient's weight gain. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have burns or abdominal surgery. Third space losses and chest tube output are isotonic, so they usually require replacement with an isotonic fluid, such as NS or LR. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient's intravascular volume status. Protein losses from chest tube drainage can be significant, occasionally necessitating that 5% albumin be used as a replacement solution.

Chapter 75

Deficit Therapy

Larry A. Greenbaum

Dehydration, most often caused by gastroenteritis, is a common problem in children. Most cases can be managed with oral rehydration (see Chapter 387). *Even children with mild to moderate hyponatremic or hypernatremic dehydration can be managed with oral rehydration.*

CLINICAL MANIFESTATIONS

The first step in caring for the child with dehydration is to assess the degree of dehydration (Table 75.1), which dictates both the urgency of the situation and the volume of fluid needed for rehydration. The infant with mild dehydration (3–5% of body weight dehydrated) has few clinical signs or symptoms. The infant may be thirsty; the alert parent may notice a decline in urine output. The history is most helpful. The infant with moderate dehydration has clear physical signs and symptoms. Intravascular volume depletion is evident from an increased heart rate and reduced urine output. This patient needs fairly prompt intervention. The infant with severe dehydration is gravely ill. The decrease in blood pressure indicates that vital organs may be receiving inadequate perfusion. Immediate and aggressive intervention is necessary. If possible, the child with severe dehydration should initially receive intravenous (IV) therapy. For older children and adults, mild, moderate, or severe dehydration represents a lower percentage of body weight lost. This difference occurs because water accounts for a higher percentage of body weight in infants (see Chapter 73).

Table 75.1 Clinical Evaluation of Dehydration

Mild dehydration (<5% in an infant; <3% in an older child or adult): Normal or increased pulse; decreased urine output; thirsty; normal physical findings
Moderate dehydration (5–10% in an infant; 3–6% in an older child or adult): Tachycardia; little or no urine output; irritable/lethargic; sunken eyes and fontanel; decreased tears; dry mucous membranes; mild delay in elasticity (skin turgor); delayed capillary refill (>1.5 sec); cool and pale
Severe dehydration (>10% in an infant; >6% in an older child or adult): Peripheral pulses either rapid and weak or absent; decreased blood pressure; no urine output; very sunken eyes and fontanel; no tears; parched mucous membranes; delayed elasticity (poor skin turgor); very delayed capillary refill (>3 sec); cold and mottled; limp, depressed consciousness

Clinical assessment of dehydration is only an estimate; thus the patient must be continually reevaluated during therapy. The degree of dehydration is underestimated in hypernatremic dehydration because the movement of water from the intracellular space (ICS) to the extracellular space (ECS) helps preserve the intravascular volume.

The history usually suggests the etiology of the dehydration and may predict whether the patient will have a normal sodium concentration (isotonic dehydration), hyponatremic dehydration, or hypernatremic dehydration. The neonate with dehydration caused by poor intake of breast milk often has hypernatremic dehydration. **Hypernatremic dehydration** is likely in any child with losses of hypotonic fluid and poor water intake, as may occur with diarrhea, and poor oral intake because of anorexia or emesis. **Hyponatremic dehydration** occurs in the child with diarrhea who is taking in large quantities of low-salt fluid, such as water or formula.

Some children with dehydration are appropriately thirsty, but in others the lack of intake is part of the pathophysiology of the dehydration. Even though decreased urine output is present in most children with dehydration, good urine output may be deceptively present if a child has an underlying renal defect, such as diabetes insipidus or a salt-wasting nephropathy, or in infants with hypernatremic dehydration.

Physical examination findings are usually proportional to the degree of dehydration. Parents may be helpful in assessment of the child for the presence of sunken eyes, because this finding may be subtle. Pinching and gently twisting the skin of the abdominal or thoracic wall detects tenting of the skin (turgor, elasticity). Tented skin remains in a pinched position rather than springing quickly back to normal. It is difficult to properly assess tenting of the skin in premature infants or severely malnourished children. Activation of the sympathetic nervous system causes **tachycardia** in children with intravascular volume depletion; diaphoresis may also be present. Postural changes in blood pressure are often helpful for evaluating and assessing the response to therapy in children with dehydration. **Tachypnea** in children with dehydration may be present secondary to a metabolic acidosis from stool losses of bicarbonate or lactic acidosis from shock (see Chapter 85).

LABORATORY FINDINGS

Several laboratory findings are useful for evaluating the child with dehydration. The serum sodium concentration determines the type of dehydration. **Metabolic acidosis** may be a result of stool bicarbonate losses in children with diarrhea, secondary **acute kidney injury** (see Chapter 572.1), or lactic acidosis from shock. The anion gap is useful for differentiating among the various causes of a metabolic acidosis (see Chapter 73). Emesis or nasogastric losses usually cause a **metabolic alkalosis**. The serum potassium (K^+) concentration may be low as a result of diarrheal losses. In children with dehydration as a result of emesis, gastric K^+ losses, metabolic alkalosis, and urinary K^+ losses all contribute to hypokalemia. Metabolic acidosis, which causes a shift of K^+ out of cells, and acute kidney injury may lead to hyperkalemia. A combination of mechanisms may be present; thus it may be difficult to predict the child's acid-base status or serum K^+ level from the history alone.

The blood urea nitrogen (BUN) value and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without parenchymal kidney injury may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This condition is secondary to increased passive resorption of urea in the proximal tubule as a result of appropriate renal conservation of sodium and water. The increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake, because urea production depends on protein degradation. The BUN may be disproportionately increased in the child with increased urea production, as occurs with a gastrointestinal bleed or

with the use of glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests acute kidney injury, although a small, transient increase can occur with dehydration. Decreased kidney perfusion is the most common etiology of acute kidney injury in a child with volume depletion, but occasionally the child may have previously undetected chronic kidney disease or an alternative explanation for the acute kidney injury. **Renal vein thrombosis** is a well-described sequela of severe dehydration in infants; findings may include thrombocytopenia and hematuria (see Chapter 562.2).

Hemoconcentration from dehydration causes increases in hematocrit, hemoglobin, and serum proteins. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin level in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak. An acute or chronic protein-losing enteropathy may also cause a low serum albumin concentration.

CALCULATION OF THE FLUID DEFICIT

Determining the fluid deficit necessitates clinical determination of the percentage of dehydration and multiplication of this percentage by the patient's weight; a child who weighs 10 kg and is 10% dehydrated has a fluid deficit of 1 L.

APPROACH TO SEVERE DEHYDRATION

The child with dehydration needs acute intervention to ensure that there is adequate tissue perfusion. This resuscitation phase requires rapid restoration of the circulating intravascular volume and treatment of **shock** with an isotonic solution, such as normal saline (NS), Ringer lactate (lactated Ringer solution, LR), or Plasma-Lyte (see Chapter 85). The child is given a fluid bolus, usually 20 mL/kg of the isotonic fluid, over approximately 20 minutes. The child with severe dehydration may require multiple fluid boluses and may need to receive the boluses as fast as possible. In a child with a known or probable *metabolic alkalosis* (e.g., child with isolated vomiting), LR or Plasma-Lyte should not be used because the lactate or acetate would worsen the alkalosis. However, LR or Plasma-Lyte may be preferable to NS in shock since it is a balanced solution (see Chapters 74 and 85); NS may cause a hyperchloremic metabolic acidosis.

Colloids, such as blood, 5% albumin, and plasma, are rarely needed for fluid boluses. A crystalloid solution (NS or LR) is satisfactory, with both lower risk of infection and lower cost. Blood is obviously indicated in the child with significant anemia or acute blood loss. Plasma is useful for children with a coagulopathy. The child with hypoalbuminemia may benefit from 5% albumin, although there is evidence that albumin infusions increase mortality in adults. The volume and the infusion rate for colloids are generally modified compared with crystalloids (see Chapter 522).

The initial resuscitation and rehydration phase is complete when the child has an adequate intravascular volume. Typically, the child shows clinical improvement, including a lower heart rate, normalization of blood pressure, improved perfusion, better urine output, and a more alert affect.

With adequate intravascular volume, it is appropriate to plan the fluid therapy for the next 24 hours. A general approach is outlined in Table 75.2, with the caveat that there are many different approaches to correcting dehydration. A balanced solution can be substituted for NS. In isonatremic or hyponatremic dehydration, the entire fluid deficit is corrected over 24 hours; a slower approach is used for hypernatremic dehydration (discussed later). The volume of isotonic fluids that the patient has received is subtracted from this total. The remaining fluid volume is then administered over 24 hours. The potassium concentration may need to be decreased or, less frequently, increased, depending on the clinical situation. Potassium is not usually included in the IV fluids until the patient voids and normal renal function is documented by measurement of BUN and creatinine. Children with significant ongoing losses need to receive an appropriate replacement solution (see Chapter 74).

MONITORING AND ADJUSTING THERAPY

The formulation of a plan for correcting a child's dehydration is only the beginning of management. *All calculations in fluid therapy are only approximations.* This statement is especially true for the assessment of percentage dehydration. It is equally important to monitor the patient during treatment and to modify therapy on the basis of the clinical situation. Table 75.3 lists the cornerstones of patient monitoring. The patient's vital signs are useful indicators of intravascular volume status. The child with decreased blood pressure and an increased heart rate will probably benefit from a fluid bolus.

The patient's intake and output are critically important in the dehydrated child. The child who, after 8 hours of therapy, has more output than input because of continuing diarrhea needs to be started on a replacement solution. See the guidelines in Chapter 74 for selecting an appropriate replacement solution. Urine output is useful for evaluating the success of therapy. Good urine output indicates that rehydration has been successful.

Signs of dehydration on physical examination suggest the need for continued rehydration. Signs of fluid overload, such as edema and pulmonary congestion, are present in the child who is overhydrated. An accurate daily weight measurement is critical for the management of the dehydrated child. There should be a gain in weight during successful therapy.

Measurement of serum electrolyte levels at least daily is appropriate for any child who is receiving IV rehydration. Such a child is at risk for sodium, potassium, and acid-base disorders. It is always important to look at trends. For example, a sodium concentration ($[Na^+]$) of 144 mEq/L is normal; but if the $[Na^+]$ was 136 mEq/L 12 hours earlier, there is a distinct risk that the child will be hypernatremic in 12 or 24 hours. It is advisable to be proactive in adjusting fluid therapy.

Both hypokalemia and hyperkalemia are potentially serious (see Chapter 73). Because dehydration can be associated with acute kidney injury and hyperkalemia, potassium is withheld from IV fluids until the patient has voided. The potassium concentration in the patient's IV fluids is not rigidly prescribed. Rather, the patient's serum K^+ level and underlying kidney function are used to modify potassium delivery. The patient with an elevated creatinine value and K^+ level of 5 mEq/L does not receive any potassium until the serum K^+ level decreases.

Table 75.2 Fluid Management of Dehydration

1. Restore intravascular volume
   Isotonic fluid (NS or LR): 20 mL/kg over 20 min
   Repeat as needed
2. Calculate 24 hr fluid needs: maintenance + deficit volume
3. Subtract isotonic fluid already administered from 24 hr fluid needs
4. Administer remaining volume over 24 hr using 5% dextrose NS + 20 mEq/L KCl
5. Replace ongoing losses as they occur

LR, Ringer lactate; NS, normal saline.

Table 75.3 Monitoring Therapy

- Vital signs
  - Pulse
  - Blood pressure
- Intake and output
  - Fluid balance
  - Urine output
- Physical examination
  - Weight
  - Clinical signs of depletion or overload
- Electrolytes

Conversely, the patient with a K^+ level of 2.5 mEq/L may require additional potassium.

Metabolic acidosis can be quite severe in dehydrated children. Although normal kidneys eventually correct this problem, a child with renal dysfunction may be unable to correct a metabolic acidosis, and a portion of the patient's IV sodium chloride may have to be replaced with sodium bicarbonate, sodium lactate (as in LR), or sodium acetate.

The serum K^+ level is modified by the patient's acid-base status. Acidosis increases serum K^+ by causing intracellular K^+ to move into the ECS. Thus, as acidosis is corrected, the serum potassium concentration ($[K^+]$) decreases. Again, it is best to anticipate this problem and to monitor the serum $[K^+]$ and adjust potassium administration appropriately.

HYPONATREMIC DEHYDRATION

The pathogenesis of hyponatremic dehydration usually involves a combination of sodium and water loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and the lost fluid contains sodium. Most fluid that is lost has a lower sodium concentration, so patients with only fluid loss would have hypernatremia. Diarrhea has, on average, a sodium concentration of 50 mEq/L. Replacing diarrheal fluid with water, which has almost no sodium, causes a reduction in the serum $[Na^+]$ (see Chapter 74). The volume depletion stimulates synthesis of antidiuretic hormone, resulting in reduced renal water excretion. Therefore the body's usual mechanism for preventing hyponatremia, renal water excretion, is blocked. The risk of hyponatremia is further increased if the volume depletion is a result of loss of fluid with a higher sodium concentration, as may occur with renal salt wasting, third space losses, or diarrhea with high sodium content (cholera).

The initial goal in treating hyponatremia is correction of intravascular volume depletion with isotonic fluid. An overly rapid (>8-10 mEq/L over the first 24 hours) or overcorrection in the serum $[Na^+]$ (>135 mEq/L) is associated with an increased risk of **osmotic demyelination syndrome** (formerly *central pontine myelinolysis*) (see Chapter 73). Most patients with hyponatremic dehydration do well with the same basic strategy outlined in Table 75.2. Again, K^+ delivery is adjusted according to the initial serum K^+ level and the patient's renal function. Potassium is not given until the patient voids.

The patient's $[Na^+]$ is monitored closely to ensure appropriate correction, and the sodium concentration of the fluid is adjusted accordingly. Patients with ongoing losses require an appropriate replacement solution (see Chapter 74). Patients with neurologic symptoms (seizures) as a result of hyponatremia need to receive an acute infusion of hypertonic (3%) saline to increase the serum $[Na^+]$ rapidly (see Chapter 73).

HYPERNATREMIC DEHYDRATION

Hypernatremic dehydration is the most dangerous form of dehydration because of complications of hypernatremia itself and of its therapy. Hypernatremia can cause serious neurologic damage, including central nervous system hemorrhages and thrombosis. This damage appears to be secondary to the movement of water from the brain cells into the hypertonic extracellular fluid (ECF), causing brain cell shrinkage and tearing blood vessels within the brain (see Chapter 73).

The movement of water from the ICS to the ECS during hypernatremic dehydration partially protects the intravascular volume. Unfortunately, because the initial manifestations are milder, children with hypernatremic dehydration are often brought for medical attention with more profound dehydration.

Children with hypernatremic dehydration are often lethargic, and they may be irritable when touched. Hypernatremia may cause fever, hypertonicity, and hyperreflexia. More severe neurologic symptoms may develop if cerebral bleeding or thrombosis occurs.

Overly rapid treatment of hypernatremic dehydration may cause significant morbidity and mortality. **Idiogenic osmoles** are generated within the brain during the development of hypernatremia; they increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage caused by movement of water out of the cells and into the hypertonic ECF. Idiogenic osmoles dissipate slowly during the correction of hypernatremia. With overly rapid lowering of the extracellular osmolality during the correction of hypernatremia, an osmotic gradient may be created that causes water movement from the ECS into the cells of the brain, producing cerebral edema. Symptoms of the resultant cerebral edema can range from seizures to brain herniation and death.

To minimize the risk of **cerebral edema** during the correction of hypernatremic dehydration, *the serum sodium concentration should not decrease by >10 mEq/L every 24 hours.* The deficits in severe hypernatremic dehydration may need to be corrected over 2-4 days (Fig. 75.1).

The initial resuscitation of hypernatremic dehydration requires restoration of the intravascular volume with NS. LR should not be used because it is more hypotonic than NS and may cause too rapid a decrease in the serum $[Na^+]$, especially if multiple fluid boluses are necessary.

To avoid cerebral edema during correction of hypernatremic dehydration, the fluid deficit is corrected slowly. The rate of correction depends on the initial sodium concentration (see Fig. 75.1). There is no general agreement on the choice or the rate of fluid administration for correcting hypernatremic dehydration; these factors are not nearly as important as vigilant monitoring of the serum $[Na^+]$ and adjustment of the therapy according to the result. The rate of decrease of the serum $[Na^+]$ is roughly related to the "free water" delivery, although there is considerable variation between patients. Free water is water without sodium. NS contains no free water, half-normal saline (½ NS) is 50% free water, and water is 100% free water. Smaller patients, to achieve the same decrease in the sodium concentration, tend to need higher amounts of free water delivery per kilogram because of **higher insensible fluid losses**. Five percent dextrose (D5) with ½ NS is usually an appropriate starting solution for correction of a patient with hypernatremic dehydration. Some patients, especially infants with ongoing high insensible water losses, may rarely need to receive D5 0.2NS, which should be used with great caution and constant monitoring. Others require D5 NS. A child with dehydration as a result of pure free water loss, as usually occurs with diabetes insipidus, usually needs a more hypotonic fluid than a child with depletion of both sodium and water from diarrhea.

Adjustment in the sodium concentration of the IV fluid is the most common approach to modify the rate of decrease in the serum concentration (see Fig. 75.1). For difficult-to-manage patients with severe hypernatremia, having two IV solutions (e.g., D5 ½ NS and D5 NS, both with the same concentration of potassium) at the bedside can facilitate this approach by allowing for rapid adjustments of the rates of the two fluids. If the serum $[Na^+]$ decreases too rapidly, the rate of D5 NS can be increased and the rate of D5 ½ NS can be decreased by the same amount. Adjustment in the total rate of fluid delivery is another approach to modifying free water delivery. For example, if the serum $[Na^+]$ is decreasing too slowly, the rate of a hypotonic IV fluid can be increased, thereby increasing the delivery of free water. There is limited flexibility in modifying the rate of the IV fluid because patients generally should receive 1.25-1.5 times the normal maintenance fluid rate. Nevertheless, in some situations, it can be a helpful adjustment.

Because increasing the rate of the IV fluid increases the rate of decline of the sodium concentration, signs of volume depletion are treated with additional isotonic fluid boluses. The serum $[K^+]$ and the level of renal function dictate the potassium concentration of the IV fluid; potassium is withheld until the patient voids. Patients with hypernatremic dehydration need an appropriate replacement solution if they have ongoing, excessive losses (see Chapter 74).

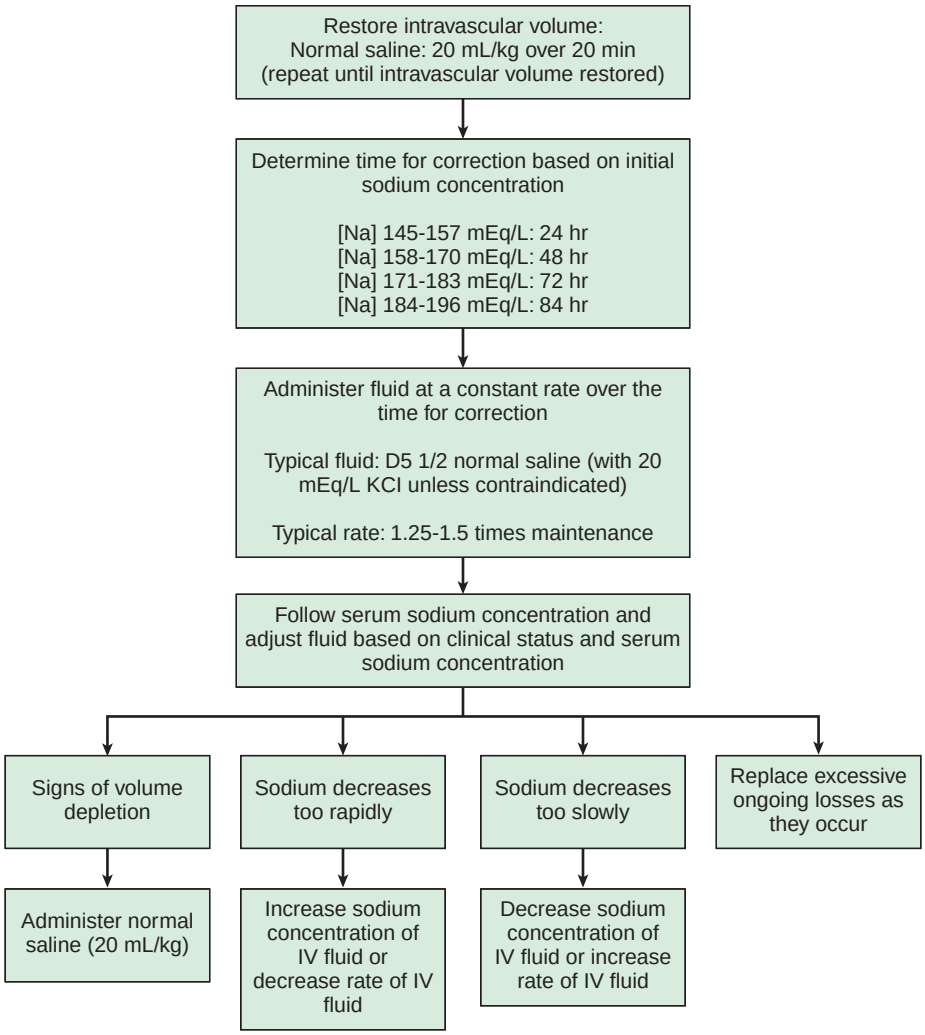

Fig. 75.1 Algorithm for the treatment of hypernatremic dehydration. *(From Londeree JT, Greenbaum LA. Dehydration and replacement therapy. In: Marcdante KJ, Kliegman RM, Schuh AM, eds. Nelson Essentials of Pediatrics, 9th ed. Philadelphia: Elsevier, 2023. Fig 33.1.)*

Seizures and a depressed level of consciousness are the most common manifestations of **cerebral edema** from an overly rapid decrease of the serum [Na^+] during correction of hypernatremic dehydration. Signs of increased intracranial pressure or impending herniation may develop quite rapidly (see Chapter 82). Acutely, increasing the serum [Na^+] through an infusion of 3% sodium chloride can reverse the cerebral edema. Each 1 mL/kg of 3% NaCl increases the serum [Na^+] by approximately 1 mEq/L. An infusion of 4 mL/kg often results in resolution of the symptoms. This strategy is similar to that used for treating symptomatic hyponatremia (see Chapter 73).

Many patients with mild to moderate hypernatremic dehydration as a result of gastroenteritis can be managed with oral rehydration (see Chapter 387). In patients with severe hypernatremia, oral fluids must be used cautiously. Infant formula, because of its low sodium concentration, has a high free water content, and especially if added to IV therapy, it may contribute to a rapid decrease in the serum [Na^+]. Less hypotonic fluid, such as an oral rehydration solution, may be more appropriate initially. If oral intake is allowed, its contribution to free water delivery must be taken into account, and adjustment in the IV fluid is usually appropriate. Judicious monitoring of the serum [Na^+] is critical.

Emergency Medicine, Critical Care, and Anesthesia

PART VII

Chapter 77

Emergency Medical Services for Children

Charles G. Macias, Katherine E. Remick, and Steven E. Krug

The overwhelming majority of the 27 million children who present annually for emergency care in the United States are seen at community-based general emergency departments (EDs). Visits to children's hospital EDs account for just 10% of initial ED encounters. Additionally, across emergency medical services, children account for approximately 10% of all transports. This distribution suggests that the greatest opportunity to optimize care for acutely ill or injured pediatric patients, on a population basis, occurs broadly as part of a systems-based approach to emergency services, an approach that incorporates the unique needs of children at every level. Conceptually, emergency medical services for children are characterized by an integrated, continuum-of-care model (Fig. 77.1). The model is designed such that patient care flows seamlessly from the primary care medical home through transport and on to hospital-based definitive care. It includes the following five principal domains of activity:

1. Prevention, both primary and secondary
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: ED and inpatient, including critical care
4. Interfacility transport, as necessary, for definitive or pediatric medical and surgical subspecialty care (see Chapter 77.1)
5. Rehabilitation

Fig. 77.1 The emergency medical services for children (EMSC) continuum of care. Seriously ill and injured children interface with a large number of healthcare personnel as they move through the EMSC system.

The federal **Emergency Medical Services for Children (EMSC)** program of the Health Resources and Services Administration Maternal and Child Health Bureau has stewarded improvements in the care of children in the context of the continuum-of-care model. The programmatic mission of the EMSC program is as follows:

- To ensure U.S. emergency care systems across the continuum of care are pediatric-ready, meaning pediatric-specific needs are incorporated into every aspect of patient care, including patient safety practices, equipment and supplies, competency requirements, policies and procedures, quality improvement efforts, and administrative oversight and coordination of care.
- To ensure access to high-quality emergency medical care for ill or injured children and adolescents of all ages regardless of geographic location.
- To ensure that pediatric services are well integrated into an emergency medical services (EMS) system and backed by optimal resources.
- To ensure that the entire spectrum of emergency services—including primary prevention of illness and injury, acute care, and rehabilitation—is provided to infants, children, and adolescents at a level equal to that of adults.

PRIMARY CARE PHYSICIAN AND OFFICE PREPAREDNESS

The primary care physician (PCP) has multiple important roles in the EMS system. Through anticipatory guidance, the PCP can help shape the attitudes, knowledge, and behaviors of parent and child, with the primary goal of preventing acute medical events, such as injury and exacerbations of illness. The point-of-care initiation for many acute problems is often the PCP office. From the standpoint of personnel, equipment, training, and protocols, the PCP office setting must be adequately prepared to initially manage acute and emergency exacerbations of common pediatric conditions, such as respiratory distress and seizures. Furthermore, on rare occasion, the PCP office environment may be confronted with a child in clinical extremis who requires resuscitation and stabilization. It is therefore incumbent on the PCP not only to ensure access to EMS, that is, 911 system activation, but also to ensure that there is adequate equipment and supplies and on-site cognitive and psychomotor skill preparation to deal with such an emergency. **Office preparedness** requires training and continuing education for staff members, protocols for emergency interventions, ready availability of appropriate resuscitation drugs and equipment, and knowledge of local EMS resources and ED capabilities. PCPs can also play a pivotal role in informing and advocating for pediatric emergency and disaster readiness for families (especially those of children and youth with special healthcare needs) and in local EMS agencies, schools and childcare programs, and community hospitals. In all communities, the medical home plays a vital role in promoting family readiness for emergencies and disasters.

Staff Training and Continuing Education

It is a reasonable expectation that all office staff, including receptionists and medical assistants, be trained in cardiopulmonary resuscitation (CPR) with recertification maintained every 2 years. Nurses and physicians should also have training in a systematic approach to pediatric resuscitation that optimizes performance of high-quality CPR. Core knowledge may be obtained through standardized courses in **advanced life support (ALS)** offered by national medical associations and professional organizations. Frequent practice and timely

recertification are important for knowledge retention and skill maintenance. Examples include the Pediatric Advanced Life Support (PALS) and Pediatric Emergency Assessment, Recognition and Stabilization (PEARS) courses sponsored by the American Heart Association (AHA), the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics (AAP) and American College of Emergency Physicians (ACEP), and the Emergency Nurses Pediatric Course (ENPC) sponsored by the Emergency Nurses Association (ENA).

Protocols

Standardized protocols for telephone triage of seriously ill or injured children are essential. When a child's clinical status is guarded and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by other means (e.g., private vehicle). This obviates the potentially serious medical consequences of relying on distraught, often untrained, parents who lack essential equipment and supplies to provide even **basic life support (BLS)** measures to an unstable child during transport. Practitioners can work with their regional pediatric emergency care resource center (e.g., children's hospital, academic medical center, trauma center) to develop and maintain written protocols for office-based management of a range of conditions, including anaphylaxis, cardiopulmonary arrest, head trauma, ingestions, shock, status asthmaticus, status epilepticus, extremity injuries, and upper airway obstruction. Regular practice using mock code scenarios improves office-based practitioner and staff performance and self-efficacy in managing these problems.

Resuscitation Equipment

Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a weight-based pediatric resuscitation cart or kit (Table 77.1). This cart or kit should be checked on a regular basis and kept in an accessible location known to all office staff. Outdated medication, a laryngoscope with a failed light source, or an empty oxygen tank represents a potential catastrophe in a resuscitation scenario. Such an incident can be easily avoided if an equipment checklist and regular maintenance schedule are implemented. A pediatric kit that includes posters to reinforce clinical management and procedures, a drug-dosing formulary, and a color-coded length-based resuscitation tape specifying weight and emergency equipment size are invaluable in avoiding critical therapeutic errors during resuscitation.

To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have designated roles. Organizing a "rapid response team" within the office ensures that necessary equipment is made available to the physician in charge, an appropriate medical record detailing all interventions and the child's response is generated, and the 911 call for EMS response or a critical care transport team is made in a timely fashion. Regular practice for these infrequent events will promote timely response when needed.

Transport

Once efforts to stabilize the child have begun, a decision must be made on how best to transport a child to a facility capable of providing definitive care. If a child requires airway or cardiovascular support, has an altered mental state or unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via privately owned vehicle, regardless of proximity to a hospital. Even when an ambulance is called, it is the PCP's responsibility to initiate essential life support measures and to attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, the PCP must be knowledgeable about the scope of service provided by each. The availability of BLS vs ALS services, the configuration of the transport team, and pediatric expertise vary greatly among agencies and across jurisdictions. BLS services provide basic support of airway, breathing, and circulation, whereas ALS units are capable of providing resuscitation drugs and procedural interventions as well. Some communities may have only BLS services available, whereas others may have a two-tiered system, providing both BLS and ALS. It may be appropriate to consider medical air transport when definitive or specialized care is not available within the community or when ground transport times are prolonged. In that case, initial transport via ground to an appropriate helicopter landing zone or a local hospital for interval stabilization may be undertaken, pending arrival

Table 77.1 Recommended Drugs and Equipment for Pediatric Office Emergencies

DRUGS/EQUIPMENT	PRIORITY
DRUGS	
Oxygen	E
Albuterol for inhalation	E
Epinephrine (1:1,000 [1 mg/mL])	E
Activated charcoal	S
Antibiotics	S
Anticonvulsants (diazepam/lorazepam)	S
Corticosteroids (parenteral/oral)	S
Dextrose (25%)	S
Diphenhydramine (parenteral, 50 mg/mL)	S
Epinephrine (1:10,000 [0.1 mg/mL])	S
Atropine sulfate (0.1 mg/mL)	S
Naloxone (0.4 mg/mL)	S
Sodium bicarbonate (4.2%)	S
INTRAVENOUS FLUIDS	
Normal saline (0.9 NS) *or* lactated Ringer solution (500-mL bags)	S
5% dextrose, 0.45 NS (500-mL bags)	S
EQUIPMENT FOR AIRWAY MANAGEMENT	
Oxygen and delivery system	E
Bag-valve-mask (450 mL and 1,000 mL)	E
Clear oxygen masks, breather and non-rebreather, with reservoirs (infant, child, adult)	E
Suction device, tonsil tip, bulb syringe	E
Nebulizer (or metered-dose inhaler with spacer/mask)	E
Oropharyngeal airways (sizes 00-5)	E
Pulse oximeter	E
Nasopharyngeal airways (sizes 12-30F)	S
Magill forceps (pediatric, adult)	S
Suction catheters (sizes 5-16F and Yankauer suction tip)	S
Nasogastric tubes (sizes 6-14F)	S
Laryngoscope handle (pediatric, adult) with extra batteries, bulbs	S
Laryngoscope blades (straight 0-2; curved 2-3)	S
Endotracheal tubes (uncuffed 2.5-5.5; cuffed 6.0-8.0)	S
Stylets (pediatric, adult)	S
Esophageal intubation detector or end-tidal carbon dioxide detector	S
EQUIPMENT FOR VASCULAR ACCESS AND FLUID MANAGEMENT	
Butterfly needles (19-25 gauge)	S
Catheter-over-needle device (14-24 gauge)	S
Arm boards, tape, tourniquet	S
Intraosseous needles (16 and 18 gauge)	S
Intravenous tubing, micro-drip	S
MISCELLANEOUS EQUIPMENT AND SUPPLIES	
Color-coded tape or preprinted drug doses	E
Cardiac arrest board/backboard	E
Sphygmomanometer (infant, child, adult, thigh cuffs)	E
Splints, sterile dressings	E
Automated external defibrillator with pediatric capabilities	S
Spot glucose test	S
Stiff neck collars (small/large)	S
Heating source (overhead warmer/infrared lamp)	S

E, essential; S, strongly suggested.

From Frush K, American Academy of Pediatrics, Committee on Pediatric Emergency Medicine. Policy statement-preparation for emergencies in the offices of pediatricians and pediatric primary care providers. *Pediatrics*. 2007;120:200-212. Reaffirmed in *Pediatrics*. 2011;128:e748.

of the air transport team. Independent of whether a child is to be transported by air or ground, copies of the pertinent medical records and any imaging or laboratory studies should be sent with the patient and a call made to the physician at the receiving facility to alert them to the referral and any treatments administered. Such notification is not merely a courtesy; direct physician-to-physician communication is essential for optimal care quality and to ensure adequate transmission of patient care information, to allow mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be more optimally treated at an alternative facility.

PEDIATRIC PREHOSPITAL CARE

Prehospital care refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. The goals of prehospital care are to further minimize systemic insult or injury through a series of well-defined and appropriate interventions and serve as the first link in high-quality emergency care. Prehospital emergency care services embrace patient safety, family-centered care, and timely and effective interventions as core tenets. Most U.S. communities have a formalized EMS system; the organizational structure and nature of emergency medical response depend greatly on local demographics and population base. EMS may be provided by volunteers or career professionals working in a fire department–based or independent third-service response system. All EMS and fire-based agencies have an identified medical director who defines provider competencies and scope of practice. Key points to recognize in negotiation of the juncture between the community physician and the local EMS system include access to the system, provider capability, and destination determination.

Access to the EMS System

Virtually all Americans have access to the 911 telephone service that provides direct access to a dispatcher who coordinates police, fire, and EMS responses. Many communities have a next-generation 911 system, in which the location of the caller is automatically provided to the call taker and/or dispatcher regardless of landline or mobile device use, permitting emergency response even if the caller, such as a young child, cannot give an address. Next-generation 911 also provides text-messaging capabilities. The extent of medical training for call takers and dispatchers varies among communities, as do the protocols by which they assign an emergency response level (BLS vs ALS). Many dispatch centers have adopted the Medical Priority Dispatch System (MPDS) to use standardized protocols and prearrival/postdispatch instructions. MPDS requires emergency medical dispatchers to ask a series of questions that determine the appropriate level of priority and EMS response. In some smaller communities, no coordinated dispatch exists, and emergency medical calls are handled by the local law enforcement agency or fire department. When activating the 911 system, the physician must make clear to the dispatcher the nature of the medical emergency and the condition of the child.

Provider Capability

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS. All EMS personnel, whether basic **emergency medical technicians (EMTs)** or paramedics, receive some initial training in pediatric emergencies; however, in most programs the dedicated time allotted to pediatric emergencies is minimal. Furthermore, state requirements vary for pediatric continuing education, and exposure to critically ill or injured children in the prehospital setting is infrequent, even in urban settings. PCPs should recognize that prehospital providers may need additional consultation or support, especially when managing children with uncommon medical conditions. PCPs can support maintenance of pediatric knowledge by EMS providers by serving as or working closely with an identified pediatric emergency care coordinator (PECC) within the EMS agency to fully integrate the needs of children into every aspect of system-based care: policies, protocols, quality improvement, patient safety, family-centered care, staff competencies, and equipment and supplies. Although children represent a minority population in the prehospital setting, the joint policy statement, *Pediatric Readiness in Emergency Medical Services Systems,* provides a comprehensive overview of how EMS systems can address the needs of children throughout all aspects of care. The identification of a PECC and physical demonstration of pediatric-specific skills represent two of the reference standards that the federal EMSC program has adopted as performance measures for state-level operational readiness to care for children in an EMS system.

First responders may be law enforcement officers or firefighters, who are dispatched to provide emergency medical assistance, or bystanders. Public safety personnel have a minimum of 40 hours of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this may be the only prehospital emergency medical response available.

In the United States the bulk of emergency medical response is provided by EMTs, who may be volunteers or paid professionals. Basic EMTs may staff an ambulance after undergoing a training program of approximately 100 hours. They are licensed to provide BLS services but may receive further training in some jurisdictions to expand their scope of practice to include intravenous catheter placement and fluid administration, management of airway adjuncts, and use of an automated external defibrillator (AED).

Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of at least 1,000 hours. Paramedic skills include advanced airway management, including endotracheal intubation; placement of peripheral vascular or intraosseous lines; intravenous administration of drugs and blood products; administration of nebulized aerosols; needle and finger thoracostomy; and cardioversion, cardiac pacing, and manual defibrillation. These professionals provide ALS services, functioning out of an ambulance equipped as a mobile intensive care unit (ICU). The joint position statement *Recommended Essential Equipment for Basic Life Support and Advanced Life Support Ground Ambulances 2020* published by the AAP, ACEP, American College of Surgeons Committee on Trauma, EMSC Innovation and Improvement Center, ENA, National Association of EMS Physicians, and National Association of EMS Officials outlines national standards for essential equipment, medications, and supplies necessary to provide BLS and ALS care across the age spectrum.

Both basic EMTs and paramedics function under the delegated licensing authority of a supervisory EMS medical director. This physician oversight of prehospital practice is broadly characterized under the umbrella term *medical control.* **Direct**, or **online**, **medical control** refers to medical direction either at the scene or in real time via voice or video transmission. **Indirect**, or **offline**, **medical control** refers to the administration of medical direction before and after the provision of care (i.e., clinical protocols). Offline activities, such as provider education and training, protocol development, and medical leadership of quality assurance/quality improvement programs, represent areas in need of greater pediatric input. Whether in the presence or absence of a PECC, a pediatric advisory committee may provide additional pediatric knowledge and expertise. Evaluation and tracking of pediatric performance is critical to ensuring high-quality care for children in a community. The National EMS Information System (NEMSIS) serves as a registry for standardized EMS data collection. EMS agency participation in NEMSIS-compliant data submission is one of the federal EMSC performance measures. The National EMS Quality Alliance (NEMQA) and the National EMS Model Clinical Guidelines complement the NEMSIS program by providing evidence-derived pediatric quality measures for adoption in any EMS agency. As a measure of the degree to which EMSC permanence is being established in state EMS systems, the federal EMSC program has required demonstration of the presence of an EMSC advisory committee at the state level. These advisory bodies are well positioned to support EMS agencies in their pediatric readiness and provide a forum for the active engagement of pediatric care experts at a system level.

Destination Determination

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or jurisdictional protocol, which is typically predicated on field assessment and, in the case of trauma, mechanism of injury. The 2021 National Guidelines for the Field Triage of Injured Patients relies on injury patterns, physiologic criteria, mechanism of injury, and other special considerations (e.g., suspicion for child maltreatment). Based on these criteria, EMS providers determine the optimal trauma center destination in the setting of injury. In communities served by an organized trauma system that incorporates pediatric designation based on objectively verified hospital capabilities (i.e., pediatric readiness), seriously injured children may be triaged by protocol to the highest-level pediatric-capable trauma center reachable within a reasonable amount of time. Other communities have established state or regional emergency care systems that use pediatric readiness criteria to recognize EDs appropriate for pediatric patients. A high level of pediatric readiness in both medical and trauma centers is linked to decreased mortality in critically ill and injured children. The mantra is to deliver the child to the *right care in the right time,* even if it requires bypassing closer hospitals.

Regionalization in the context of EMS is defined as a geographically organized system of services that ensures access to care at a level appropriate to patient needs while maintaining efficient use of available resources. This system concept is especially germane in the care of children, given the relative scarcity of facilities and their associated providers that are capable of managing the full range and scope of pediatric conditions (Fig. 77.2). Regionalized systems of care coordinated with emergency medical dispatch, field triage, and EMS transport have demonstrated efficacy in improving outcomes for pediatric medical and trauma patients. The existence of statewide or regional standardized systems that formally recognize hospitals able to stabilize and/or manage pediatric medical and traumatic emergencies is a federal EMSC performance measure against which operational capacity to provide optimal pediatric emergency care in the United States is currently being evaluated. Over 15 states now offer pediatric medical facility recognition programs. For the majority, hospital participation in these programs is voluntary. EMSC state partnership programs in the respective jurisdiction can provide further guidance on the application process and requirements for participation. Similarly, several state trauma systems now integrate elements of pediatric readiness into trauma center designation. Moreover, beginning in 2023, the American College of Surgeons (ACS) Committee on Trauma requires all ACS-verified trauma centers to adhere to specific pediatric readiness criteria.

In communities that do not have a hospital with the equipment and personnel resources to provide definitive pediatric inpatient care, **interfacility transport** of a child to a regional pediatric center should be undertaken after initial stabilization (see Chapter 77.1). In the end, all emergency care facilities must stand ready to provide care to ill and injured children of all ages.

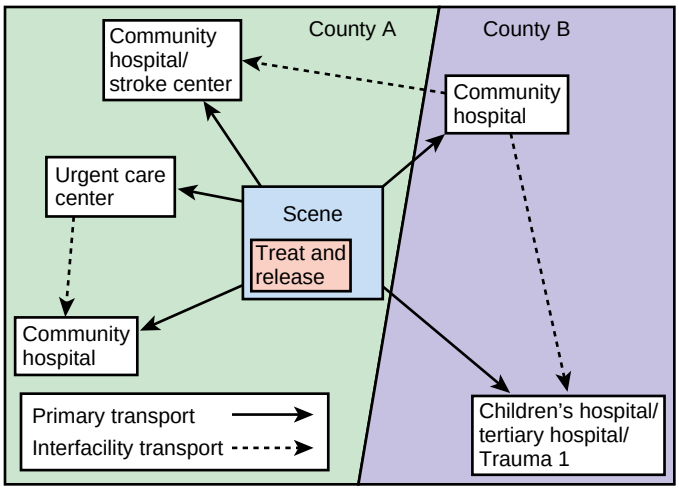

Fig. 77.2 Transport options within a coordinated, regionalized emergency medical services system model. The objective is to ensure access to definitive care at a level appropriate to meet patient needs. *Solid arrows,* Primary transport; *dashed arrows,* interfacility transport. *(Adapted from Institute of Medicine, Committee on the Future of Emergency Care in the U.S. Health System.* Hospital-Based Emergency Care: At the Breaking Point. *Washington, DC: National Academies Press; 2006.)*

THE EMERGENCY DEPARTMENT

The ability of EDs to respond to critically ill and injured children depends on all aspects of pediatric readiness: administrative oversight, staff competencies, pediatric-specific policies and procedures, patient and medication safety, quality improvement, and equipment and supplies. Training, awareness, and experience of the staff as well as access to support services, pediatricians, and medical and surgical subspecialists also play a key role. The majority of children who require emergency care are evaluated in community EDs. Emergency care staff, including physicians, nurses, and advanced practice providers, may have variable degrees of pediatric training and experience. Although children account for approximately 25% of all ED visits, only a fraction of these encounters represents true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in lower-volume EDs often have limited opportunity to reinforce and sustain their knowledge and skills in the assessment and stabilization of severely ill or injured children. Indeed, nearly 70% of U.S. EDs provide care for <15 children per day. General pediatricians from the community or pediatric hospitalists may be consulted when a seriously ill or injured child presents to the ED, and they should have a structured approach to the initial evaluation and treatment of an unstable child of any age, regardless of the underlying diagnosis. Telemedicine and e-health may serve as a mechanism to provide better connectivity between patients, primary care, EDs, and tertiary/quaternary institutions. *Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system function and rapid intervention to correct those abnormalities are key to successful resuscitation and stabilization of the pediatric patient.*

The **National Pediatric Readiness Project (NPRP)** is a national quality improvement initiative started by the federal EMSC program, AAP, ACEP, and ENA to ensure high-quality emergency care for all children. The effort began in 2013 with a national assessment of pediatric readiness in U.S. EDs (as measured by compliance with published guidelines). Initial results demonstrated a high level of engagement in pediatric readiness but notable gaps in the ability of U.S. EDs to meet the needs of children: 48% of EDs had a physician PECC; 59% of EDs had a nurse PECC; 46% of EDs included pediatric-specific needs in quality improvement efforts; and 47% had a disaster plan that addressed the needs of children. Higher readiness levels are seen in larger-volume EDs and in EDs with physician and nurse PECCs and/or quality improvement plans that included children. Since then, numerous efforts, including national quality improvement collaboratives, have targeted key areas of readiness. A second NPRP assessment was completed in 2021, and national efforts continue to promote widespread adoption of pediatric readiness within U.S. EDs. In 2019, the National Prehospital Pediatric Readiness Project launched with similar efforts focused on ensuring high-quality prehospital emergency care for children. Table 77.2 lists essential policies, procedures, and protocols specifically addressing the needs of children in the ED. ED staff and other stakeholders can access pediatric readiness checklists and toolkits and identify opportunities to participate in pediatric readiness efforts on the website of the EMSC Innovation and Improvement Center, https://emscimprovement.center/. Given the link between pediatric readiness and increased survival for critically ill and injured children, baseline readiness standards must be met by all EDs and EMS agencies to ensure that children receive the best emergency care possible.

The way the family supports the child during a crisis, and consequently how the family is supported by the local EMS agency and in the ED when caring for the child, are critical to patient recovery,

Table 77.2 Guidelines for Pediatric-Specific Policies, Procedures, and Protocols for the Emergency Department (ED)

- Illness and injury triage
- Pediatric patient assessment and reassessment
- Documentation of pediatric vital signs, abnormal vital signs, and actions to be taken for abnormal vital signs
- Identification and notification of the responsible provider of abnormal vital signs (age or weight based)
- Immunization assessment and management of the underimmunized patient
- Sedation and analgesia for procedures, including medical imaging
- Consent (including situations in which a parent is not immediately available)
- Social and mental health issues
- Physical or chemical restraint of patients
- Child maltreatment (physical and sexual abuse, sexual assault, and neglect) mandated reporting criteria, requirements, and processes
- Death of the child in the ED
- Do-not-resuscitate orders
- Lack of a medical home
- Children with special healthcare needs
- Family-centered care, including:
  1. Involving families in patient care decision-making and in medication safety processes
  2. Family and guardian presence during all aspects of emergency care, including resuscitation
  3. Education of the patient, family, and regular caregivers
  4. Discharge planning and instruction
  5. Bereavement counseling
- Communication with patient's medical home or primary healthcare provider
- Telehealth and telecommunications
- Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with ALARA (as low as reasonably achievable) principles
- All-hazard disaster preparedness plan that addresses the following pediatric issues:
  1. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters
  2. Pediatric surge capacity for both injured and noninjured children
  3. Decontamination, isolation, and quarantine of families and children of all ages
  4. Minimization of parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families
  5. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster
  6. Disaster drills, which should include a pediatric mass casualty incident at least every 2 years
  7. Care of children with special healthcare needs
  8. A plan that includes evacuation of pediatric units and pediatric critical care and specialty units
- Evidence-based clinical pathways, order sets, or decision support tools
- Written interfacility transfer procedure and agreements that include the following components:
  1. Defined process for initiation of transfer, including the roles and responsibilities of the referring facility and referral center (including responsibilities for requesting transfer, method of transport, and communication)
  2. Transport plan to deliver children safely (including the use of child passenger restraint devices) and in a timely manner to the appropriate facility capable of providing definitive care
  3. Process for selecting the appropriate care facility for pediatric specialty services not available at the hospital
  4. Process for selecting the appropriately staffed transport service to match the patient's acuity level (i.e., level of care required and equipment needed for transport) and appropriate for children with special healthcare needs
  5. Process for patient transfer (including obtaining informed consent)
  6. Plan for transfer of critical patient information (i.e., medical record, imaging, copy of signed transport consent), as well as personal belongings and provision of directions and referral institution information to family
  7. Process for return transfer of the pediatric patient to the referring facility as appropriate
  8. Integration with telehealth/telecommunications processes and mobile integrated health/community paramedicine as appropriate

Adapted from Remick K, Gausche-Hill M, Joseph MM, Brown K, Snow SK, Wright JL; American Academy of Pediatrics Committee on Pediatric Emergency Medicine and Section on Surgery; American College of Emergency Physicians Pediatric Emergency Medicine Committee; Emergency Nurses Association Pediatric Committee. Pediatric readiness in the emergency department. *Pediatrics*. 2018;142(5):e20182459.

family satisfaction, and mitigation of behavioral and mental health impact. Commitment to patient- and family-centered care in the ED ensures that the patient and family experience guides the practice of culturally sensitive care and promotes patient dignity, comfort, and autonomy. In both the ED and EMS settings, particular issues, such as family presence, deserve specific attention. Surveys of parents have indicated that most want to be with their child during invasive procedures and even during resuscitation. Allowing their presence has been shown to reduce parental and patient anxiety and does not interfere with procedure performance. Patient- and family-centered care practices are also strongly associated with improved care quality and patient safety.

Disaster Preparedness

Throughout a public health emergency or catastrophic event, natural or human-made, several unique factors place children at disproportionate, increased risk. Combined with other factors, global climate change has promoted increased frequency and severity of weather-related disasters. During an average workday, an estimated 69 million U.S. children are separated from their families in schools and childcare centers, where mass casualty events can easily occur. This separation adds the further challenge of safe and timely reunification of children with family during or after an incident. Furthermore, in the event of a biologic, chemical, or radio-nuclear attack, unique anatomic, developmental, and physiologic features make children especially vulnerable to absorption, ingestion, or inhalation of toxic agents and related morbidity and mortality (see Chapter 763).

Pediatric planning considerations include training of first responders and other care providers, patient triage, decontamination, surge capacity and capabilities, medical countermeasures (medications, vaccines, equipment, supplies), evacuation, transport, sheltering, and family reunification. The community plays a significant role in preparedness and is inclusive of schools, school nurses, faith-based organizations, and other community entities.

All levels of the healthcare system must be prepared for disaster-driven surges in patient care needs. Surge capacity refers to the ability to evaluate and care for a markedly increased volume of patients—one that challenges or exceeds normal variations in operating capacity. Surge capability refers to the ability to provide specialized medical services for unique patient populations, such as children, that may not be routinely available under normal operating conditions. Surges may require alternative care processes and additional resources to meet the demand for services. Critical surges may require consideration of contingency plans that typically require activation of alternative care standards. Surges that exceed the additional capacity of contingency plans may require implementation of crisis care standards as a means to increase capacity beyond levels that exceed normal daily operations. During a public health emergency, surge requirements may extend beyond direct patient care to include tasks such as laboratory screening or epidemiologic investigations. All levels of the healthcare system may be challenged to increase their capabilities, providing medical services for patient populations, such as children, that may not be routinely available. As an example, the community hospital that routinely transfers higher-acuity ill or injured children or children with medical

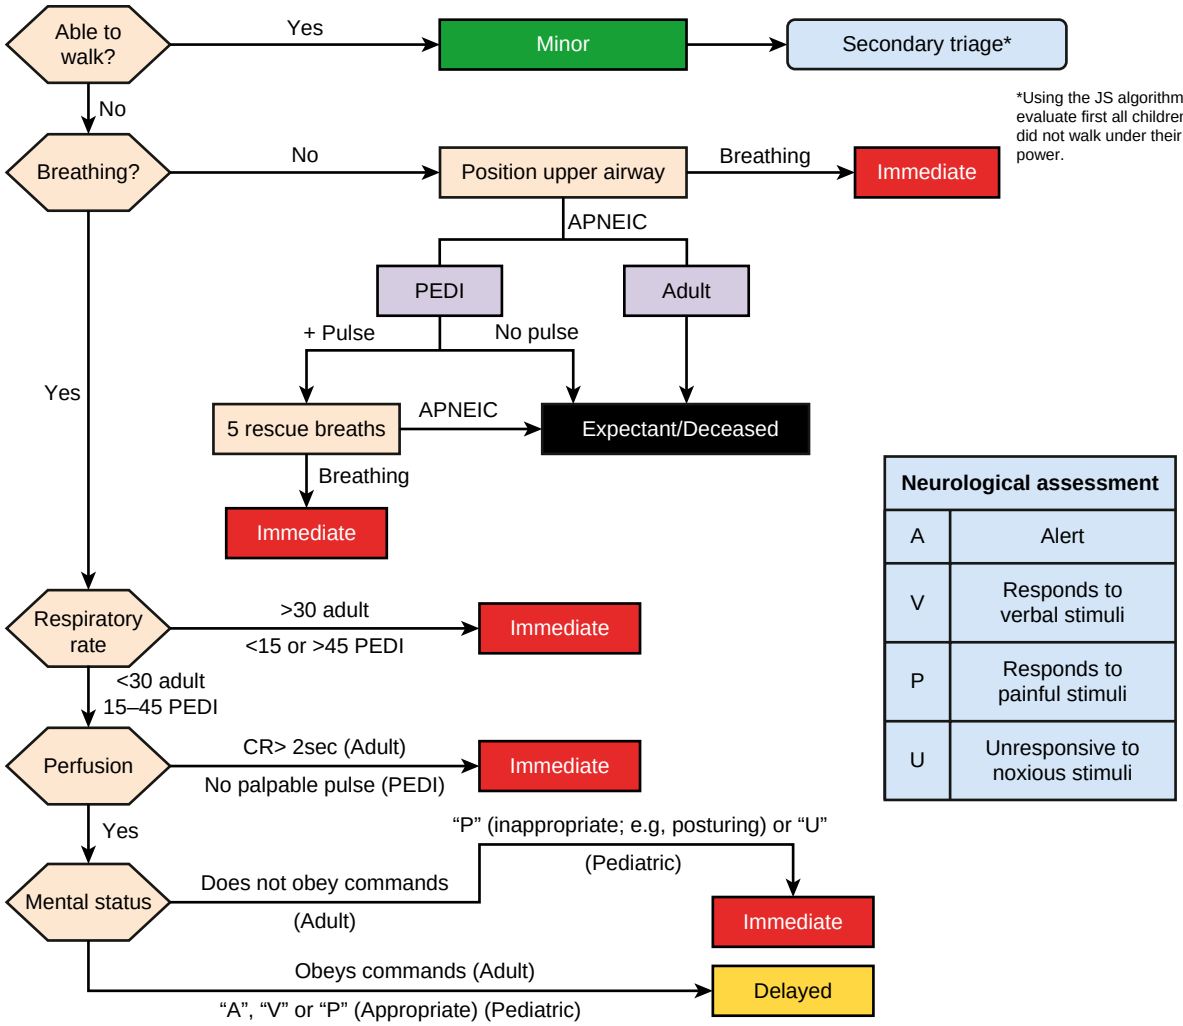

Fig. 77.3 Combined START/Jump START triage algorithm. (*Copyright 2002, Lou Romig, MD.*)

complexity to a pediatric tertiary center may be unable to do so during a disaster. Mechanisms for remote consultation and support of pediatric care, leveraging community pediatricians and tertiary pediatric subspecialists via telemedicine, should be considered.

Beyond acute medical treatment needs, pediatric planning must also consider the typically broad mental and behavioral health impact disasters have on children and families. Mental and behavioral health concerns commonly represent the largest impact of disasters on children and adolescents. Pediatric plans must also be in place for locations where children congregate, such as schools and childcare; these plans must be aligned with local jurisdiction planning and communicated to families.

Community practice and healthcare system readiness and resiliency begin with *personal and family readiness planning* engaged by healthcare providers and support staff; these efforts should also include attention to provider wellness.

The AAP's Children and Disasters website* (https://www.aap.org/en/community/aap-councils/council-on-disaster-preparedness-and-recovery-codpr/) contains toolkits, checklists, and other resources pertinent to pediatric readiness within the community, schools, the medical home, and hospitals; educational materials are also available for families. Reliable information and excellent disaster readiness resources are also located on the websites of the EMSC Innovation and Improvement Center and U.S. Department of Health and Human Services (HHS) and Assistant Secretary for Preparedness and Response (ASPR) Eastern Great Lakes Pediatric Disaster Center of Excellence (https://emscimprovement.center), U.S. Centers for Disease Control and Prevention (https://emergency.cdc.gov), U.S. Department of Health and Human Services (https://www.phe.gov/preparedness/Pages/default.aspx), U.S. HHS ASPR Technical Resources, Assistance Center, and Information Exchange (TRACIE) (https://asprtracie.hhs.gov/), U.S. Federal Emergency Management Agency (https://www.fema.gov), HHS ASPR Western Regional Alliance for Pediatric Emergency Management (WRAPEM) (https://www.wrap-em.org/index.php/resources-edocman-public), and HHS HRS Pediatric Network (PPN) (https://pedspandemicnetwork.org/).

Triage in Disaster Pediatric Medical Care

Mass causality events (hurricanes, bombings, gas leaks, bus or plane crashes, earthquakes, mass shootings, fires, others) require *scene-based* assessment, assignment, and tagging (Figs. 77.3 and 77.4). Assessment must be rapid (~30 seconds) and includes breathing, circulation, and mental status. These parameters are incorporated in the **START** (simple triage and rapid treatment) triage tool for adolescent and adults and the **Jump START** assessment for 0- to 14-year-old children. The combined algorithm is noted in Figure 77.3. The "jump" in Jump START relates to one difference between pediatric and adult approaches wherein children are given a rescue breath if they remain apneic with a pulse after positioning the airway (see Fig. 77.3). Triage categories are color coded (see Fig. 77.4) at the site of the disaster based on risk. **Red** – immediate life-threatening injury; **Yellow** – potentially stable for a short period; **Green** – minor injury, walking wounded; **Black** – dead or not expected to survive.

77.1 Interfacility Transport of the Seriously Ill or Injured Pediatric Patient

*Corina Noje, Mary Beth Howard, and Bruce L. Klein**

Patients often seek treatment at facilities that lack sufficient expertise to treat their conditions, necessitating transfer to more appropriate specialty centers. This is especially pronounced in pediatrics. Emergency medical services (EMS) providers or parents usually take children to local emergency departments (EDs) first, where their conditions and physiologic stabilities are assessed. Although bringing a child directly to the local ED may be proper logistically, community-based local EDs can be less than ideal for pediatric emergencies. Children have been reported to account for about 20% of all ED visits, but not all EDs have the necessary supplies for pediatric emergencies. Also, general EDs are less likely to have pediatric expertise or policies in place for the care of children. Outcomes for critically ill children treated in pediatric intensive care units (PICUs) are better than for those treated in adult ICUs. When pediatric critical care is required, transport to a regional PICU is indicated. In addition, often the type of subspecialty care needed (e.g., pediatric orthopedics) is available only at the pediatric center.

Pediatric transport medicine consists of the interfacility transfer of infants, children, and adolescents from community facilities to pediatric centers that can provide the needed level of expertise. Transport is performed by professionals proficient in pediatric transport using age-equipped ground, rotorcraft, or fixed-wing ambulances. Pediatric transport medicine is a multidisciplinary field comprising pediatric critical care and pediatric emergency medicine (PEM) physicians (and, sometimes for newborn infants, neonatologists); nurses, respiratory therapists, and paramedics with advanced training for pediatric transport; and communications specialists. The goal is to deliver quality pediatric care to the region's children, while optimizing the use of regional resources. For the individual child, the aim is to stabilize and, when appropriate, begin treating as soon as possible—that is, at the local ED and during transport, well before arrival at the referral center.

Models for pediatric transport services vary depending on the needs and available resources in a geographic region, but all should have certain basic components: a network of community hospitals and regional pediatric centers; an established communications and dispatch system that easily facilitates transfer to the pediatric center; ground and/or air ambulances; medical and nursing leadership from pediatric critical care or PEM (or neonatology); experienced pediatric **medical control physicians (MCPs)**; a multidisciplinary team of pediatric transport professionals specially trained and equipped to provide the appropriate level of care required during transport; operational and clinical policies and procedures that guarantee safe, state-of-the-art, and timely pediatric critical care transport; and a database for quality and performance assessment.

COMMUNICATIONS AND DISPATCH CENTER

Communications are one of the most vital components of a regional transport system. Treating a critically ill or injured child is generally an uncommon event for most community physicians. Therefore they need to know *whom, how,* and *when* to call for assistance in the stabilization and transfer of a pediatric patient. The communications and dispatch center provides a single telephone number for such calls.

The communications and dispatch center coordinates communications among the outlying facility, receiving unit, MCP, transport team, and other consultants. This center may be part of a hospital unit (e.g., ED, PICU), self-contained in a single institution (e.g., emergency communications and information center), or based off-site as a freestanding center coordinating communications and dispatch for multiple transport programs.

Staffing varies depending on the type of center. On-duty nurses or physicians may receive calls at unit-based models with low volumes. In contrast, dedicated communications specialists usually staff self-contained or freestanding centers, which tend to be busier. The communications specialist has numerous responsibilities, including answering the referring physician's call promptly; documenting essential patient demographic information; arranging for immediate consultation with the MCP; dispatching the transport team to the referring facility expeditiously; updating the referring facility with any changes in the arrival time; and coordinating medical control and other necessary transport-related calls. The transport team must be able to contact the receiving and referring facilities immediately, when necessary. Furthermore, with advances in technology and wireless communication systems, **telemedicine**—either *interactive* (synchronous) or *store and forward* (asynchronous)—is being used during pediatric transport, and certain programs have incorporated it into their routine transport operations.

MEDICAL CONTROL PHYSICIAN

The MCP is involved in the clinical care and safe transport of the patient from the time of referral through arrival at the receiving hospital unit. The MCP's oversight increases once the transport team arrives at the referring facility. The MCP should have expertise in pediatric critical care or PEM (or sometimes neonatology). Besides having the knowledge required to stabilize a critically ill or injured child, the MCP must be familiar with the transport environment; the transport team members' resources and capabilities; the program's policies and procedures; and the region's geography, medical resources, and regulations regarding interhospital transport. The MCP must possess good interpersonal and communication skills and must be able to maintain

* Adapted initially from Dr. Lorry R. Frankel's chapter in the 18th edition of this book. We also want to thank Dr. Beth Edgerton, who co-authored a prior version of this chapter.

collegiality with the referring hospital's staff during a potentially difficult and stressful situation.

Once a transport call is received, the MCP must be immediately available to confer with the referring physician. Although the MCP may have other responsibilities, these transport responsibilities take priority in order to avoid undue delays when transferring a critically ill child. Often the MCP recommends further testing or therapeutic interventions that can be delivered by the referring hospital before the transport team arrives. The MCP may seek additional guidance from other specialists, as necessary. Because the child's condition may change rapidly, the MCP must remain ready to give additional advice. All conversations and recommendations regarding the care of the patient should be documented. Some centers record these conversations.

After discussion with the referring physician—and when warranted, with the transport staff—the MCP determines the best team composition and vehicle for transport. The MCP usually does not accompany the team but remains available to supervise care. With advances in video conferencing capabilities, there has been increased use of telemedicine in the pediatric transport medical direction process. For some acutely ill patients or those requiring visual diagnoses, telemedicine has been reported to improve disposition at the receiving hospital, potentially leading to improved clinical outcomes.

TRANSPORT TEAM

Transport team composition varies greatly among programs—and sometimes within an individual program. The team's composition is based on a variety of factors, including the child's age; the severity of the illness or injury; the distance to the referring facility; the transport vehicle used; the team members' advanced practice scope and abilities; the referrer's insistence that a physician be present; the program's historical professional makeup; and the region's staffing regulations. The pediatric transport workforce may include physicians, advanced practice providers, nurses, respiratory therapists, and paramedics who have expertise in pediatric critical care, PEM, or neonatology (in some cases), as well as advanced education and training in those cognitive and procedural areas important for pediatric critical care transport. Physician trainees—usually fellows and, less often, residents—may also participate in transport in some capacity. There is a lower incidence of transport-related morbidity for critically ill and injured children transported by pediatric specialty teams than for those transported by generalist teams. Nevertheless, in-transit critical events occur in ~10% of pediatric critical care transports.

Various scoring systems that can help guide team composition and/or mode of transport have been developed to aid in transport planning. A team member's training, experience, and skill in treating critically ill patients are more important considerations than that team member's professional degree. Team members must understand basic pediatric pathophysiology and collectively must be able to assess and monitor a critically ill or injured child; manage the airway and provide respiratory support; obtain vascular access; perform point-of-care testing; and administer fluids and medications (including infusions) typically used in pediatric critical care transport. They must be familiar with the physiologic alterations and practical difficulties of the transport environment and, importantly, must be comfortable working in an out-of-hospital setting. Physicians are less often deployed on transport teams in part because of the advanced training that other healthcare professionals on the transport team receive.

The transport team should have a designated team leader who, in addition to the team leader's many other responsibilities, interacts with the MCP during the transport. Once the team arrives at the referring facility, the team should reassess the child's condition, review all the pertinent diagnostic studies and therapies, and discuss the situation with the referring staff and parents. If the patient's condition has changed significantly, the team leader may need to contact the MCP for additional advice. Otherwise, the team leader should generally notify the MCP before starting to bring the child to the receiving facility. Any care delivered by the team during transport should be documented, and copies of all medical records—including laboratory data, radiographs, and scans—should accompany the child to the pediatric center. The receiving unit must be updated before arrival so it can finalize preparations for the patient.

GROUND VS AIR AMBULANCE

Transport vehicle options include ground, rotorcraft, and fixed-wing ambulances. Vehicle selection depends on the child's emergency needs, transport team's capabilities, any out-of-ordinary staffing or equipment requirements (e.g., extracorporeal membrane oxygenation, inhaled nitric oxide, heliox), referring facility's abilities, distance, terrain, traffic patterns, ground or air ambulance availability, helicopter landing pad or airport access, weather conditions, and expense.

The transport vehicle must be equipped with electrical power, oxygen, and suction and must have sufficient space for the equipment and supplies that the team brings along—stretcher or isolette, monitor, ventilator, oxygen tank(s), medication pack(s), infusion pumps, and more. Compared with helicopters, ambulances typically are more spacious and able to carry more weight, so they can accommodate larger teams and more equipment. Another advantage of ground ambulance transport is the ability to stop en route if the patient's condition deteriorates; this may facilitate the performance of certain interventions or procedures, such as intubation.

An airplane may be able to fly to an area when distance (>150 miles), altitude, or weather precludes helicopter use. However, the use of an airplane necessitates several ambulance transfers, with their attendant delays and additional risks. There also are delays when the plane must fly from a remote base to the program's jurisdiction.

TRANSPORT PHYSIOLOGY

When possible, the transport team tries to provide the same care during transport as the patient would receive in the specialty center. This can be difficult, however, because of limitations in personnel, equipment, and space, as well as other environmental challenges.

The team and child are subjected to variable intensities of background noise and vibration while traveling in the vehicle cabin. **Noise** can impair the team's ability to auscultate breath sounds and heart sounds or accurately measure the blood pressure manually—another reason for monitoring vital signs mechanically and relying on other assessment modalities, such as the level of mentation, skin color, and capillary refill. For rotor transports in particular, the crew and patient should wear helmets or headphones (or another wearable noise attenuator) to mitigate noise. **Motion** and **vibration** are additional transport hazards and can lead to increased metabolic rate, shortness of breath, and fatigue in the patient, as well as motion sickness in the patient and staff.

On fixed-wing or certain rotary-wing transports, the patient may suffer adverse physiologic effects from **altitude**. With increasing altitude, the barometric (atmospheric) pressure decreases, and gas expands to occupy a greater volume due to the decreased pressure exerted on it. Therefore, as barometric pressure drops with altitude, the partial pressures of inspired oxygen (Pio_2) and, consequently, arterial oxygen (Pao_2) decrease, as does the arterial oxygen-hemoglobin saturation (Spo_2). For example, at 8,000 feet—an elevation at which unpressurized airplanes may fly, as well as the effective cabin altitude for many pressurized airplanes flying at 35,000-40,000 feet—the barometric pressure, Pio_2, Pao_2, and Spo_2 fall to 565 mm Hg, 118 mm Hg, 61 mm Hg, and 93%, respectively. In comparison, the barometric pressure, Pio_2, Pao_2, and Spo_2 are 760 mm Hg, 159 mm Hg, 95 mm Hg, and 100% at sea level. Although healthy individuals usually tolerate these changes well, patients with respiratory insufficiency, pulmonary hypertension, significant blood loss, or shock may decompensate and should receive supplemental oxygen and/or have the cabin pressurized at sea level.

Gases expand up to 10% at the few thousand feet where helicopters typically fly, and approximately 30–40% at 8,000 feet. Gases within the body itself also expand as the altitude increases. The degree of gas expansion must be considered during transport via air of any patient with pneumocephalus, pneumothorax, bowel obstruction, or another condition involving entrapped gas. Before transport, a pneumothorax should generally be decompressed and a nasogastric tube inserted for ileus.

SAFETY

Safety is of paramount importance and mandates constant vigilance by everyone involved. Accident rates for pediatric air and ground transport have been estimated at approximately 1 in 1,000 transports. The team should routinely attend pilot briefs and perform safety inspections of the vehicles and equipment, aided by checklists. When in doubt, the MCP should solicit input from the staff about whether to transport via air or ground ambulance or to employ lights and sirens, decisions that cannot be taken lightly. The pilot's or driver's judgment as to the safety of proceeding during inclement weather or with a mechanical problem must not be overruled.

Organizations such as the Federal Aviation Administration (FAA) and the National Transportation Safety Board (NTSB) play a role in ensuring safe interfacility transport. The **Commission on Accreditation of Medical Transport Systems (CAMTS)** is an independent, peer-review organization established in 1990 in response to the number of air medical accidents in the 1980s. CAMTS, through voluntary participation, audits and accredits fixed-wing, rotary-wing, and ground interfacility medical transport services.

FAMILY-CENTERED CARE

Family-centered care represents a philosophy that respects the important role that family members play in a child's care. It recognizes family members and healthcare providers as partners in caring for the child. Family presence during transport is beneficial because it provides support to both children and parents in stressful situations and assists healthcare providers in delivering care to patients with complex and chronic medical problems.

As care is transitioned from the referring hospital, it is the transport team's responsibility to maintain culturally sensitive, family-centered care. The team meets with family members to explain the transport process, help obtain consent, and discuss anticipated management. When possible, the transport team should attempt to accommodate a family member's presence onboard. However, the family member and child may need to be separated when the child is critically ill and rapid transport is essential, or in case of space or weight limitations in the air or ground ambulance. In these situations, it is important that family members have a clear understanding of how the child will be cared for during the separation.

REFERRING HOSPITAL RESPONSIBILITIES

Transfer of a child to another facility requires written documentation by the referring physician of the need and reasons for transfer, including a statement that the risks and benefits, as well as any alternatives, have been discussed with the parents. Informed consent should be obtained from the parent/legal guardian before transfer.

Federal law under the Emergency Medical Treatment and Active Labor Act (EMTALA), part of the Consolidated Omnibus Budget Reconciliation Act (COBRA), imposes specific requirements that a patient presenting to an ED be given a medical screening examination without regard for ability to pay. If on examination an emergency medical condition is found, the hospital is required to stabilize the patient or to transfer the patient to another facility if unable to stabilize the patient (or if requested by the patient in writing after being informed of the risks). The primary requirement is that the referring physician must certify that the medical risks of transfer are outweighed by its potential benefits. The receiving hospital must agree to accept the patient if it has the space and staff to provide the necessary level of care. The transferring hospital is responsible for arranging for the transfer and ensuring that it is performed by qualified medical personnel with appropriate equipment. The transferring hospital must also send copies of the patient's medical records and test results, even those that become available after the transfer is complete.

Some referring hospitals have entered into transfer agreements with specialty centers to facilitate the smooth and safe transfer of pediatric patients. Having prepared forms for all the purposes noted earlier also aids in the transfer process.

Each hospital needs to review its facility's guidelines; if established guidelines do not exist, the Emergency Medical Services for Children National Resource Center in partnership with the Emergency Nurses Association and the Society of Trauma Nurses has developed the "Interfacility Transfer Tool Kit for the Pediatric Patient" (available at: https://emscimprovement.center/education-and-resources/toolkits/interfacility-transfer-toolbox/). This tool kit includes the essentials for comprehensively and safely transferring the pediatric patient to the most appropriate level of care in a timely manner.

EDUCATIONAL OUTREACH

Besides safe and rapid transport, regional pediatric transport programs (and their specialty centers) have an obligation to provide educational opportunities to community healthcare providers so that these providers can acquire the necessary skills to evaluate and stabilize a critically ill or injured child until the transport team arrives. These learning activities may include transport case reviews; lectures on pediatric acute care topics; resuscitation and related programs such as the Pediatric Advanced Life Support (PALS) course, Advanced Pediatric Life Support (APLS) course, Pediatric Education for Prehospital Professionals (PEPP) course, and S.T.A.B.L.E. (sugar and safe care, temperature, airway, blood pressure, lab work, emotional support) program; and rotations through the specialty center's pediatric ED and PICU. These activities also help cement relationships with the referring facility's staff.

77.2 Risk Adjustment and Outcomes Measurement of Pediatric Emergency Medical Services

Anna K. Weiss

Health services research has demonstrated wide variation in implementation of equitable, evidence-based care for pediatric patients in U.S. hospitals, a reality that can negatively affect the health of children and youth (see Chapter 2). The complexities of delivering high-quality, evidence-based care are magnified in the emergency department (ED), where patients are often in crisis, patient-physician interactions are brief, and the variety and volume of complaints and diagnoses are immense. In the context of this frenetic environment, practitioners can only assess their local system relative to recognized benchmarks and standards of care if there are clear guidelines for measurement of performance. However, no two places of practice are the same, and a single ED may differ significantly from a theoretical "best practice" standard. To reflect this, practitioners seeking to make local improvements must assess not only raw outcomes (e.g., throughput times, mortality, patient satisfaction) but must also adjust for severity of illness, case mix, and risk of morbidity.

OUTCOME MEASURES IN EMERGENCY MEDICAL SERVICES FOR CHILDREN

To ensure delivery of equitable, evidence-based care in the ED, pediatric emergency medical systems must support the use of national standards for emergency care performance measurement. The *Donabedian structure-process-outcome model* provides a framework for most contemporary quality measurement and improvement activities. In this framework, **structural** elements provide indirect quality-of-care measures related to a physical setting and resources (e.g., available staff, equipment, and supplies). **Process** indicators provide a measure of the quality of care and services by evaluating the method or process by which care is delivered, including both technical and interpersonal components. **Outcome** elements describe valued results related to lengthening life, relieving pain, reducing disabilities, and satisfying the consumer.

A true *outcome-based* approach to **performance improvement** describes observable measures such as mortality, risk of organ system failure, and disability. An alternative approach is a *resource-based* outcome measure with a definition that is relative to the level of care required. Children who are more ill generally require more resources; therefore resource use across groups of patients reflects relative **severity of illness** within the groups, provided clinicians have a similar approach to practice. Examples of resource-based outcomes include need for hospital admission (ED disposition), ED length of stay, costs, and diagnostic and therapeutic interventions performed in the ED. Although this approach provides a measurement of clinical activity, when used in a vacuum it does not indicate whether the patient receiving the therapeutic interventions or resources actually needed them (i.e., data may also reflect physician behavior and/or [lack of] experience). Therefore some other assessment is needed that incorporates information on *how sick* the patient is or their specific diagnosis.

Table 77.3 provides a list of performance measures for pediatric ED care developed by the **Emergency Medical Services for Children Innovation and Improvement Center** supported by the Health Resources and Services Administration of the U.S. Department of Health and Human Services.

RISK ADJUSTMENT

The purpose of measuring outcomes in the ED is to evaluate **performance**—offering EDs and other components of the healthcare system the opportunity to make meaningful improvements over time using benchmarks within and between units. When making comparisons over time, one must ensure that patient-related attributes (e.g., age, preexisting conditions, severity of illness) have not changed; otherwise, one may be looking at changes in demography and case mix rather than at true change in performance. To ensure fair and meaningful measurement across time, **risk adjustment** is necessary to *level the playing field*. As an example, illness severity typifies the concept of *risk*—the higher the severity, the higher the risk of a given outcome. Without risk adjustment, EDs with sicker patients may appear to have poorer outcomes.

Risk Adjustment Tools in the ED

Although other risk adjustment scoring systems—such as the PRISM score for pediatric critical care—use mortality and morbidity as primary outcomes, this approach is not appropriate for the ED setting. Across U.S. EDs, pediatric mortality is low, and a patient's presenting physiology may reflect interventions performed in the prehospital setting. Similarly, eventual morbidity and/or mortality may reflect what happens in the PICU or during hospital ward care.

Table 77.3 Stakeholder-Endorsed Performance Measures for Pediatric Emergency Care

- Measuring weight in kilograms for patients <18 years of age
- Presence of a method to identify age-based abnormal pediatric vital signs
- Pediatric equipment in the ED
- Presence of on-site pediatric coordinator(s)
- Parent/caregiver understanding of discharge instructions
- Door to provider time
- Total length of stay
- Reducing pain in children with acute fractures
- Children with minor head trauma receiving a head CT scan
- Protocol for suspected child abuse in place
- Systemic corticosteroids in asthma patients with acute exacerbation
- Evidence-based guideline for bronchiolitis
- Reducing antibiotic use in children with viral illnesses
- Return visits within 48 hours resulting in admission
- Medication error rates

ACEP, American College of Emergency Physicians; AAP, American Academy of Pediatrics; ENA, Emergency Nurses' Association; GCS, Glasgow Coma Score; CT, computed tomography.

In the ED, the choice of a risk adjustment tool depends on ED-specific outcomes of interest. Two general risk adjustment tools have been developed specifically for PEM, the second-generation Pediatric Risk of Admission (PRISA II) score and the Revised Pediatric Emergency Assessment Tool (RePEAT).

Pediatric Risk of Admission II

PRISA II uses components of acute and chronic medical history as well as acute physiology to determine the probability of hospitalization. The outcome measure of interest is *mandatory hospital admission* (admissions using therapies that are best delivered in the inpatient setting). Table 77.4 lists the patient-related attributes contributing to the PRISA II risk adjustment score. Analytic models, including the PRISA II score, have good **calibration** (how well the probabilities predicted from the model correlated with the observed outcomes in the population) and **discrimination** (the ability to categorize subjects correctly into the categories of interest) with respect to mandatory hospital admission. Construct validity of the PRISA II score has been demonstrated by measuring rates of the secondary outcomes: mandatory admission, PICU admission, and mortality. As the probability of hospital admission rises, the proportion of patients with these increasing care requirements also increases. This finding supports the use of the PRISA II score as a measure of illness severity. PRISA II has also been used to demonstrate racial/ethnic differences in severity-adjusted hospitalization rates, as well as variation in hospitalization rates between teaching and nonteaching hospitals.

Revised Pediatric Emergency Assessment Tool

RePEAT uses a limited set of data collected at the time of ED triage to model severity of illness as reflected by the level of care provided in the ED—for example, routine assessment (clinical examination only ± nonprescription medicine) vs specific ED care (ED diagnostics and/or therapeutics) vs hospital admission. In this model, it is assumed that patients needing a higher level of care have a higher severity of illness. Table 77.5 lists the patient-related attributes contributing to

Table 77.4 Elements of the PRISA II Score

- Age
- Injury severity
- Temperature
- Referral status (e.g., self-referral vs referral from physician's office or from another ED)
- Presence of:
  - Abdominal pain in an adolescent
  - Immunodeficiency
  - Indwelling medical device
  - Controller asthma medication
  - Decreased mental status
  - Low systolic blood pressure (<70 neonates and infants; <83 children; <100 adolescents)
  - High diastolic blood pressure (>59 neonates and infants; >70 children; >90 adolescents)
  - Low serum bicarbonate value (<20 mEq/L)
  - High potassium value (>4.9 mEq/L)
  - High blood urea nitrogen value (>80 mg/dL)
  - High white blood cell count (>20,000/mm^3)
  - Oxygen therapy other than during inhaled bronchodilator treatments
  - Low bicarbonate and high potassium values

Table 77.5 Elements of the RePEAT Score

- Age
- Chief complaint
- Triage category
- Current use of prescription medications
- Arrival via EMS (ground/air)
- Heart rate (relative to age-based norms)
- Respiratory rate (relative to age-based norms)
- Temperature

the RePEAT risk adjustment score. Analytic models such as RePEAT have good calibration and discrimination with respect to predicting ED care and hospital admission. Furthermore, analytic models that compare costs and length of stay between EDs are improved by adjusting for severity of illness using the RePEAT score. RePEAT is a reasonable objective marker of severity of illness that could be used in the administrative process comparing outcomes between EDs. With implementation of scoring systems such as PRISA II and RePEAT, U.S. EDs can benchmark the care that they provide to children and make meaningful improvements to ensure that this care is equitable and evidence-based.

77.3 Principles Applicable to the Developing World

David M. Walker and Victorio R. Tolentino Jr.

The maturity of pediatric emergency medicine (PEM) in any given area depends on the healthcare priorities and resources of that geographic or physical setting. The places in which emergency care takes place range from the community (especially for those with no access to organized medical care) to state-of-the-art pediatric emergency departments (EDs), typically in larger population centers. The scope ranges from the care of the individual patient to the management of populations of children involved in large-scale disasters. Barriers to quality care vary in each situation and in each part of the world, with the implication for the PEM practitioner that the care provided must be relevant to the local context of healthcare.

CONTINUUM-OF-CARE MODEL

This Emergency Medical Services for Children (EMSC) framework can also be applied to discussion of emergency care for children on a global level (see Chapter 77). Although medical infrastructure in some parts of the developing world may not be consistent or well organized, or has been weakened by civil strife, natural disasters, or economic loss, the EMSC framework can still apply generally to individual healthcare systems.

Prevention

Infectious Diseases

International child health has focused mainly on reducing the incidence of preventable childhood illnesses, primarily through immunization initiatives. Enormous advances have been realized in measles, neonatal tetanus, and polio; wild-type smallpox was eradicated in 1978. Although there are advocates for providing primary care interventions (e.g., vaccinations) in the ED, the role of the PEM practitioner in this area of prevention has been limited.

Injuries

Injuries are a leading cause of childhood morbidity and mortality. Unintentional injuries constitute 90% of injury mortality to children 5-19 years old and are the cause of 9% of the world's mortality (see Chapter 14). Intentional injuries, which remain underrecognized and underreported, make a smaller but significant contribution. Unintentional injuries cause more than 2,000 childhood deaths daily, or 950,000 annually worldwide. The burden of these deaths is borne disproportionately by children in middle- and lower-income countries, where >95% of all injury-related deaths occur. For each of these deaths, many more children are permanently disabled, and an even larger number are treated and released without permanent sequelae.

Traffic-related injuries, burns, and drowning are the main causes of injury-related mortality in children. The World Health Organization (WHO) and United Nations Children's Fund (UNICEF) have outlined several proven injury prevention strategies of which child health practitioners in the global community must be aware. Although these strategies have proved effective, the data are based on U.S. research and may not be generalizable to other countries.

Out-of-Hospital Care

Out-of-hospital care comprises access to emergency services, prehospital care, and interfacility transport of patients. Morbidity and mortality arise from delayed or limited access to emergency care, lack of prehospital care, transport without proper monitoring or trained personnel, or delayed transport to a higher level of care. Safe transport of seriously ill children is a neglected global health issue. An emergency response system must address the following links in the patient's care: a communication system with prompt activation of emergency medical services (EMS), the correct assessment and initial treatment of the patient, and the rapid transport to definitive care.

Access to Care

When a child is injured or ill, a parent or caretaker must be able to access help and activate EMS. In the majority of low- and middle-income countries, no universal emergency numbers have been established, requiring access by direct dialing to an ambulance, if such private services exist. In countries that have a universal emergency number, barriers remain related to absence of phones in some households, unclear addresses in rural areas, and insufficient reach of the emergency system.

In most low- and middle-income countries, the family must bring the ill or injured child to the health facility for stabilization and treatment. For this to occur, families must also overcome financial and geographic barriers, which can result in delayed presentation for care. This delay predictably increases the likelihood of associated complications and decreases the likelihood of full recovery and survival.

Prehospital Care

In regions with maturing EMS systems, there must be adequately trained personnel to stabilize and transport the child to a medical facility. The quality and level of training of such prehospital personnel vary among countries and within regions of the same country. In urban areas, there is a greater concentration of medical care and therefore a greater opportunity to have strong prehospital training. In most of Asia and sub-Saharan Africa, trained personnel are used primarily to transfer patients between health facilities, not from the initial site of illness or injury. In most high-income countries, medical services are dispatched to the patient.

Around the world, the effort to establish standardized approaches to prehospital care exists primarily in the form of courses to educate EMS and hospital personnel in the emergency management of patients. The WHO manuals *Prehospital Trauma Care Systems* and *Guidelines for Essential Trauma Care* focus on guidelines for prehospital and trauma care systems that are affordable and sustainable. The American Academy of Pediatrics (AAP) course "Pediatric Education for Prehospital Professionals" is a dynamic, modularized teaching tool designed to provide specific pediatric prehospital education that can be adapted to any EMS system. Table 77.6 describes additional prehospital resources.

Although most middle- and high-income countries have a system of trained EMS workers, lower-income countries lack this advanced tier of emergency care. In these countries, commercial drivers, volunteers, and willing bystanders provide the first line of care. Training a cadre of first responders can rely on existing networks of aid or can be drawn from specific populations, such as students, soldiers, or public servants. Training needs to emphasize basic lifesaving and limb-saving interventions, including how to stop bleeding and support breathing, access advanced care, and splint broken limbs. In Ghana, for example, taxi drivers participated in a first-aid course that relied heavily on demonstration and practice rather than knowledge transfer through didactic sessions. Taxi drivers were selected because they already provided much of the transport for injured patients. Two years after the course, external evaluators favorably rated the quality

International nonprofit organization dedicated to preventing unintentional childhood injury.
Website: www.safekids.org

of their care compared with untrained drivers. In rural areas, such first responders become vital in providing emergency interventions when more definitive care is distant. Thus a system of trained first responders forms the foundation of an effective prehospital system.

In the French model, a physician, often an emergency medicine specialist, will review calls for acuity and can dispatch a physician-led team by ambulance to go to the patient's home to assess, stabilize, and initiate treatment. This Franco-German system is used in other countries, including many in Latin America and Europe. There are no clear data on the cost-effectiveness and patient outcomes associated with delivery of patients to the nearest facility vs bringing hospital resources to the patient.

Methods of Transport

In many low-income countries, there is no reliable means of transport. Health centers may only have one vehicle for transport to a

higher-level facility. This vehicle may also be used for outreach primary care services, such as offering immunizations and collecting drugs and equipment from a central supply location, and sometimes, improperly for personal reasons by local officials or politicians. In large cities, taxis and auto rickshaws are frequently used because they are rapidly available, well disseminated, and able to pass around traffic jams. Where organized prehospital systems exist, different types of vehicles are adapted for emergency transportation. The WHO recommends identifying transport vehicles in advance, choosing vehicles that can be repaired and maintained locally, and equipping the vehicles according to recognized standards. The provision of available and appropriately staffed and equipped transport vehicles is crucial to the realization of recommended emergency care plans.

Hospital-Based Care

Once a child has reached a medical facility for the care of an injury or illness, adequate emergency services should be available. In many countries the ED serves only as a triage area where patients are distinguished by their likely disease process and directed for admission to the corresponding unit within the hospital. Strengthening emergency services includes seeing the ED as a unit where definitive treatment can be provided to the ill and injured child. Critically ill children must receive not only prompt care but also correct care. Such expedience and accuracy are ensured by implementation of an effective triage system, moving the sickest patients to immediate care and standardizing the initial care of emergency conditions.

Triage

Too often, children presenting to EDs are treated on a first-come first-served basis in an approach that creates long waiting times for critically ill children, a contributor to unnecessary mortality. Medical facilities should adopt an efficient and effective triage system to respond rapidly to the needs of patients and to assign the appropriate amount of resources. The WHO has developed a course entitled **Emergency Triage Assessment and Treatment (ETAT)**. This course teaches emergency, priority, or nonurgent signs and how to provide emergency treatment for life-threatening conditions. ETAT emphasizes the evaluation of a patient's ABCD status to identify emergency situations—the patency of the airway (A), the quality of breathing (B), the quality of circulation and presence of coma or convulsions (C), and the presence of severe dehydration (D).

One of the benefits of the ETAT guidelines is that they can be adapted to centers with limited resources and are applicable to areas with high morbidity and mortality from meningitis, dehydration, malaria, respiratory illness, and malnutrition. Another benefit is that the care algorithms are based on limited diagnostic studies, that is, hemoglobin measurement, blood smear for malaria, and bedside blood glucose testing. Widely accepted triage assessment guidelines are teachable to emergency care staff, and their adoption can provide better organization within a healthcare center. At the Queen Elizabeth Central Hospital in Blantyre, Malawi, for example, the institution of triage and rapid treatment in its emergency care center led to a 50% decrease in the mortality of children within 24 hours of presentation to the hospital, with a further 50% decrease as implementation and practice of triaging patients have continued.

Beyond triage, education on overall emergency center organization is a low-resource intervention that can reduce some of the obstacles to quality care delivery. Additionally, the arrangement of short-stay areas (hydration and infusion rooms) within or near the ED can lessen the burden on inpatient units.

Pediatric-Specific Emergency Centers

Anecdotally, most countries have developed at least one pediatric-capable center, usually as part of an academic medical center. The emergency services in these centers are variable, but certainly can be a starting point from which to build overall improvement in pediatric emergency care.

Practitioners

Throughout the world, nurses, paramedics, nonphysician clinicians, and nonspecialist physicians deliver most of the care to acutely ill or injured children. The majority of sick children attend local clinics or district or central hospitals, where financial and human resources are not always matched to the potential acuity of presenting patient complaints. Nominal supervision is provided to staff attending these patients. Pediatric EDs located in tertiary hospitals are often staffed by training physicians with little or no supervision from faculty, who themselves may have limited exposure to or training in pediatric emergencies. General hospitals lack dedicated pediatric staff; guidelines as to which patients should be moved to a higher level of care are often not standardized and depend on local influences and/or cultural beliefs about health and illness.

Clinical Guidelines

The **Integrated Management of Childhood Illnesses (IMCI)** guidelines were developed by the WHO and UNICEF to provide assistance in the initial triage and management of the presenting signs and symptoms of the major killers of children <5 years old in first-level health facilities (e.g., clinics, health centers, outpatient departments of hospitals). The flow charts within each chapter of the IMCI manuals allow easy accessibility to materials that can enhance education and outreach to less experienced health workers.

Evaluations in various countries of the implementation of IMCI guidelines have shown improvements in health worker performance and quality of care, as well as decreases in delay in treatment and mortality of the under-5 population. These guidelines also dramatically reduce the cost of healthcare. The WHO website provides all the necessary implementation tools, including course manuals and evaluation tools.

The International Federation of Emergency Medicine developed Standards of Care for Children in Emergency Departments to improve emergency care globally. These standards are not just aimed at dedicated EDs, but at any setting where emergency care takes place, regardless of the providers or the resources available. At the same time, however, the existence of the standards allows sites to advocate for improved resources dedicated to expertise in the various aspects of providing quality emergency care for children. The standards address design of care spaces, child- and family-centered care, assessment of ill and injured children, staff training and competencies, quality and safety, and disaster response.

Trauma

Morbidity and mortality from trauma are among the most prevalent problems for children worldwide. Trauma care presents the challenge of sequential, often simple, interventions that must be performed in a timely manner to limit the severity of the outcome. However, with lack of specific training, signs and symptoms of pediatric trauma may go unrecognized or may be underappreciated. Trauma courses such as Advanced Trauma Life Support (ATLS) are educational tools that can be disseminated to improve the quality of care at emergency centers worldwide. For low-resource settings, the WHO has developed the Integrated Management for Emergency and Essential Surgical Care toolkit, which provides clear directions and reasoning for the initial care of injured patients. Not expressly addressed in the ATLS course is specific concern about child abuse as the cause of trauma. This is an area of pediatric care that many countries do not yet address comprehensively in their medical training, their law enforcement, or their judicial systems. The epidemiologic need for reliable trauma registries is great, as is the need to identify personnel with trauma management skill sets and dedicated trauma centers to serve as higher-level referral sites.

Equipment

Pediatric emergency equipment guidelines are available for a variety of settings where acutely ill and injured children would present. Although these equipment guidelines may represent minimum supplies to treat

the widest variety of pediatric emergencies, the roles of substitution and improvisation often provide for the equivalent function of recommended supplies.

Inpatient Services

After the initial stabilization, children requiring ongoing care are admitted to the hospital. The quality of inpatient services varies greatly depending on institutional and provider experience, comfort with pediatric conditions, and the resources available to treat them. The WHO has produced the *Pocket Book of Hospital Care for Children,* which is based on IMCI guidelines and focuses on inpatient management of high-morbidity/high-mortality illnesses common in developing countries.

Mental Health Emergencies

The recognition of mental health conditions among the pediatric population is continuing to evolve. It is estimated that about 15% of children globally suffer from anxiety, depression, or other mental health challenges. The prevalence of mental health problems is likely higher, as much of the existing data comes from Europe and North America, whereas a majority of children live in middle- and lower-income regions of the world.

Mental health capacity varies by country and is reflective of cultural beliefs about mental health and the priority and funding that local governments have allocated to address these concerns. It is widely accepted that the current global mental health infrastructure fails to meet the existing demands of the world's population. These concerns are amplified in the developing world and disproportionately affect children whose lives are often touched by emotional and social trauma (e.g., poverty, natural disasters, armed conflict).

Increasingly, children are presenting to emergency settings in crisis. In many developing countries, mental health services are concentrated in urban settings and lacking in rural areas. Where there is no shortage of medical personnel, expertise in child psychiatry corresponds with the local development of this specialty. In areas with no formal mental health system, care is provided by an informal network of family members, faith healers, or community leaders who do not have formal medical training. It is essential that children presenting for mental health evaluation receive a comprehensive examination, as certain psychiatric presentations can be rooted in infectious diseases conditions or inadequate nutrition, which are prevalent in some developing world contexts.

The WHO has provided examples of best practice in the acute treatment of mental health conditions in *Hospital-Based Mental Health Services: Promoting Person-Centered and Rights-Based Approaches*. This document is available as a section of the *Guidance and Technical Packages on Community Mental Health Services* available on the WHO website. Although the publication does not include examples of pediatric-specific care, the document is meant to be tailored to the local context and can be adapted to the needs of children.

Telemedicine

Telemedicine technology is one way to overcome provider shortages or geographic challenges that can affect the care of acutely ill and injured children. Patients and families can potentially access basic emergency care through video-based platforms. The responding provider can use established triage techniques to help determine the severity of illness and the need for consultation at a healthcare center; they can also recommend basic first aid as needed.

Access to real-time lectures, case discussions, and conferences, led by experts in PEM, can increase the capacity of those in limited-resource settings to provide care for pediatric emergency patients. These educational offerings can also provide a forum for a bilateral exchange of ideas and perspectives. Expert consultations via real-time telemedicine programs or a store-and-forward process, in which the request for consultation is recorded and sent to an expert who can reply typically over email, can be used. Additionally, within a given region, telemedicine can link the referring hospital to the receiving hospital in order to collaborate on decisions about management and the need for transfer.

The success of telemedicine collaborations depends on a variety of factors, including availability of easy-to-use technology and reliable internet access.

HUMANITARIAN DISASTERS

Children are a vulnerable population who experience disproportionate suffering during humanitarian emergencies, either natural (earthquakes, tsunamis, hurricanes, floods, droughts) or manmade (armed conflicts, terrorist attacks). The under-5 population is especially susceptible to infectious diseases, malnutrition, and trauma after disasters.

The WHO *Manual for the Health Care of Children in Humanitarian Emergencies* is based on IMCI guidelines and addresses the emergency care of children in disaster situations where hospital facilities and resources are not immediately available. It goes beyond the IMCI guidelines by discussing initial assessment and management of trauma, burns, poisonings, neonatal illness, and psychosocial problems, which are considered high priority in acute care settings.

Exchange and Dissemination of Information

The WHO established the internet-based **HINARI** Access to Research for Health Programme in 2002 to provide institutions in low-resource countries free or reduced-cost access to medical literature. Registration for the program is required. Eligibility is based on national economic or development criteria.

Another valuable tool is the website pemdatabase.org. This nonproprietary site was started as an online resource for PEM practitioners. It contains links to PEM abstracts and articles, evidence-based reviews, pediatric resuscitation websites, and relevant journals, as well as PEM conferences and professional organizations.

In countries where internet access continues to be a barrier, resources for education and research may be limited to out-of-date textbooks and journals.

Chapter 78

Triage of the Acutely Ill Child

Anna K. Weiss and Frances B. Balamuth

Identifying the acutely ill child in the ambulatory setting is a challenge. Children presenting to pediatricians' offices, urgent care practices, and emergency departments (EDs) may have a range of illnesses from simple viral infections to life-threatening emergencies. Although most children in this setting will have a benign course of illness, it is incumbent on the pediatric practitioner to discern quickly and accurately which children are likely to deteriorate from potentially serious or life-threatening disease. When assessing an acutely ill child, practitioners must remember that the early signs of severe illness may be subtle. There are about five pediatric triage system tools that assess the severity of illness and thus the degree of needed interventions. One example is presented in Table 78.1.

ASSESSMENT OF VITAL SIGNS

Assessment of vital signs is critical in all pediatric visits for acute illness, including temperature, heart rate, respiratory rate, and blood pressure. Normal vital signs vary with age. Although there have been increasing efforts to build evidence-based vital sign cutoffs for different age-groups, most institutions use nonempirically derived cutoffs such as those in Pediatric Advanced Life Support (PALS). **Tachycardia** is common in children presenting for acute care and can result from benign (fever, pain, dehydration) to life-threatening (septic shock, hemorrhage, multisystem inflammatory system in children [MIS-C], dysrhythmia, heart failure, hyperthyroidism) conditions. An abnormal heart rate should prompt a full history and physical examination, as described later, and careful *reassessment* (often multiple times) after the presumed cause is identified and treated. Most children will improve after initiation of simple interventions such as antipyretics or analgesia. Tachycardia that persists after fever, pain, and dehydration have been treated *must* be evaluated further, particularly if the child appears ill or has a deficit in perfusion or altered mental state.

Tachypnea is also common among ill children and has many causes, including fever, respiratory conditions (bronchiolitis, asthma, pneumonia), cardiac disease (heart failure), and metabolic acidosis (shock, poisoning, diabetic ketoacidosis). Like tachycardia, tachypnea often resolves with antipyretics in febrile children and should be reassessed to ensure resolution once fever has been managed. In cases where bronchiolitis and asthma have been ruled out, persistent tachypnea and fever can be a sign of pneumonia, even in the absence of focal lung findings on examination. Consider evaluation for metabolic acidosis in cases of significant tachypnea without apparent pulmonary or cardiac causes. **Apnea** is a sign of respiratory failure and should be *treated emergently with bag-valve-mask ventilation and immediate ED evaluation.*

Hypotension is rare in children and, when present, it is a sign of critical illness. Children with hypotension should be evaluated in an ED. Hypotension is evidence of decompensated circulatory shock and can result from severe dehydration, sepsis, hemorrhage, neurogenic spinal shock, anaphylaxis, or cardiogenic shock.

Pulse oximetry (oxygen-hemoglobin saturation, Spo_2) should be assessed in children with respiratory or cardiac illness/compromise and in children with underlying abnormalities of oxygenation. Healthy children have Spo_2 >95%. The practitioner should consider evaluating for any underlying respiratory or cardiac causes in children with Spo_2 <93–95%. For children with underlying abnormalities, the child's baseline Spo_2 should be assessed and alterations from that baseline should be investigated further.

The combination of bradycardia, hypertension, and altered breathing known as **Cushing triad** can be a sign of life-threatening increased intracranial pressure (ICP) and should be evaluated in an ED. Anisocoria and a sixth cranial nerve palsy are other signs of increased ICP. **Toxidromes** should also be considered in children with abnormal combinations of vital signs (see Chapter 94).

HISTORY

A thorough history is paramount to identifying patients whose condition will require prompt intervention. Obtaining an accurate history from young patients is challenging, particularly with preverbal or anxious children who are unable or unwilling to localize the source of their discomfort. In such instances, parents or caretakers often provide the most important information, and their perceptions of the child's course of illness must be carefully considered. Pediatricians should be guided by the patient's chief complaint to ask *open-ended questions* that help distinguish between benign and potentially life-threatening disease entities. The most common complaints leading to acute care visits among children include fever, headache and altered mental status, trauma, abdominal pain and vomiting, respiratory distress, and chest pain. Table 78.2 describes signs and symptoms and risk factors that should prompt immediate transfer to an ED or, if already in the ED, initiation of rapid intervention.

Fever is the most common reason for a sick-child visit. Most cases of fever are the result of self-limited viral infection. However, pediatricians need to be aware of the age-dependent potential for serious bacterial or viral infections, such as urinary tract infection (UTI), sepsis, meningitis, pneumonia, acute abdominal infection, and osteoarticular infection.

During the first 2 months of life, the neonate is at risk for sepsis caused by pathogens that are uncommon in older children. These organisms include group B streptococcus, *Escherichia coli, Listeria monocytogenes,* and herpes simplex virus (HSV). In neonates, the history must include maternal obstetric information and the patient's birth history. Risk factors for sepsis include untreated maternal group B streptococcus colonization, prematurity, chorioamnionitis, and prolonged rupture of membranes. If there is a maternal history of sexually transmitted infections (STIs) during the pregnancy, the differential diagnosis must be expanded to include infection with those pathogens. Septic infants can present with lethargy, poor feeding, grunting respirations, and cool or mottled extremities in addition to fever (or hypothermia). Febrile infants in the first 1 to 2 months of life should be evaluated broadly for infection, including sampling blood, urine, and, in some cases, cerebrospinal fluid (CSF) (see Chapter 220).

When the infant matures beyond 2 months of age and receives their first set of vaccinations, serious bacterial infections become less common. Evaluation to rule out serious infection is an important part of treating the febrile older child. Children with fever should have a full set of vital signs, history, and physical examination to ensure that critical illness is absent and to identify any focal source. Red flags for **septic shock** include hypotension, poor perfusion, altered mental status, or the presence of purpuric or erythrodermic rash. Red flags for **meningitis** include severe headache, meningismus, and altered mental state. The presence of any of these signs should prompt emergency evaluation in the ED or rapid treatment if the patient is already in the ED.

Additional focal findings to consider include evaluation for acute otitis media, pharyngitis, pneumonia, abdominal infections (bacterial enteritis, appendicitis), skin and soft tissue infections, septic arthritis, and osteomyelitis. Occult UTI should be considered if three of the following risk factors are present: age <1 year, fever >39°C, fever >48 hours, and no focal source of fever. Pneumonia should be considered in the presence of tachypnea, hypoxia, or focal findings on chest examination. Bacteremia is rare in the post–pneumococcal and *Haemophilus influenzae* vaccine era but should be considered if staphylococcal infection or meningococcemia is suspected and in unvaccinated children or children with signs of septic shock. In addition to infection, inflammatory conditions to consider include juvenile idiopathic arthritis (JIA), macrophage activating syndrome (MAS), Kawasaki disease (KD), and MIS-C. The diagnosis of KD, MIS-C, or MAS should be considered if

Table 78.1 Definition of Emergency Severity Index for Children

LEVEL 1	LEVEL 2	LEVEL 3	LEVEL 4	LEVEL 5
Cardiac arrest Respiratory arrest Severe respiratory distress SpO_2 <90 Critically injured and unresponsive trauma patient Severe respiratory distress with agonal or Gasping-type respirations Severe bradycardia or tachycardia with signs of Hypoperfusion Hypotension with signs of hypoperfusion Trauma patient who needs resuscitation Anaphylactic reaction Baby who is flaccid Hypoglycemia with a change in mental status	Seizures Sepsis, severe dehydration Diabetic ketoacidosis Child abuse, burns Head trauma Vitamins/iron or other overdoses/ingestions Infant less than 28 days of age with a fever of 38°C (100.4°F) or greater 1-3 mo of age with a fever of 38°C (100.4°F) or greater may be considered up to II Vital signs not stable	Multiple resources needed 3 mo to 3 yr of age T >39°C (102.2°F)	Single resource needed	Only history, physical exam required

From Wang L, Zhou H, Zhu JF. Application of emergency severity index in pediatric emergency department. *World J Emerg Med.* 2011;2(4):279-282, Table 1, p. 280.

the patient meets the diagnostic criteria for that illness, although some patients may have an atypical or incomplete presentation (see Chapters 207 and 208).

For patients presenting in an **altered mental state**, the pediatrician should inquire about symptoms such as fever or headache. Screening questions should explore feeding changes, medications in the household, ill contacts, and the possibility of trauma. Parents will often describe a febrile child as lethargic, but further questioning will reveal a tired-appearing child who interacts appropriately when no longer febrile. The child who appears ill only when febrile must be differentiated from the lethargic patient who presents with suspected sepsis or meningitis and from the child whose altered behavior is secondary to an intracranial emergency or seizure. Infants with meningitis, sepsis, or cardiac defects may have a history of irritability, inconsolability, poor feeding, grunting breathing, seizures, poor urine output, and/or color changes such as pallor, mottling, or cyanosis. Patients with poisoning or inborn error of metabolism can also present with lethargy, poor feeding, unusual odors, seizures, and vomiting. **Nonaccidental trauma** should always be considered in a lethargic infant, particularly in the absence of additional signs or symptoms. In infants and young toddlers, rapidly growing head circumference or bulging anterior fontanel may signal increased ICP. Older children may present with altered mental state as a result of meningitis/encephalitis, trauma, or ingestions. School-age children and adolescents with meningitis may have a history of fever and neck pain; other associated symptoms may include rash, headache, photophobia, or vomiting. Children with ingestions can present with other abnormal neurologic symptoms, such as ataxia, slurred speech, and seizures, or with characteristic constellations of vital sign changes and other physical findings consistent with certain toxidromes.

In patients with **headache**, ask questions about the chronicity of the headache and any accompanying symptoms. Headaches that occur upon arising in the morning, that are worse when lying flat, or that are accompanied by vomiting are concerning for increased ICP. Similarly, headache accompanied by focal neurologic deficit(s) should be referred to an ED for urgent head imaging. Although migraine headaches in teenagers are similar in presentation to those in adults (unilateral, throbbing, accompanied by an aura), pediatric practitioners should be aware that migraines in prepubertal children may have a nonclassic presentation; may be bilateral; and may not be accompanied by aura, photophobia, or phonophobia.

Parents may interpret a variety of symptoms as **respiratory distress**, and care must be taken to distinguish normal and benign respiratory patterns from true respiratory distress. Tachypnea secondary to fever is a common source of parental anxiety, and parents of newborn infants are sometimes alarmed by the presence of periodic breathing. Parents should be questioned about their child's other symptoms, such as fever, limitation of neck movement, drooling, choking, and the presence of stridor or wheezing. A history of apnea or cyanosis warrants further investigation. Practitioners should also remember that tachypnea in a child without evidence of true respiratory distress may be evidence of compensation for shock or metabolic acidosis, both of which will require rapid treatment. Although wheezing is often secondary to bronchospasm, it can also be caused by cardiac disease or congenital airway anomalies such as vascular rings. Parents may interpret **stridor** as noisy breathing or wheezing. Stridor is most frequently caused by upper airway obstruction such as croup. However, anatomic abnormalities such as laryngeal webs, laryngomalacia, subglottic stenosis, and paralyzed vocal cords also cause stridor. Toddlers who present with breathing difficulty after a coughing or choking episode should be evaluated for **foreign body aspiration**. In these cases, practitioners must ask about the possibility of button-battery ingestion, as this constitutes a true medical emergency that warrants immediate endoscopic removal or transfer to a facility that can perform the procedure. In toxic-appearing children with stridor, the pediatrician should consider epiglottitis, bacterial tracheitis, or a rapidly expanding retropharyngeal abscess. The incidence of epiglottitis has greatly declined with the advent of the *H. influenzae* type b (Hib) vaccine, but it remains a possibility in the unimmunized or partially immunized patient. Children with retropharyngeal abscesses may also present with drooling and limitation of neck movement (especially hyperextension) after a recent upper respiratory infection or penetrating mouth injury.

Abdominal pain is a common complaint in the ambulatory setting and can herald either acute intraabdominal or pelvic pathology, or it can be a subtler sign of systemic illness. Both relatively benign (e.g., streptococcal infection, UTI, pneumonia) and severe abdominal (e.g., appendicitis) or systemic (e.g., diabetic ketoacidosis, MIS-C) illness can present with abdominal pain, and questions to the patient and parent should include whether there is an extraabdominal source of discomfort. Questions should include details about pain onset and location; presence of accompanying symptoms, such

Table 78.2 History and Examination Findings that Should Prompt Immediate Intervention and/or Transfer to Emergency Department

HISTORY AND EXAM FINDINGS	RISK FACTORS
RED FLAGS FOR RESPIRATORY FAILURE	
Tachycardia	Tracheostomy
Tachypnea	Ventilator dependence
Cyanosis	History of critical airway
Apnea	
Brief resolved unexplained event (BRUE) with cyanosis or change in tone	
Suspected button-battery ingestion	
Foreign body aspiration with respiratory distress	
Sitting up, leaning forward, drooling	
Respiratory distress with hypoxemia	
Altered mental status	
RED FLAGS FOR CIRCULATORY FAILURE	
Tachycardia	Oncology (or other immunosuppressed) patients
Tachypnea	Bone marrow or solid organ transplants
Cyanosis	Sickle cell (or otherwise asplenic) patients
Cold extremities, poor pulses	Infants <60 days old
Apnea	Unrepaired or repaired congenital heart disease with change from baseline pulse oximetry
Petechial or purpuric rashes	Bleeding disorder with trauma
Erythroderma	
Peritonitis	
Bilious emesis	
Post-tonsillectomy or post-adenoidectomy with bleeding	
Extremity trauma with neurovascular deficits	
RED FLAGS FOR NEUROLOGIC FAILURE	
Tachycardia	Ventriculoperitoneal shunt
Bradycardia-hypertension	Diabetes or metabolic disease with altered mental status
Double vision	Hypoxic-ischemic encephalopathy
Ptosis	Clotting disorder with neurologic change(s)
Unequal pupils	Drug ingestion
Apnea	
Frequent or prolonged seizure(s)	
Focal neurologic deficit(s)	
Acute onset of severe headache	
Suicidal or homicidal ideation	
Psychosis	

Adapted from Farah MM, Tay Y, Lavelle J. A general approach to ill and injured children. In: Shaw KN, Bachur RG, eds. *Fleischer and Ludwig's Textbook of Pediatric Emergency Medicine*, 8th ed. Philadelphia: Lippincott, Williams & Wilkins; 2020.

as fever and abdominal distention; and changes in feeding, urination, and stooling patterns. Care should be taken to elicit a history of peritonitis or obstruction, including worsening pain with abrupt movements and persistent or bilious vomiting.

In neonates, a tender abdomen with or without bilious emesis should raise concern for the presence of a small bowel obstruction (e.g., volvulus). These infants appear ill and may have a history of decreased stooling. Pediatricians should be wary of neonates with abdominal tenderness and bloody stools, as 10% of cases of necrotizing enterocolitis occur in term infants. Infants with milk protein intolerance can also present with bloody stools, but these infants appear well and do not have abdominal tenderness. In older patients the differential diagnosis for emergency causes of abdominal pain expands to include intussusception and appendicitis. Patients with intussusception present in a variety of ways, ranging from colicky abdominal pain but otherwise well between episodes to being lethargic or in shock. The diagnosis of appendicitis in the child younger than 3 years is extremely difficult because children in this age-group cannot localize pain well. In adolescent females with abdominal pain, practitioners must obtain a menstrual and sexual history, as acute lower abdominal pain may be caused by adnexal pathology, including ovarian torsion or ectopic pregnancy.

For patients with **vomiting**, pediatricians should ask if they have experienced bilious or blood-stained emesis, abdominal distention or constipation, weight changes, and diarrhea or bloody stools. An infant with bilious emesis and abdominal distention may have intestinal obstruction (as with midgut volvulus or Hirschsprung disease), whereas an infant who appears immediately hungry after nonbilious projectile vomiting may have pyloric stenosis. In an older child, vomiting may be caused by peritonitis or obstruction and by systemic illnesses, including diabetic ketoacidosis, ingestion, or trauma. Patients with headache and vomiting raise the concern for increased ICP and should be questioned about neurologic changes, meningismus, and fever.

Practitioners should also obtain a thorough account of the child's **past medical history**. It is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness. Children with sickle cell anemia, indwelling central venous access devices, or immune compromise are at increased risk for bacteremia and sepsis. Similarly, children with prior surgery, including ventriculoperitoneal shunt placement or intraabdominal procedures, can develop complications from their previous surgeries.

PHYSICAL EXAMINATION

Observation is important when evaluating the acutely ill child. Most observational data that the pediatrician gathers should focus on assessing the child's response to stimuli. Does the child awaken easily? Does the child smile and interact with the parent or with the examiner? Evaluating these responses requires knowledge of normal child development and an understanding of the manner in which normal responses are elicited, depending on the child's age.

During the physical examination, the pediatric practitioner seeks evidence of illness. The portions of the exam that require the child to be most cooperative are completed first. Initially, it is best to seat the child on the parent's lap; the older child may be seated on the examination table. It is also important to assess the child's willingness to move, as well as ease of movement. It is reassuring to see the child moving about on the parent's lap with ease and without discomfort. *Vital signs are often overlooked but are invaluable in assessing ill children.* The presence of tachycardia out of proportion to fever and the presence of tachypnea and blood pressure abnormalities raise the suspicion for more serious illness. The respiratory evaluation includes determining respiratory rate; noting the presence or absence of hypoxia by Spo_2; and noting any evidence of inspiratory stridor, expiratory wheezing, grunting, coughing, or increased work of breathing (e.g., retractions, nasal flaring, accessory muscle use). The **skin** should be carefully examined for rashes. Frequently, viral infections cause an exanthem, and many of these eruptions are diagnostic, such as the reticulated rash and slapped-cheek appearance of parvovirus infections and the stereotypical appearance of hand-foot-and-mouth disease caused by coxsackieviruses, as well as measles, chickenpox, and roseola. The skin examination may also yield evidence of more serious infections, including petechiae and purpura associated with bacteremia and erythroderma associated with a toxin-producing systemic infection. Cutaneous perfusion should be assessed by warmth and capillary refill time. The extremities may then be evaluated not only for ease of movement but also for the presence of swelling, warmth, tenderness, or alterations in perfusion. Such abnormalities may indicate focal infections (e.g., cellulitis, bone/joint infection) or vascular changes (e.g., arterial or venous thromboembolus).

When an infant is seated and is least perturbed, the examiner should assess the anterior fontanel to determine whether it is depressed, flat, or bulging. While the child is calm and cooperative, the **eyes** should be examined to identify features that might indicate an infectious or neurologic process. Often, viral infections result in watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial,

results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of the tissues surrounding the eye may be present, as well as proptosis, altered visual acuity, and impaired extraocular movements. Abnormalities in pupillary response, extraocular movements, or ptosis may also be indicators of cranial nerve abnormalities and, if new, are indications for head imaging.

During this initial portion of the physical examination, when the child is most comfortable (and therefore most likely to be quiet), the **heart and lungs** are auscultated. It is important to assess the adequacy of air entry into the lungs; the equality of breath sounds; and any evidence of adventitial breath sounds, especially wheezes, rales, or rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child's nose and then compensating for this sound as the chest is auscultated. The cardiac examination is next; findings such as pericardial friction rubs, loud murmurs, irregular rhythms, gallop rhythm, and distant heart sounds may indicate cardiac inflammation or infection. In the neonate, murmurs may herald congenital heart disease, especially in the presence of cyanosis, unequal extremity pulses, or a differential in upper- vs lower-extremity blood pressures. A complete cardiac exam should also look for displacement of the point of maximal impulse (PMI) and the presence of jugular venous distention or facial plethora.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the **neck** is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. Resistance to neck movement should prompt evaluation for signs of meningeal irritation or retropharyngeal abscess. During examination of the **abdomen**, the diaper—if present—is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. Every attempt should be made to quiet a fussing child during this part of the exam; if this is not possible, practitioners should note that increased crying as the abdomen is palpated may indicate tenderness, especially if this finding is focally reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound tenderness (including tenderness to percussion); these findings indicate peritoneal irritation, as may be seen in appendicitis. During palpation of the abdomen, practitioners should look for signs of hepatomegaly or splenomegaly. When palpating the bottom-most edge of the liver or spleen, examiners should begin in the pelvis and work upward toward the ribs, because severe organomegaly can be missed if the examiner begins palpating in the mid-abdomen. The **inguinal area and genitals** are then examined. One should assess the inguinal area for hernias. Care should be taken to examine the testicles of males with abdominal pain; testicular trauma, testicular torsion, and epididymitis all may present with abdominal discomfort. A unilateral swollen or painful testicle with an absent cremasteric reflex on the affected side is concerning for testicular torsion and should be referred for emergent ultrasound and urologic consultation. After the genital exam, the child is then placed in the prone position, and abnormalities of the **back** are sought. The spine and costovertebral angle areas are percussed to elicit any tenderness; such findings may be indicative of vertebral osteomyelitis or diskitis and pyelonephritis, respectively.

Examining the **ears and throat** completes the physical examination. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. During the oropharyngeal examination, it is important to document the presence of enanthems; these may be seen in many infectious processes, such as stomatitis caused by herpes or enteroviruses. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may indicate viral or bacterial infection. Findings such as trismus or unilateral tonsillar swelling are concerning for peritonsillar abscess and for infections in the parapharyngeal and retropharyngeal spaces; such cases should be referred for specialist ear, nose, and throat evaluation and potential imaging of the neck.

Repeating portions of the assessment may be indicated. If the child cried continuously during the initial clinical evaluation, the examiner may not be certain whether the crying was caused by the high fever, stranger anxiety, or pain or is indicative of a serious or localizing illness. Constant crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, efforts to make the child as comfortable as possible are indicated. In young infants, **persistent irritability**, even when the examiner is absent from the room, is concerning for meningitis, encephalitis, or other causes of meningeal irritation (e.g., intracranial injury from nonaccidental trauma). When faced with a truly inconsolable infant, practitioners should have a low threshold to obtain head imaging and/or perform lumbar puncture, as the clinical scenario dictates.

MANAGEMENT

Most patients who present to the pediatrician's office with an acute illness will not require acute stabilization. However, the pediatrician needs to be prepared to evaluate and begin resuscitation for the seriously ill or unstable child. Outpatient pediatric offices and urgent care facilities should be stocked with appropriate equipment necessary to stabilize an acutely ill child. Maintenance of that equipment and ongoing training of the office staff in its use are required, and every effort should be made to ensure that pediatric clinicians are PALS certified (see Chapter 79).

The evaluation of the potentially unstable child must begin with assessment of the ABCs—airway, breathing, and circulation. When assessing the **airway**, chest rise should be evaluated and evidence of increased work of breathing sought. The examiner should ensure that the trachea is midline and should listen carefully for evidence of air exchange at the level of the extrathoracic airway. If the airway is patent and no signs of obstruction are present, the patient is allowed to assume a position of comfort. If the child shows signs of airway obstruction, repositioning of the head with the chin-lift maneuver may alleviate the obstruction. An oral or nasal airway may be necessary in patients in whom airway patency cannot be maintained. These devices are not well tolerated in conscious patients because they may induce gagging or vomiting; instead, they are most often used to facilitate effective bag-valve-mask ventilation in semiconscious or unconscious children. Once airway patency has been established, the adequacy of **breathing** should be evaluated. Slow respiratory rates or cyanosis may signal impending respiratory failure. If the airway is patent but the child's respiratory effort is inadequate, positive pressure ventilation via bag-valve-mask support should be initiated. Oxygen should be administered to all seriously ill or hypoxic children via nasal cannula or face mask. Auscultation of the lung fields should assess for air entry, symmetry of breath sounds, and presence of adventitious breath sounds such as crackles or wheezes. Bronchodilator therapy can be initiated to alleviate bronchospasm. Racemic epinephrine is indicated for stridor at rest in a patient with upper airway obstruction (e.g., croup). Once airway and breathing have been addressed, **circulation** must be evaluated. Symptoms of *shock* include tachycardia, cool extremities, delayed capillary refill time, mottled or pale skin, and effortless tachypnea. In children, hypotension is a late finding in shock and indicates that significant decompensation has already taken place. Vascular access is necessary for volume resuscitation in patients with impaired circulation, and an intraosseous line should be considered early if there is any difficulty in obtaining vascular access for a patient requiring resuscitation. Each time an intervention is performed, the clinician should **reassess the patient** to determine whether interventions have been successful and whether additional care is needed.

DISPOSITION

Most children evaluated for acute illness in the office or urgent care setting can be managed on an **outpatient** basis. These patients should have a reassuring physical examination, stable vital signs, and an adequate follow-up plan before being sent home. A mildly dehydrated

patient can be discharged home for a trial of oral rehydration. Patients with respiratory illness who exhibit signs of mild respiratory distress may be monitored at home, with a repeat examination scheduled the next day. Depending on the child's condition, the comfort of the parents, and the relationship of the family with the physician, telephone follow-up may be all that is necessary. When no specific diagnosis has been established at the first outpatient visit, a follow-up examination may yield the diagnosis and can provide reassurance for both the caregiver and the practitioner that a child's severity of illness has not progressed.

However, if it is deemed that the child needs a higher level of care, it is the pediatrician's responsibility to decide what method of transfer is appropriate. Physicians may be reluctant to call for help because of a misperception that emergency 911 services should be activated only for ongoing resuscitation. Emergency medical services (EMS) transport should be initiated for any child who is physiologically unstable (e.g., with severe respiratory distress, hypoxia, signs of shock, or altered mental state). If the family's ability to adhere promptly to a recommendation for ED evaluation is in question, this patient also should be transported by EMS. Some physicians and families may defer calling EMS because of the perception that a parent can reach the hospital faster by private motor vehicle. Although rapidity of transport should be considered, the need for further interventions during transport and the risk of clinical decompensation are other important factors in the decision to activate EMS. Ultimately, the legal responsibility for choosing an appropriate level of transport for a patient lies with the referring physician until responsibility of care is officially transferred to another medical provider.

Chapter 79

Pediatric Cardiorespiratory Emergencies and Resuscitation

Ryan W. Morgan and Alexis A. Topjian

Children in the community and those in the hospital are at risk for a variety of injuries and life-threatening disease processes that lead to cardiac or respiratory compromise, which require prompt evaluation and intervention.

ASSESSMENT AND EVALUATION OF CHILDREN WITH CARDIORESPIRATORY EMERGENCIES

The first response to a pediatric emergency of any cause is a rapid and systematic **general assessment** of the scene and the child to identify immediate threats to the child, care providers, and others. If an emergency is identified, the emergency response system (emergency medical services [EMS]) should be activated immediately. Care providers should then proceed through **primary**, **secondary**, and **tertiary** assessments as allowed by the child's condition, safety of the scene, and resources available. This standardized approach organizes what might otherwise be a confusing or chaotic situation and ensures that key elements of assessment and treatment are not omitted. If at any point during these assessments the provider identifies a life-threatening problem, progression through the systematic assessment is paused and targeted lifesaving interventions are prioritized. Further assessments and interventions should be delayed until other providers arrive to assist or until the life-threatening condition is successfully treated or stabilized.

General Assessment

Upon arrival at the scene of a critically ill or injured child or upon the child's presentation for medical care, a provider's first task is a quick survey of the scene itself. Is the rescuer or child in imminent danger because of circumstances at the scene (e.g., fire, high-voltage electricity)? If so, can the child be safely extricated to a safe location for assessment and treatment? Can the child be safely moved with the appropriate precautions (e.g., cervical spine protection) if indicated? A rescuer is expected to proceed only if these important safety conditions have been met so that they do not jeopardize their own safety.

Once the provider's and child's safety have been ensured, the provider performs a rapid **visual survey** of the child, assessing the child's **general appearance** and **cardiopulmonary function**. This action should only take a few seconds and includes assessment of (1) general appearance, determining color, tone, alertness, and responsiveness; (2) adequacy of breathing, distinguishing between normal, comfortable respirations versus respiratory distress or apnea; and (3) adequacy of circulation, identifying cyanosis, pallor, or mottling. If a child is found unresponsive or becomes unresponsive during the provider's assessment, the provider should stimulate the patient and assess the patient's response to voice. If there is no response, the provider should assess for breathing. If the child is breathing but ineffectively, rescue breathing should be started. If the child is not breathing or has agonal respirations, the provider should initiate cardiopulmonary resuscitation (CPR) and follow Basic Life Support (BLS) pediatric cardiac arrest algorithms for one rescuer or two or more rescuers (Figs. 79.1 and 79.2).

Primary Assessment

Once the emergency response system has been activated and the child is determined not to require CPR, the provider should proceed with a primary assessment that includes a brief, hands-on evaluation of cardiopulmonary and neurologic function. This assessment includes a limited physical examination, evaluation of vital signs, and measurement of pulse oximetry if available. The American Heart Association (AHA), in its Pediatric Advanced Life Support (PALS) curriculum, supports the structured format of **airway, breathing, circulation, disability, exposure (ABCDE)**. *The goal of the primary assessment is to obtain a focused, systems-based assessment of the child's injuries or abnormalities so that resuscitative efforts can be rapidly targeted to these areas;* if the provider identifies a life-threatening abnormality, further evaluation is postponed until appropriate corrective action has been taken.

The exam and vital sign data can be interpreted only if the provider has a thorough understanding of normal values. In pediatrics, normal respiratory rate, heart rate, and blood pressure have age-specific norms (Table 79.1). These ranges can be difficult to remember, especially if used infrequently, and providers should therefore maintain ready access to these normal ranges. Hypotension is defined as blood pressure less than the fifth percentile for age. This is considered a systolic blood pressure of <60 mm Hg for neonates up to 28 days, <70 mm Hg for infants from 1 month to 1 year, <70+ (age in years ×2) mm Hg for children 1-10 years, and <90 mm Hg for children older than 10 years of age.

Airway and Breathing

The most common precipitating event for cardiac instability in infants and children is respiratory failure (the inability to adequately oxygenate or ventilate). Therefore *rapid assessment for respiratory failure and immediate restoration of adequate ventilation and oxygenation remain the first priorities in the resuscitation of a child.* Using a systematic approach, the provider should first assess whether the child's airway is patent and maintainable. A **patent** airway is unobstructed, allowing normal respiration without noise or effort. A **maintainable** airway is one that is either already patent or can be made patent with a simple maneuver. To assess airway patency, the provider should look for breathing movements in the child's chest and abdomen, listen for breath sounds, and feel for the movement of air at the child's mouth and nose. Abnormal breathing sounds (e.g., snoring or stridor), increased work of breathing,

AED, Automated external defibrillator; ALS, advanced life support; CPR, cardiopulmonary resuscitation. (*From Topjian AA, Raymond TT, Atkins D, et al. Part 4: Pediatric Basic and Advanced Life Support: 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation. 2020;142[16 Suppl 2]:S469-S523.*)

and apnea are all findings potentially consistent with airway obstruction. If there is evidence of obstruction, the provider should start with repositioning and "head-tilt, chin-lift" if neck injury is not suspected or a jaw thrust if neck injury is a concern (Fig. 79.3). Suctioning of the airway or placement of adjunct airway devices such as a nasopharyngeal airway should be considered based on the exam findings and the likely etiologies of airway obstruction. Maneuvers to relieve the obstruction should be instituted before the provider proceeds to evaluate the child's breathing.

Assessment of breathing includes evaluation of the child's respiratory rate, respiratory effort, breath sounds, and peripheral oxygen saturation via pulse oximetry. Normal breathing appears comfortable, is quiet, and occurs at an age-appropriate rate. Abnormal respiratory rates include apnea and rates that are either abnormally slow (bradypnea) or fast (tachypnea). *Bradypnea and irregular respiratory patterns (such as gasping or agonal respirations) require urgent attention because they are often signs of impending respiratory failure, apnea, or cardiorespiratory arrest.* Signs of increased respiratory effort include nasal flaring, grunting, chest or neck muscle retractions, head bobbing, and seesaw respirations. Hypoxemia, measured by pulse oximetry, often accompanies parenchymal lung disease, apnea, or airway obstruction. However, providers should keep in mind that adequate perfusion is required to produce a reliable peripheral oxygen saturation measurement. Central cyanosis is a sign of severe hypoxemia and indicates an emergent need for oxygen supplementation and respiratory support.

Table 79.1 Normal Vital Signs According to Age

AGE	HEART RATE (beats/min)	BLOOD PRESSURE† (mm Hg)	RESPIRATORY RATE+ (breaths/min)
Premature	120-205*	60-76/31-45	40-70
Neonate	100-205*	67-84/35-53	35-55
Infant	100-180	72-104/37-56	30-53
Toddler	98-140	86-106/42-63	22-37
Preschooler	80-120	89-112/46-72	20-29
School-age child	75-118	97-120/57-80	18-25
Adolescent	60-100	110-131/64-83	12-20

*In sleep, heart rates may be significantly lower, but if perfusion is maintained, no intervention is required.
†A blood pressure cuff should cover approximately two-thirds of the arm; too small a cuff yields spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings. Values are systolic/diastolic and assume 50th percentile for height for children 1 year and older.
+The respiratory rate is expected to increase in the presence of fever and stress.
‡Approximately equal to postconception age in weeks (may add 5 mm Hg).

Circulation

Cardiovascular function is assessed by evaluation of skin color and temperature, heart rate, heart rhythm, presence and quality of pulses, capillary refill time, and blood pressure. In nonhospital settings, much of this important information can be obtained without measuring the blood pressure; lack of blood pressure data should not prevent the provider from determining adequacy of circulation or implementing lifesaving support. Mottling, pallor, delayed capillary refill, cyanosis, weak pulses, and cool extremities are all signs of diminished perfusion and compromised cardiac output. **Tachycardia** is the earliest and most common sign of shock but lacks both sensitivity and specificity and should be correlated with other components of the exam, such as weakness, threadiness, or absence of pulses. An age-specific approach to heart rate assessment will yield the most reliable interpretation. **Bradycardia** can be normal in athletic children but should be assessed in the context of the child's perfusion, blood pressure, mental status, and oxygen saturation, as it can be a sign of impending cardiac arrest.

Disability

In the setting of a pediatric emergency, *disability* refers to a child's neurologic function in terms of the level of consciousness and cortical function. Standard evaluation of a child's neurologic condition can be done quickly with an assessment of pupillary response to light (if one is available) and use of either of the standard scores used in children: the Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale and the Glasgow Coma Scale (GCS) (Tables 79.2 and 79.3). The

Table 79.4 Pupillary Responses

DILATED (MYDRIASIS)	PINPOINT (MIOSIS)
Bilateral Anticholinergic agents (systemic, topical) Sympathomimetic agents Serotonin syndrome Botulism Brain death (fixed, nonreactive usually midposition)	Bilateral Opiates Organophosphates Barbiturates Pontine lesions
Unilateral Third nerve compression with uncal herniation	Unilateral Horner syndrome

causes of decreased level of consciousness in children are numerous and include conditions as diverse as respiratory failure with hypoxia or hypercarbia, hypoglycemia, poisonings or drug overdose, trauma, seizures, infection, and shock. *Most often, an acutely ill or injured child has an altered level of consciousness because of respiratory compromise, circulatory compromise, or both.* Any child with a depressed level of consciousness should be immediately assessed for abnormalities in cardiorespiratory status.

Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale: The AVPU scoring system is used to determine a child's level of consciousness and cerebral cortex function (see Table 79.2). Unlike the GCS, the AVPU scale is not developmentally dependent—a child does not have to understand spoken language or follow commands, merely respond to a stimulus. The child is scored according to the amount of stimulus required to obtain a response, from *alert* (no stimulus; the child is already awake and interactive) to *unresponsive* (child does not respond to any stimulus).

Glasgow Coma Scale (GCS): Although it has not been systematically validated as a prognostic scoring system for infants and young children, the GCS is frequently employed to describe level of consciousness and neurologic status. It has value as a way to communicate mental status to other providers and when used serially to detect improvement or deterioration. The GCS has three components: eyes, verbal, and motor. Individual scores for eye opening, verbal response, and motor response are added together, with a maximum of 15 points (see Table 79.3). There are numerous versions of the pediatric GCS, but most importantly, the pediatric GCS accounts for differences in development and the inability for children <2 years of age to follow commands and talk. Patients who have severe head injury with a GCS score ≤8 require aggressive management, generally including securement of the airway with endotracheal intubation and breathing with mechanical ventilation and, if indicated, placement of an intracranial pressure monitoring device.

The Full Outline of Unresponsiveness (FOUR) score is a neurologic assessment that incorporates brainstem reflex components and is associated with outcomes; it is commonly used in the intensive care unit setting (Table 82.1).

The pupillary response can give insight to causes of altered mental status. Pinpoint pupils can be due to many conditions, including narcotic ingestion, and dilated *asymmetric* pupils (anisocoria) can be caused by uncal herniation (Table 79.4 and Fig. 79.4). If a patient has a normal mental status, other causes of pupillary dilation and asymmetry should be considered.

Lesion/process associated with coma	Pupils	Comment
Metabolic		Normal
Bilateral hypothalamic		Small but reactive
Uncal herniation		Ipsilateral "blown," unreactive pupil, ptosis
Tectal		Midposition and unreactive to light
Midbrain		Dilated and unreactive
Pontine		Pinpoint but reactive
Brain death		Midposition to large, unreactive

Exposure

Exposure is the final component of the pediatric primary assessment. This component of the exam is reached only after the child's airway, breathing, circulation, and disability have been assessed and reasonably stabilized. In this setting, *exposure* stands for the dual responsibility of the provider both to expose the child to assess for previously unidentified injures and to consider prolonged exposure in a cold environment as a possible cause of hypothermia and cardiopulmonary instability. The provider should undress the child (as is feasible and reasonable) to perform a physical exam, assessing for burns, bruising, bleeding, joint laxity, and fractures. If possible, the provider should assess the child's temperature. All maneuvers should be performed with careful maintenance of cervical spine precautions when indicated.

Secondary and Tertiary Assessment

Secondary Assessment

For healthcare providers in community or outpatient settings, transfer of care of a child to emergency or hospital personnel may occur before a full secondary assessment is possible. However, before the child is removed from the scene and separated from witnesses or family, a brief history should be obtained for medical providers at the accepting facility. The components of a secondary assessment include a **focused history** and **focused physical examination**.

The history should be targeted to information that could explain cardiorespiratory or neurologic dysfunction and should take the form of a **SAMPLE history**: signs/symptoms; allergies; medications; past medical history; timing of last meal; and events leading to this situation. Medical personnel not engaged in resuscitative efforts can be dispatched to elicit history from witnesses or relatives. The physical examination during the secondary assessment is a thorough head-to-toe exam, although the severity of the child's illness or injury could necessitate curtailing portions of the exam or postponing nonessential elements until a later time.

Tertiary Assessment

The tertiary assessment occurs in a hospital setting, where ancillary laboratory and radiographic assessments contribute to a thorough understanding of the child's condition. A basic blood chemistry profile, complete blood count, liver function tests, coagulation studies, and arterial blood gas analyses provide estimates of renal function, acid-base balance, cardiorespiratory function, and presence or absence of shock. Chest radiographs can be useful to evaluate both the heart and

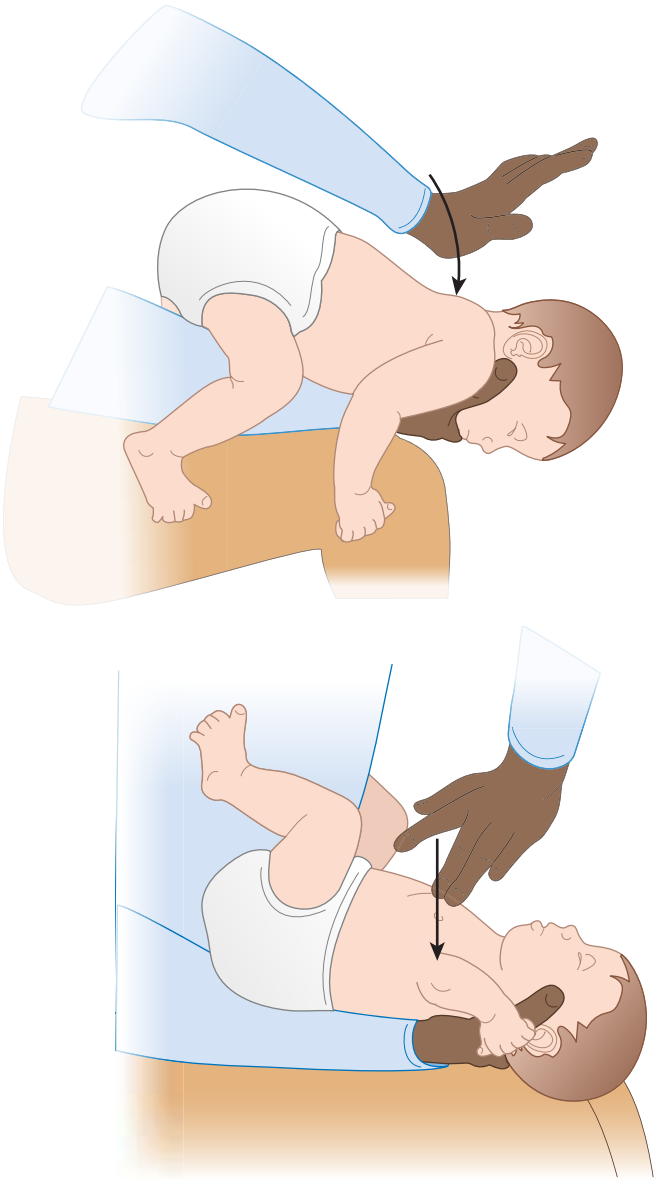

Fig. 79.5 Back blows *(top)* and chest thrusts *(bottom)* to relieve foreign body airway obstruction in the infant.

Fig. 79.6 Abdominal thrusts with the conscious victim standing or sitting.

lungs, although more detailed assessment of cardiac function can be performed with echocardiography.

RECOGNITION AND TREATMENT OF RESPIRATORY DISTRESS AND FAILURE

The goals of initial management of respiratory distress or failure are to rapidly stabilize the child's airway and breathing and to identify the cause of the problem so that further therapeutic efforts can be appropriately directed.

Airway Obstruction Due to Foreign Body

Children under 5 years of age are particularly susceptible to foreign body aspiration and choking. Liquids are the most common cause of choking in infants, whereas small objects and food (e.g., grapes, nuts, hot dogs, candy) are the most common source of foreign bodies in the airways of toddlers and older children. A history consistent with foreign body aspiration is considered diagnostic. Any child in the proper setting with the sudden onset of choking, stridor, or wheezing should be considered to have a foreign body aspiration until proven otherwise. Unfortunately, this classic history is not always present in all cases of foreign body aspiration.

Airway obstruction is treated with a sequential approach starting with the head-tilt/chin-lift maneuver to open and support the airway, followed by inspection for a foreign body, and finger-sweep clearance or suctioning if one is visualized. *Blind suctioning or finger sweeps of the mouth are not recommended.* A conscious child suspected of having a partial foreign body obstruction should be permitted to cough spontaneously until coughing is no longer effective, respiratory distress and stridor increase, or the child becomes unconscious. They can be allowed to find a comfortable position to facilitate air entry.

For *conscious infants,* providers should administer five back blows and then five chest thrusts (Fig. 79.5). After each cycle of back blows and chest thrusts, the child's mouth should be visually inspected for the presence of the foreign body. If identified within finger's reach, it should be removed with a gentle finger sweep. If no foreign body is visualized and the child is conscious, repeat back blows and chest thrusts. Do not blindly sweep for objects if they are not visible, as this can push the object farther into the airway.

For *conscious children* older than 1 year, providers should give a series of five abdominal thrusts **(Heimlich maneuver)** with the child standing or sitting (Fig. 79.6). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, abdominal thrusts should be repeated. For both infants and children, the sequence is repeated until the object is expelled or the patient loses consciousness, at which time CPR with ventilations should be initiated.

If the child becomes *unconscious,* the child should be gently placed on the ground in a supine position and ventilations should be initiated; compressions should also be started if the child is pulseless. The airway should be inspected for a foreign body at the time of ventilations.

Airway Obstruction or Narrowing from Other Causes

Airway obstruction can also be caused by airway narrowing in both the upper and lower airways. Upper airway obstruction refers to narrowing of the extrathoracic portion of the airway, including the oropharynx, larynx, epiglottitis, and trachea. In the upper airways, narrowing is most often caused by airway edema (e.g., croup or anaphylaxis) or epiglottic edema (e.g., epiglottitis) and often manifests with stridor. Stridor, in cases of extrathoracic airway obstruction, is a high-pitched sound heard on inspiration. When airway obstruction is intrathoracic, stridor can be biphasic, heard during both inspiration and expiration. Lower airway obstruction affects all intrathoracic airways, notably the bronchi and bronchioles. **Bronchiolitis** and acute **asthma** exacerbations are the major causes of intrathoracic airway obstruction in children, causing lower airway narrowing through a combination of airway swelling, mucus production, and circumferential smooth muscle constriction of smaller airways.

The approach to upper airway obstruction is dictated by both the underlying condition and the clinical severity of the problem. In cases of mild upper airway obstruction, the child has minimally increased work of breathing (evidenced by tachypnea and absent to mild retractions). Stridor, if present at all, should be audible with only coughing or activity. Children with these findings can often be supported with supplemental oxygen as needed. In cases with moderate obstruction, in which the child has more significant work of breathing or more pronounced stridor, nebulized **racemic epinephrine** and oral or intravenous (IV) **dexamethasone** can be added, particularly for **croup** (i.e., laryngotracheobronchitis) (see Chapter 434). **Heliox** (combined helium-oxygen therapy) administration may also be considered. Children with severe upper airway obstruction have marked intercostal retractions, prominent stridor, and decreased air entry on auscultation of the lung fields. They can also be hypoxemic, dyspneic, and either agitated or somnolent. A child in severe distress that does not rapidly respond to therapies may require endotracheal intubation to overcome the area of obstruction. Clinicians need to carefully observe patients, as impending respiratory failure may be initially confused with improvement. Stridor becomes quieter and retractions less prominent when a child's respiratory effort begins to diminish. This can either be the result of improvement or progressive respiratory failure with less air entry. The child in respiratory failure may have poor air movement on auscultation and decreased level of consciousness from hypercarbia, hypoxia, or both. When **anaphylaxis** is suspected as the cause for upper airway edema, providers should administer an intramuscular dose of epinephrine as needed (see Chapter 190). Racemic epinephrine can also help decrease localized airway edema. **Epiglottitis** often presents with a muffled voice, drooling, and difficulty swallowing. Epiglottitis is a medical emergency for which the initial focus should be on alerting otolaryngology and/or anesthesiology experts to be immediately present while keeping the patient calm. These patients usually need to have their airway secured in an operating room with contingency planning for emergency surgical airway placement. No matter the cause, any child with upper airway obstruction and impending respiratory failure should be prepared to undergo endotracheal intubation and respiratory support. Prompt notification of providers trained in advanced airway management is essential.

In cases of lower airway obstruction, therapies are targeted to both relieve the obstruction and reduce the child's work of breathing. For asthma, **inhaled bronchodilators**, such as albuterol, augmented by oral or IV **corticosteroids**, remain the mainstay of therapy in mild to moderate acute distress. Children with more significant obstruction appear dyspneic, with tachypnea, retractions, forced expiration, and audible wheezing or reduced breath sounds. In these cases, the addition of an anticholinergic agent, such as nebulized ipratropium bromide, or a smooth muscle relaxant, such as magnesium sulfate, may provide further relief, although the evidence for these measures remains controversial (see Chapter 185). Supplemental oxygen and IV fluid hydration can be useful adjuncts. Infants and young children with bronchiolitis often present with tachypnea. Patients with moderate to severe disease may have retractions, nasal flaring, or grunting and can be hypoxemic. These patients often do not respond to bronchodilators. Supportive care with chest physiotherapy to support mucous clearance and noninvasive positive pressure ventilation support can be used as these patients recover from this lower airway viral disease process.

Fig. 79.7 Rescue breathing in an infant. The rescuer's mouth covers the infant's nose and mouth, creating a seal. One hand performs the head-tilt while the other hand lifts the infant's jaw.

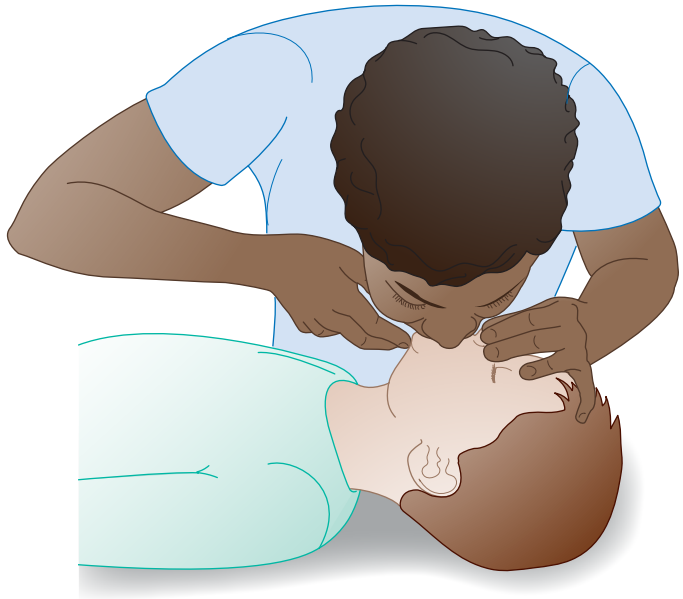

Fig. 79.8 Rescue breathing in a child. The rescuer's mouth covers the child's mouth, creating a mouth-to-mouth seal. One hand maintains the head-tilt; the thumb and forefinger of the same hand are used to pinch the child's nose. The other hand lifts the child's jaw.

Impending respiratory failure in children with lower airway obstruction can be insidious. When diagnosed early in a school-age child who is cooperative, respiratory failure can potentially be averted through judicious use of noninvasive support, including heated, high-flow nasal cannula (HFNC) therapy, continuous positive airway pressure (CPAP), or bilevel positive airway pressure (BiPAP). Endotracheal intubation should be performed only by skilled providers, preferably in a hospital setting, because there is a high risk of cardiorespiratory compromise in patients with lower airway obstruction during the procedure.

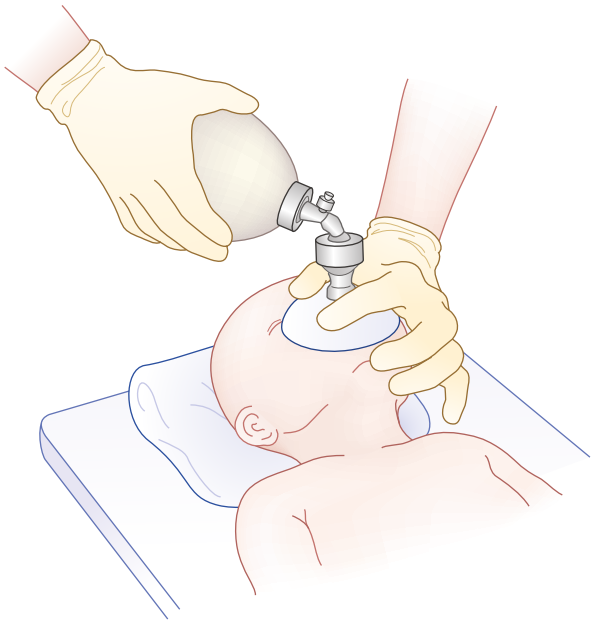

Fig. 79.9 "C-E" grip to secure a mask to a child's face with appropriate seal.

Parenchymal Lung Disease

Parenchymal lung disease includes a heterogeneous list of conditions, such as pneumonia, pediatric acute respiratory distress syndrome (PARDS), pneumonitis, bronchiolitis, bronchopulmonary dysplasia, cystic fibrosis, and pulmonary edema. The commonalities of these conditions are their effects on the small airways and alveoli, including inflammation and exudation leading to consolidation of lung tissue, decreased gas exchange, and increased work of breathing. Clinical management of these conditions includes specific treatment as indicated (e.g., antibiotics for bacterial pneumonia) and supportive care with oxygen, noninvasive respiratory support (e.g., HFNC, CPAP, or BiPAP), or invasive mechanical ventilation. The severity of work of breathing and degree of oxygenation or ventilation failure determine the degree of respiratory support needed and should be expected to evolve with time.

Airway and Breathing Management

Rescue Breathing

If a child is unconscious and not breathing effectively or apneic, **rescue breathing** should be provided. The provider should open the airway with the head-tilt/chin-lift maneuver and attempt mouth-to-mouth ventilation (Figs. 79.7 and 79.8). In trauma patients with suspected cervical spine injuries, a jaw thrust should be performed without the head-tilt maneuver. If ventilation is unsuccessful, the airway is repositioned, and ventilation should be attempted again.

Bag-Mask Ventilation

Ventilation with a bag-mask apparatus can be as effective as endotracheal intubation and safer when the provider is inexperienced with intubation. Bag-mask ventilation (BMV) requires training to ensure that the provider is competent to select the correct mask size, open the child's airway, form a tight seal between the mask and the child's face, deliver effective ventilation, and assess the effectiveness of ventilations. An appropriately sized mask is one that fits over the child's mouth and nose but does not extend below the chin or over the eyes. An adequate seal is best achieved through a combination "C-E" grip on the mask, in which the thumb and index finger form the letter "C" on top of the mask, holding the mask onto the child's face, and the remaining three fingers form an "E" grip under the child's mandible, holding the jaw forward without pressing on the soft tissues and extending the head up toward the mask. Using this method, the care provider can secure the mask to the child's face with one hand and use the other hand to compress the ventilation bag (Fig. 79.9).

The provider may have to move the head and neck through a range of positions to find the one that best maintains airway patency with adequate chest rise. In infants and young children, optimal ventilation is often provided when the child's head is in the neutral sniffing position without hyperextension of the head. Poor chest rise or persistent hypoxemia indicate inadequate ventilation. In this setting, the care provider should recheck the mask's seal on the child's face, reposition the child's head, and consider suctioning the airway. If these maneuvers do not restore ventilation, the provider should consider placement of a nasopharyngeal or oral airway. The inability to ventilate a patient with positive pressure after the previous measures is an emergency requiring expert consultation while preparing for endotracheal intubation.

Endotracheal Intubation

A child generally requires intubation when at least one of these conditions exists: (1) the child is unable to maintain airway patency or protect against aspiration (as occurs in settings of neurologic compromise such as seizures or traumatic brain injury); (2) the child is failing to maintain adequate oxygenation despite supplemental oxygen or noninvasive therapies; (3) the child cannot be adequately ventilated with evidence of elevated blood carbon dioxide levels and an unsafe acid-base balance; (4) sedation and/or paralysis is required for a procedure; (5) the need to decrease metabolic demand by sedating the patient to support extrapulmonary organs (e.g., septic shock or heart failure) is present; and (6) providers anticipate a deteriorating course that will eventually lead to any of the first five conditions. It should be noted that in centers experienced in noninvasive respiratory support, a trial of HFNC, CPAP, or BiPAP may be indicated based on the specific clinical scenario.

There are few *absolute contraindications* to tracheal intubation, but experts generally agree that in settings of known complete airway obstruction (e.g., severe subglottic stenosis), endotracheal intubation should be avoided, and emergency cricothyroidotomy or tracheostomy performed instead. It is important to assess a patient's airway before initiating endotracheal intubation. Any history of a difficult airway (difficult to intubate) or critical airway (unable to bag-mask ventilate) should prompt further investigation and expert consultation. Both history and physical exam features such as limited mouth opening, limited neck mobility, or micrognathia should raise concern for further assessment. Another important consideration is to ensure that providers maintain appropriate cervical spine (C-spine) protection during the intubation procedure when neck or spinal cord injury is suspected.

A critical phase of the intubation procedure is the preprocedural preparation, when the provider ensures all the equipment and staff needed for safe intubation are present and functioning. An easy pneumonic for this is **SOAP MM**: *suction* (Yankauer suction catheter attached to wall suction); *oxygen* (both preoxygenation of the patient and devices needed to deliver oxygen, such as a bag-mask); *airway* (appropriately sized endotracheal tube and laryngoscope as well as adjunct airway devices); *people* (all those needed during and immediately after the procedure, including respiratory therapists and nurses); *monitor* (pulse oximetry, ECG, blood pressure, capnography); and *medications* (sedation and often neuromuscular blockade to facilitate intubation). A simple formula for selecting the appropriately sized endotracheal tube (ETT) is:

$$\text{Uncuffed ETT size (in mm)} = \left(\frac{\text{age in years}}{4}\right) + 4$$

Cuffed ETTs should generally be 0.5 mm smaller. Providers should always have a range of ETTs available, given the heterogeneity of patients and airway size. The use of cuffed ETTs is recommended in most pediatric populations, as it may decrease the need for ETT changes caused by difficulty ventilating and may decrease the risk of aspiration.

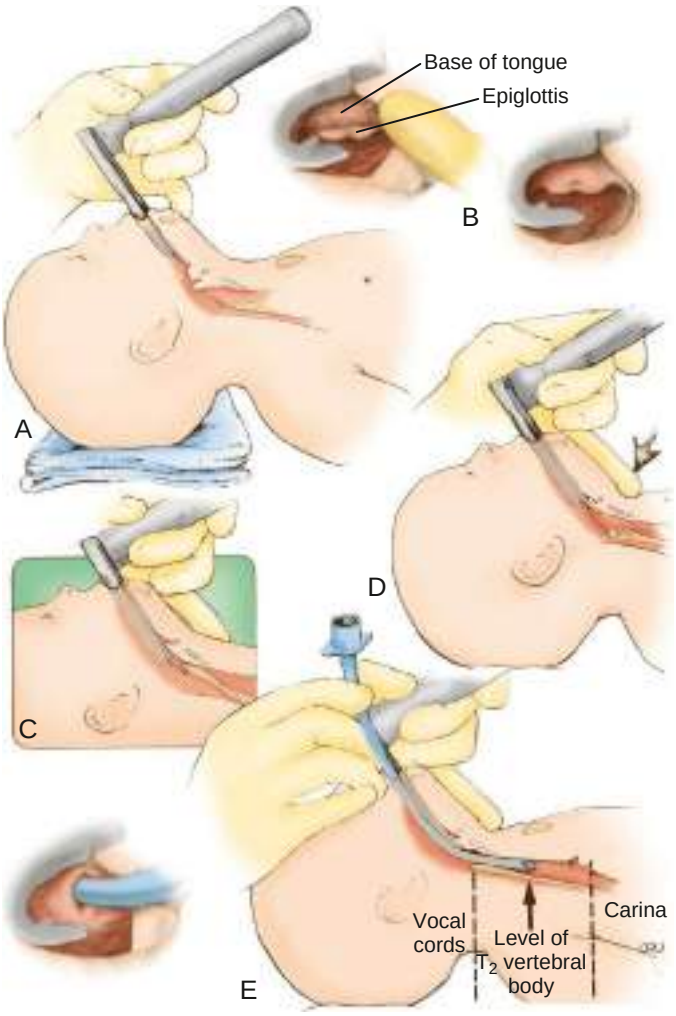

Fig. 79.10 A-E, Tracheal intubation technique. (*From Fleisher G, Ludwig S. Textbook of Pediatric Emergency Medicine, Baltimore: Williams & Wilkins;1983:1250.*)

Analgesia is recommended to reduce metabolic stress, discomfort, and anxiety during intubation. Pretreatment with a sedative, an analgesic, or an anesthetic or dissociative medication and potentially a neuromuscular relaxing agent (paralytic agent) is recommended unless the situation is emergent (e.g., cardiac arrest) and the administration of drugs would cause an unacceptable delay. Neuromuscular blocking agents should generally be avoided in patients who cannot be bag-mask ventilated because if the patient cannot be successfully intubated and cannot be bag-mask ventilated, they may progress to cardiopulmonary arrest.

Because many intubations in critically ill children are emergency procedures, providers should be prepared to rapidly intubate (Fig. 79.10). Rapid sequence intubation (RSI)—the process of intubating with a sedative (etomidate, ketamine, propofol) and neuromuscular blockade (rocuronium, succinylcholine) preintubation medications (order of administration not important)—is not always feasible in critically patients because BMV is necessary to maintain oxygenation and ventilation due to severe lung disease or intracranial hypertension. The routine use of cricoid pressure is not recommended because it does not decrease the risk of regurgitation of stomach contents, and it can impede effective BMV and airway visualization. Although there is a risk of regurgitation and aspiration, supporting the patient during induction and supporting rapid intubation is critical to minimize the risk to the patient.

Once the patient is intubated, proper ETT placement should be assessed by auscultation of breath sounds, observation of symmetric chest rise, and analysis of exhaled carbon dioxide (CO_2) by a colorimetric device or a capnographic device that quantifies CO_2 elimination. Chest radiography should be obtained to confirm appropriate tube position. Clinicians should assess ETT cuff pressures to minimize the risk of airway trauma.

RECOGNITION AND MANAGEMENT OF SHOCK

Shock occurs when oxygen and nutrient delivery to the tissues is inadequate to meet metabolic demands (see Chapter 85). A diagnosis of shock does not require the presence of hypotension. It is important for providers to recognize that **shock can occur with hypertension, normotension, or hypotension**. In early *compensated* shock, blood pressure is maintained, and oxygen delivery is mostly preserved through compensatory mechanisms such as tachycardia, increased systemic vascular resistance, or increased cardiac contractility. When compensatory mechanisms fail or are inadequate, the patient progresses to *decompensated* shock, which is defined by hypotension and organ dysfunction. If shock is not rapidly identified and treated, it can progress to multisystem organ dysfunction, cardiac arrest, and death.

Shock is also often described according to the underlying pathophysiology, which dictates the appropriate therapeutic response. **Hypovolemic shock** is the most common type of shock in children worldwide, usually related to fluid losses from severe diarrhea. Hemorrhagic shock is a specific type of hypovolemic shock after trauma or other causes of bleeding. **Distributive shock** occurs because of pathogenic dilation of the body's blood vessels and is often accompanied by relative intravascular hypovolemia due to capillary leak and "third-spacing" of intravascular fluids into the extravascular compartment. The most common causes of distributive shock are sepsis, anaphylaxis, and burn injuries, in which release of inflammatory cytokines causes massive capillary leak of fluid and proteins, leading to low oncotic pressure and intravascular volume. In the setting of myocardial dysfunction, a child has tissue hypoperfusion from **cardiogenic shock**. Common causes of cardiogenic shock are myocarditis, cardiomyopathy, and congenital heart disease, often in the postoperative setting. Severe sepsis and septic shock are often accompanied by myocardial dysfunction, and children with septic shock thus frequently manifest components of hypovolemic, distributive, and cardiogenic shock. **Obstructive shock** occurs when cardiac output is lowered by obstruction of blood flow to the body, as occurs with pericardial tamponade, tension pneumothorax, or massive pulmonary embolism. **Dissociative shock** manifests with normal cardiac and volume status but poor oxygen delivery due to severe anemia and carbon monoxide or cyanide poisoning.

The evaluation of a child in shock should proceed based on the primary, secondary, and tertiary assessments. Initial resuscitation should include the administration of crystalloid fluids in 10-20 mL/kg aliquots up to 60 mL/kg in the first hour if hypotension is present while paying close attention for signs of volume overload. If shock persists, volume overload is evident, or myocardial dysfunction is suspected, vasoactive infusions (e.g., epinephrine, norepinephrine) should be initiated. In hospital settings, catecholamine-dependent shock should trigger providers to consider placing a central venous catheter for stable venous access and an arterial line for continuous blood pressure monitoring. Laboratory assessment should include studies of renal and liver function; acid-base balance, including the presence of lactic acidosis, hypoxemia, and/or hypercapnia; and evidence of coagulopathy or disseminated intravascular coagulation to assess for signs of end-organ dysfunction and response to treatment. Assessment of peripheral perfusion, mental status, and urine output are also important to monitor. Treatment of the various etiologies of shock is noted in Chapter 85.

RECOGNITION AND TREATMENT OF ARRHYTHMIAS

In the advanced life support setting, arrhythmias are most usefully classified according to the observed heart rate (i.e., bradycardia or tachycardia) and the presence of cardiopulmonary compromise (e.g., altered mental status, hypotension, signs of shock). If the primary survey identifies a child with an abnormal heart rate and altered mental

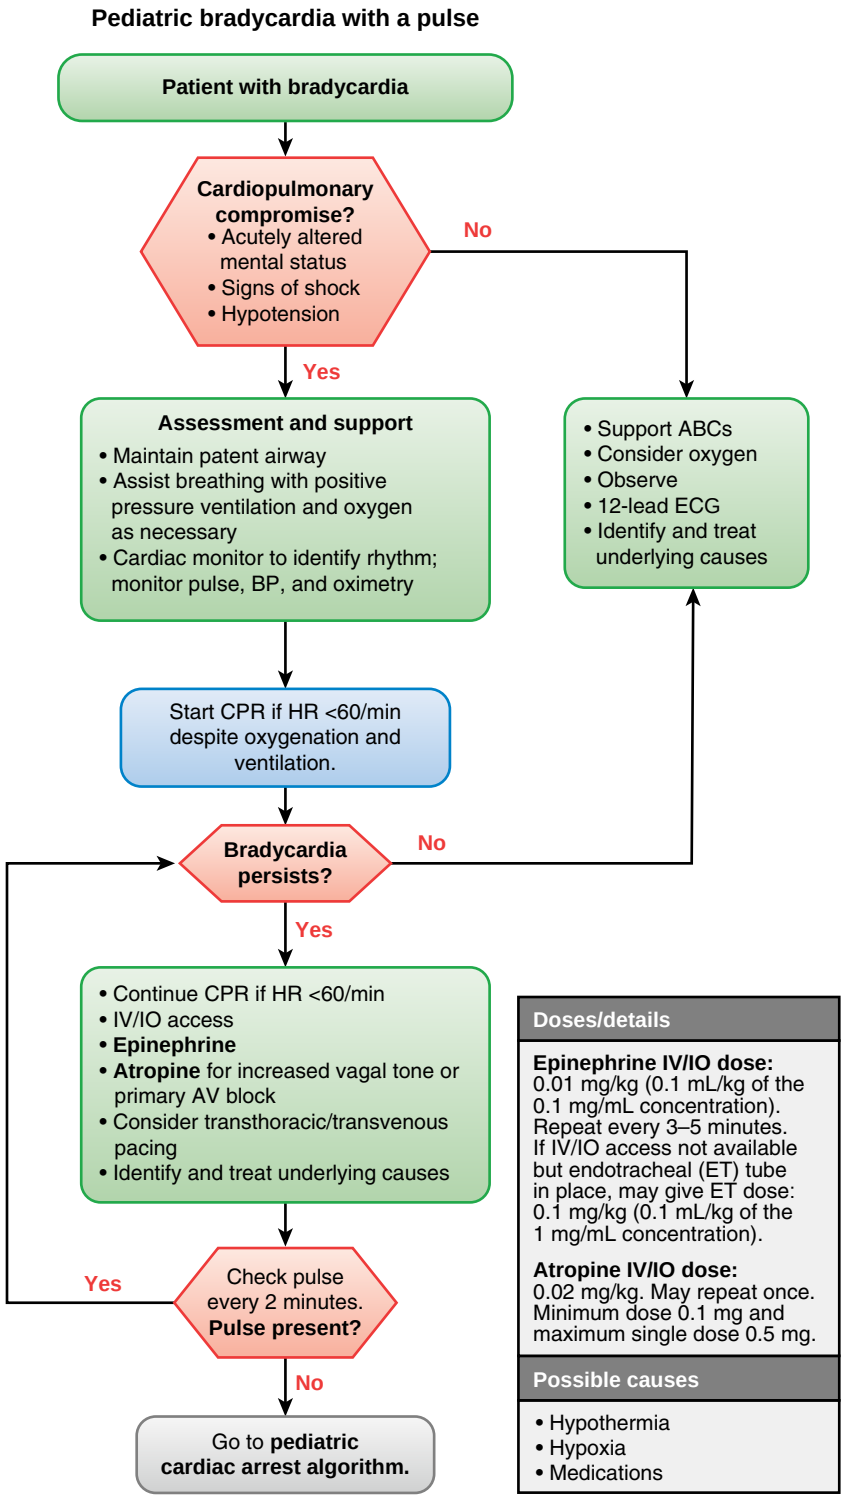

Fig. 79.11 Pediatric advanced life support: Bradycardia with a pulse algorithm. ABCs, Airway, breathing, and circulation; AV, atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate; IO/IV, intraosseous/intravenous. (*From Topjian AA, Raymond TT, Atkins D, et al. Part 4: Pediatric Basic and Advanced Life Support: 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation. 2020;142[16 Suppl 2]:S469-S523.*)

status or other signs of shock or hypotension, the rhythm is inadequate no matter its rate.

Bradyarrhythmias

By definition, a child is *bradycardic* when the heart rate is slower than the normal range for age (see Table 79.1). Sinus bradycardia can be a harmless incidental finding in an otherwise healthy person and is not usually associated with cardiac compromise. A clinically significant bradycardia occurs when the heart rate is slow and there are signs of systemic hypoperfusion (i.e., pallor, altered mental status, hypotension, acidosis). Symptomatic bradycardia occurs most often in the setting of hypoxemia but can also be caused by hypoglycemia, hypocalcemia, other electrolyte abnormalities, hypothermia, heart block, and intracranial hypertension. Bradyarrhythmias are often the most common *prearrest* rhythms in young children.

Initial management of symptomatic bradycardia includes support or opening of the airway and confirming or establishing adequate oxygenation and ventilation (Fig. 79.11). After adequate oxygenation and ventilation have been confirmed, the child should be reassessed for continued bradycardia and poor perfusion. If cardiac

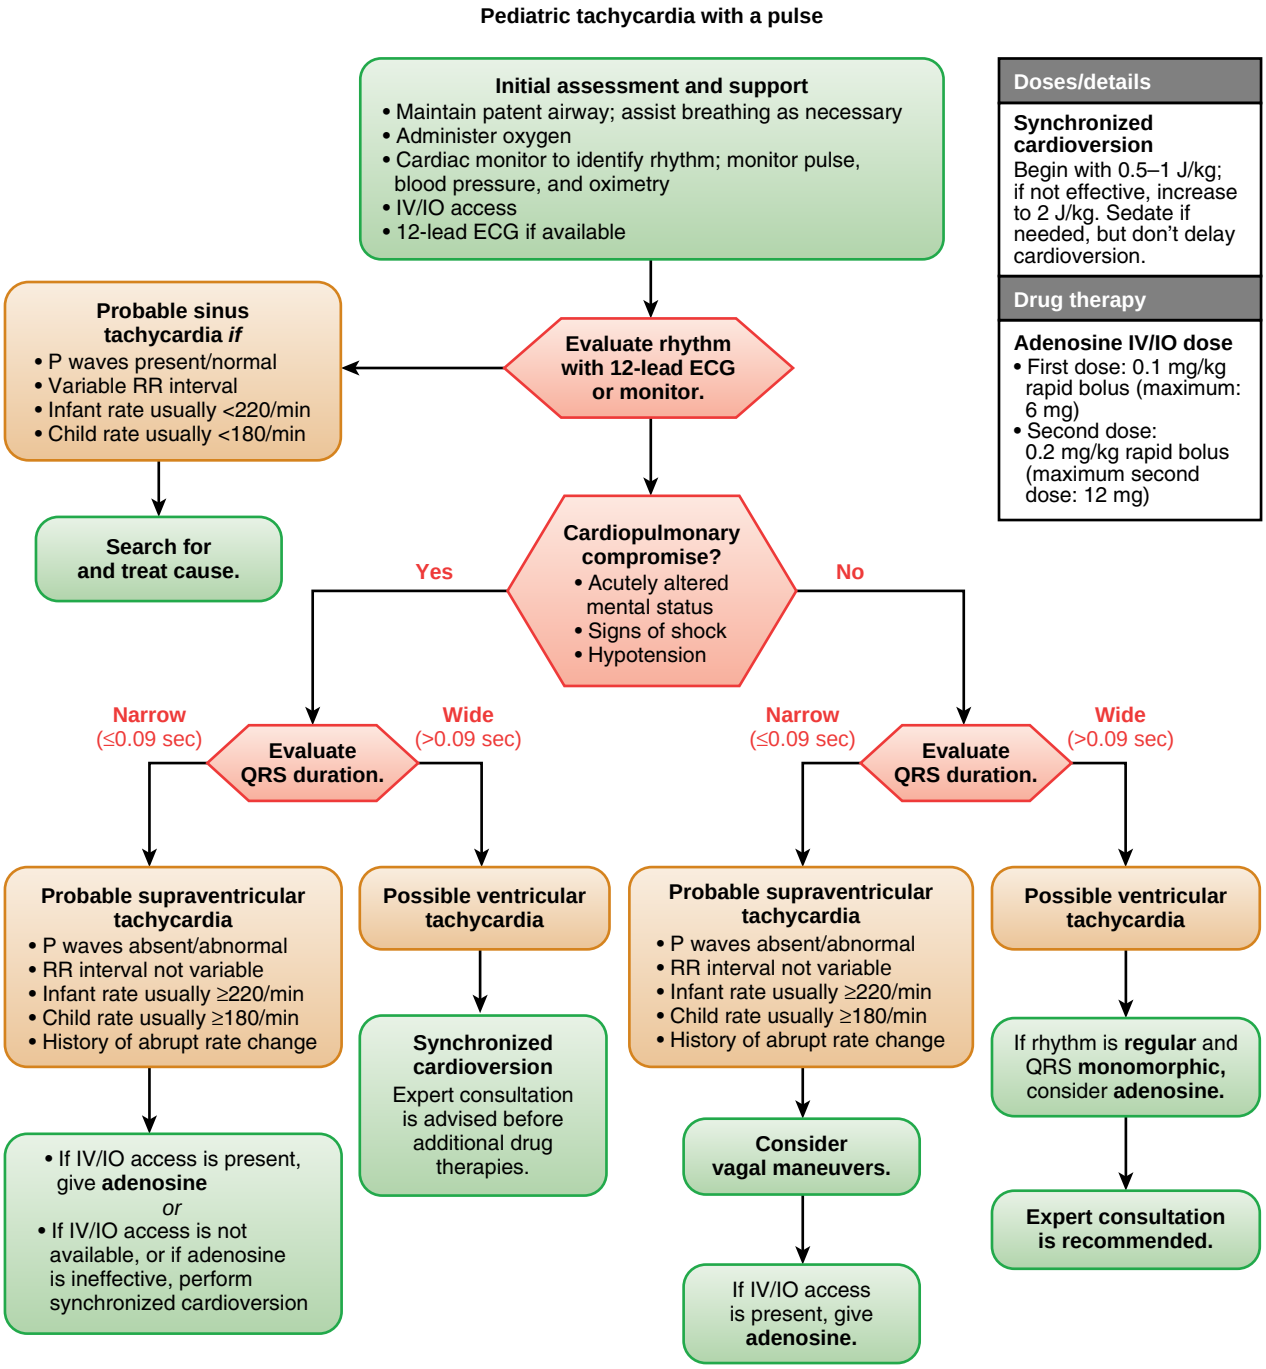

Fig. 79.12 Pediatric advanced life support: Tachycardia with a pulse algorithm. AV, Atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate; IO/IV, intraosseous/intravenous. (*From Topjian AA, Raymond TT, Atkins D, et al. Part 4: Pediatric Basic and Advanced Life Support: 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation. 2020;142[16 Suppl 2]:S469-S523.*)

compromise was solely the result of respiratory insufficiency, support of the child's airway and breathing may have been sufficient to restore normal hemodynamics. If respiratory support does not quickly correct the perfusion abnormalities, further care is based on the quality of perfusion and degree of bradycardia. *A heart rate <60 beats/min with cardiopulmonary compromise is an indication to begin CPR,* including the administration of epinephrine. If increased vagal tone or primary atrioventricular block is suspected, atropine can be administered. For cases of refractory bradycardia, cardiac pacing should be considered (see Fig. 79.11).

Tachyarrhythmias

Tachyarrhythmias represent a wide variety of rhythm disturbances of atrial and ventricular origin (see Chapter 484). Sinus tachycardia is a normal physiologic response to the body's need for increased cardiac output or oxygen delivery, as occurs with fever, exercise, or stress. It can also occur in more pathologic states, such as hypovolemia, anemia, pain, anxiety, thyrotoxicosis, and shock. Non–sinus tachyarrhythmias that do not originate in the sinus node are often categorized as either *narrow complex rhythms* (i.e., originating in the atrium, such as supraventricular tachycardia or atrial flutter) or *wide*

Table 79.5 Medications for Pediatric Resuscitation and Arrhythmias

MEDICATION	DOSE	REMARKS
Adenosine	0.1 mg/kg (max dose: 6 mg) Repeat: 0.2 mg/kg (max dose: 12 mg)	Monitor ECG Rapid IV/IO bolus with flush
Amiodarone	5 mg/kg IV/IO; repeat 5 mg/kg doses up to 15 mg/kg Max dose: 300 mg	Monitor ECG and blood pressure, as it can cause hypotension Give over 20-60 min (can give via IV push for patients in cardiac arrest) Use caution when administering with other drugs that prolong QT interval (consider expert consultation)
Atropine	IV/IO: 0.02 mg/kg Minimum dose: 0.1 mg for bradycardia treatment Max dose: • Child: 0.5 mg • Adolescent: 1 mg Repeat once if needed ETT* 0.04-0.06 mg/kg Max dose: 2 mg	Higher doses may be used with organophosphate poisoning ETT dosing only if no IV/IO access
Calcium chloride (10%) Calcium gluconate	20 mg/kg IV/IO 50-100 mg/kg Max dose: 2 g	Administer slowly; fast push can cause heart block/asystole Use only with documented hypocalcemia
Dextrose	0.5-1 g/kg IV/IO • D10W: 5-10 mL/kg • D25W: 2-4 mL/kg • D50W: 1-2 mL/kg	Recheck serial blood sugars after administration, as hypoglycemia can recur
Epinephrine	IV/IO: 0.01 mg/kg (0.1 mL/kg of the 0.1 mg/mL concentration) Max dose: 1 mg ETT*: 0.1 mg/kg (0.1 mL/kg of the 1 mg/mL concentration) Max dose: 2.5 mg	May repeat every 3-5 min as needed Only give via ETT if no IV/IO access
Lidocaine	IV/IO: 1 mg/kg bolus Max dose: 100 mg Infusion: 20-50 µg/kg/min ETT*: 2-3 mg/kg	Repeat bolus dose if infusion is initiated >15 min after initial bolus
Magnesium sulfate	25-50 mg/kg IV/IO Max dose: 2 g	Can cause hypotension Administer over 10-20 min; faster in torsades de pointes
Naloxone	IV/IO/IM/SQ: 0.1 mg/kg for full reversal Max dose 2 mg IN: 4 mg spray; may repeat q2-3min ETT*: 2-3 times IV dose	Use lower doses in patients with opioid-induced respiratory depression from therapeutic opioid dosing (0.001-0.005 mg/kg) May need to redose every 2-3 minutes, as half-life is shorter than most narcotics ETT if IV/IO routine not available
Sodium bicarbonate	1 mEq/kg IV/IO	Administer slowly; ensure adequate ventilation

*Flush with 5 mL of normal saline and follow with 5 ventilations.
D5W, 5% Dextrose in water; IO, intraosseous; IV, intravenous; ETT, endotracheal tube; IM, intramuscular; IN, intranasal.

complex rhythms (i.e., rhythms of ventricular origin, such as ventricular tachycardia).

The initial management of tachycardia should include assessment for cardiopulmonary compromise (Fig. 79.12). If the patient has evidence of cardiopulmonary compromise (i.e., hypotension, altered mental status, or other signs of shock), further treatment is based on whether the QRS complex of the ECG is narrow (≤0.09 sec) or wide (>0.09 sec). For narrow complex tachycardia, providers must distinguish between sinus tachycardia and supraventricular tachycardia (SVT). In **sinus tachycardia**, the history and onset are consistent with a known cause of tachycardia, such as fever or dehydration. Sinus tachycardia usually has some degree of rate variability, and p-waves are consistently present on the ECG and are of normal morphology and axis. Treatment is then geared toward identifying and treating the cause of sinus tachycardia. In **SVT**, onset is often abrupt without prodrome, and p-waves are absent or have a nonsinus ECG axis. When SVT is associated with cardiopulmonary compromise, providers should rapidly move to convert the child's heart rhythm back to sinus rhythm. If the child already has IV access, adenosine should be administered (Table 79.5). Adenosine has an extremely short half-life, so administration through an IV close to the heart (e.g., upper extremity) is best. Adenosine should be administered with a three-way stopcock inline so that it can be given and immediately flushed into the circulation. If the child does not have IV access or adenosine does not successfully convert the heart rhythm back to sinus rhythm, then **synchronized cardioversion** (0.5-1.0 joule [J]/kg) should be performed. For wide-complex tachycardia (i.e., **ventricular tachycardia [VT]**) with a pulse and evidence of cardiopulmonary compromise, synchronized cardioversion should be performed.

For patients with tachycardia without cardiopulmonary compromise, the rhythm assessment proceeds in the same fashion, but treatment potentially differs. Vagal maneuvers can be considered for SVT in the stable patient, followed by administration of adenosine and obtaining expert consultation. Wide-complex tachyarrhythmias without cardiovascular compromise should also trigger expert consultation before administration of antiarrhythmic medications. If the rhythm is monomorphic, adenosine can be given, as some stable wide-complex tachycardias are SVT with aberrant conduction and thus have a wide QRS complex. Patients should be continually reassessed for development of cardiovascular compromise.

CARDIAC ARREST AND CARDIOPULMONARY RESUSCITATION

Overview

Cardiac arrest occurs when the heart fails as an effective pump and blood flow ceases. Outwardly, the patient in cardiac arrest presents as unresponsive and apneic with no palpable pulse. Internally, the cessation of cardiac output and oxygen delivery causes progressive tissue ischemia and organ failure. If not rapidly reversed, cardiac arrest leads to progressive deterioration in brain, heart, and other organ function, such that resuscitation and recovery are no longer possible. Cardiac arrest outcomes in children have improved as a result of improvements in the recognition of deteriorating patients and delivery of high-quality CPR. Prehospital and hospital providers should understand that pediatric cardiac arrest is an intervenable process for which favorable outcomes are common. Early recognition and rapid treatment with high-quality CPR can be lifesaving.

Prevention of Cardiac Arrest

Out-of-hospital cardiac arrest (OHCA) occurs due to a variety of causes, including sudden infant death syndrome (SIDS), drowning, foreign body aspiration, poisoning or drug overdose, and trauma. Sudden cardiac arrest due to arrhythmias or cardiac disease do occur (usually in adolescents and those with preexisting congenital heart disease) and should be recognized and promptly treated, but most pediatric OHCAs have an underlying respiratory etiology. Preventive measures such as "back to sleep" for infants to lower the risk of SIDS (see Chapter 423), child supervision around bodies of water, and minimizing access to high-risk choking foods substantially decrease the incidence of cardiac arrest. Recognition of the child with respiratory distress or impending respiratory failure and delivery of appropriate care, as outlined earlier, is the most common and practical means of preventing pediatric OHCA.

In hospitalized children, cardiac arrest is most often the result of the progression or worsening of an underlying respiratory, cardiac, or neuromuscular disease process. Most pediatric in-hospital cardiac arrests (IHCAs) occur in the setting of progressive respiratory failure or shock. Recognition of deteriorating patients, transfer to monitored settings (i.e., intensive care units), and institution of appropriate directed and supportive therapies are effective means of preventing IHCA or ensuring that if it does occur, care is delivered in a well-equipped and prepared setting.

Recognition of Cardiac Arrest

Cardiac arrest is recognized from general assessment and primary survey findings consistent with a pale or cyanotic child who is unresponsive, apneic, and pulseless. Even experienced providers have a relatively high error rate when asked to determine presence or absence of pulse in a child. Therefore lay rescuers should begin CPR immediately for any patient without signs of life. Healthcare providers can palpate for a pulse for up to 10 seconds but should provide CPR unless a pulse is definitively felt.

Although initial responders should focus on signs of lifelessness when determining if a patient requires CPR, recognition and understanding of cardiac arrest rhythms is also important for providers. Most pediatric cardiac arrest rhythms are "nonshockable" (i.e., asystole, pulseless electrical activity [PEA], or bradycardia with cardiopulmonary compromise). It is important pediatric providers recognize that bradycardia with cardiopulmonary compromise that does not swiftly resolve with ventilation and oxygenation should be treated with CPR. "Shockable" rhythms (ventricular fibrillation [VF] and pulseless VT) account for a relatively small proportion of pediatric OHCAs or IHCAs. However, these rhythms can occur as a secondary rhythm later in arrest. Because these rhythms require prompt defibrillation in addition to high-quality CPR, it is important to recognize and be prepared to treat VF or pulseless VT when present.

Fig. 79.13 Hand position for infant CPR for the single provider. The two-finger technique.

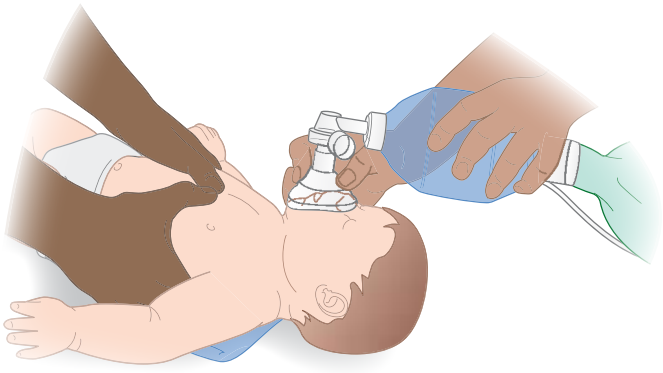

Fig. 79.14 Hand position for infant CPR for two providers. The 2-thumb-encircling hands technique.

Basic Life Support

The AHA Pediatric BLS algorithms for both single- and two-rescuer scenarios are depicted in Figures 79.1 and 79.2. Upon recognition of cardiac arrest, rescuers should begin CPR with both chest compressions and rescue breaths. Single rescuers who witness a sudden collapse should activate the emergency response system and retrieve an automated electronic defibrillator (AED) or defibrillator, if immediately available, before starting compressions, as many of these children have shockable rhythms. For single rescuers treating children in cardiac arrest without a witnessed sudden collapse, CPR should begin immediately with cycles of 30 compressions followed by two rescuer breaths for at least 2 minutes. An AED should be applied, and automated directions followed as soon as it is available. When two or more rescuers are present, one rescuer should be responsible for activating the emergency response system and retrieving an AED while the other rescuer(s) begins CPR. When both rescuers are providing CPR for an infant or prepubescent child, cycles of 15 compressions followed by two ventilations should be provided. Adolescents should receive cycles of 30 compressions and two ventilations regardless of the number of rescuers.

Components of High-Quality Cardiopulmonary Resuscitation

The goal of CPR is to provide temporary blood flow and oxygen delivery to the body during cardiac arrest. High-quality CPR that meets established goals and metrics optimizes this blood flow and is associated with improved outcomes from cardiac arrest. **Components of high-quality CPR include optimal hand positioning, appropriate chest compression rate, adequate chest compression depth, allowing for full chest recoil, minimization of interruptions, and appropriate ventilation rate.**

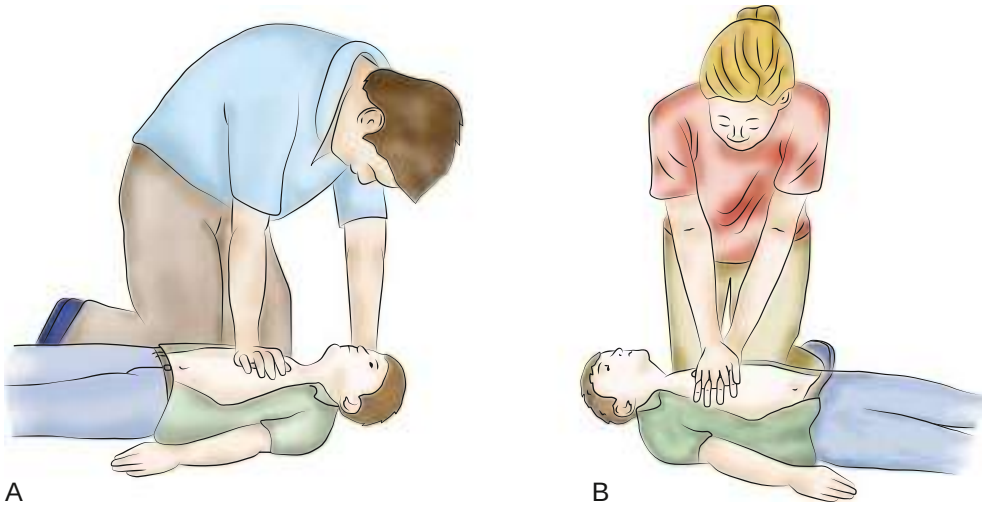

Fig. 79.15 Hand position for child CPR. A, One-handed chest compressions in a child. B, Two-handed chest compressions in a child or adult.

Hand positioning and CPR technique: Chest compressions in infants <1 year old performed by a single provider may be performed by placing two fingers or two thumbs just below the intramammary line (Fig. 79.13). When two providers are present, the two-thumb-encircling hands technique (Fig. 79.14) is recommended unless the rescuer cannot physically encircle the victim's chest, in which case two fingers can be used. If goal depths cannot be reached with these techniques, it is reasonable to use the heel of one hand for chest compressions. For children >1 year old, the care provider should perform chest compressions over the lower half of the sternum with the heel of one hand, or with two hands as used for adult resuscitation (Fig. 79.15). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a backboard should be placed under the child's back and the hospital bed should be placed into "CPR mode" when applicable to maximize the effectiveness of compressions.

Chest compression mechanics: Chest compressions should be provided at a rate of **100-120 compressions per minute**. The goal chest compression depth for infants and children is at least **one-third the anterior-posterior diameter of the chest**, which is approximately 4 cm (1.5 inches) in infants and 5 cm (2 inches) in children. For children who have reached puberty, the adult depth of 5-6 cm can be used. Rescuers should avoid leaning and **allow the chest to fully recoil** after each compression in order to facilitate venous return to the heart. Resuscitation teams should seek to **minimize the duration and frequency of chest compression interruptions** during CPR. These chest compression mechanics can be measured during CPR through CPR quality-monitoring defibrillators, which are now widely used.

Advanced Life Support

The AHA PALS algorithm for cardiac arrest is depicted in Figure 79.16. Chest compressions should be delivered as detailed earlier. Ventilation is a key component of pediatric CPR because most patients have concomitant respiratory failure. For children without an advanced airway in place, chest compressions are paused to allow for the delivery of ventilations via mask with the compression-to-ventilation ratios discussed previously. For children with an advanced airway at the time of arrest, ventilations should be provided asynchronously (i.e., without interrupting chest compressions) at a rate of 20-30 breaths/minute. Providers should avoid overventilation during CPR, as this may increase intrathoracic pressure and decrease venous return to the heart.

Epinephrine is administered during CPR to increase systemic vascular resistance and coronary perfusion pressure in order to restore spontaneous circulation. Epinephrine should be administered intravenously or intraosseously (IO), though it can be administered via ETT if IV or IO access is not available (see Table 79.5). **The first dose of epinephrine should be given within 5 minutes of the onset of cardiac arrest and repeated every 3-5 minutes** until return of spontaneous circulation (ROSC) is achieved. Pulse and rhythm checks should be performed approximately every 2 minutes but should not last more than 10 seconds.

CPR quality can also be gauged by monitoring the patient's physiologic response to resuscitation. End-tidal carbon dioxide, which reflects pulmonary blood flow, can be an indicator of the adequacy of chest compressions. Diastolic blood pressure, measured via an arterial line, is used as a surrogate of coronary perfusion pressure, and values are therefore correlated with the likelihood of ROSC. Either of these tools can be used during CPR by practitioners appropriately trained in the nuances of their interpretation.

Defibrillation and Antiarrhythmic Medications

For those children with VF or pulseless VT, emergency defibrillation is indicated (see Fig. 79.16). Defibrillator pads should be applied to the bare chest during CPR regardless of initial rhythm, as these rhythms can develop later during cardiac arrest. Lay providers should follow the verbal instructions given by the AED. Ideally, the AED used for children <8 years of age should deliver an attenuated adult dose or should be designed for children; if neither of these options is available, a standard adult AED should be used. Healthcare providers should use either an AED or a manual defibrillator. An **initial defibrillation should be provided at a dose of 2 J/kg** with subsequent dosing per the PALS algorithm. CPR should be promptly resumed after each defibrillation attempt, with additional rhythm assessments and defibrillation attempts every 2 minutes while a shockable rhythm persists. Either amiodarone or lidocaine can be given as an antiarrhythmic for shock-refractory VF or VT (see Table 79.5).

Identification and Treatment of Underlying Causes of Cardiac Arrest

Pediatric cardiac arrest can occur because of a discrete and clear event (e.g., drowning), due to the progression of underlying disease processes (e.g., refractory hypoxemic respiratory failure), or for reasons that are unclear to the resuscitation team at the time of the arrest. In addition to providing high-quality CPR, reversing the underlying cause of cardiac arrest is critical in order to restore and maintain spontaneous circulation. Focused evaluation of likely etiologies based on the patient's history, risk factors, physical exam, and other findings often reveals addressable cause. Additionally, providers should systematically address common and correctable causes of cardiac arrest (e.g., the "Hs and Ts"; Table 79.6).

Duration of CPR

Unsurprisingly, children who receive prolonged CPR have worse outcomes than those who require brief CPR. However, previous assertions

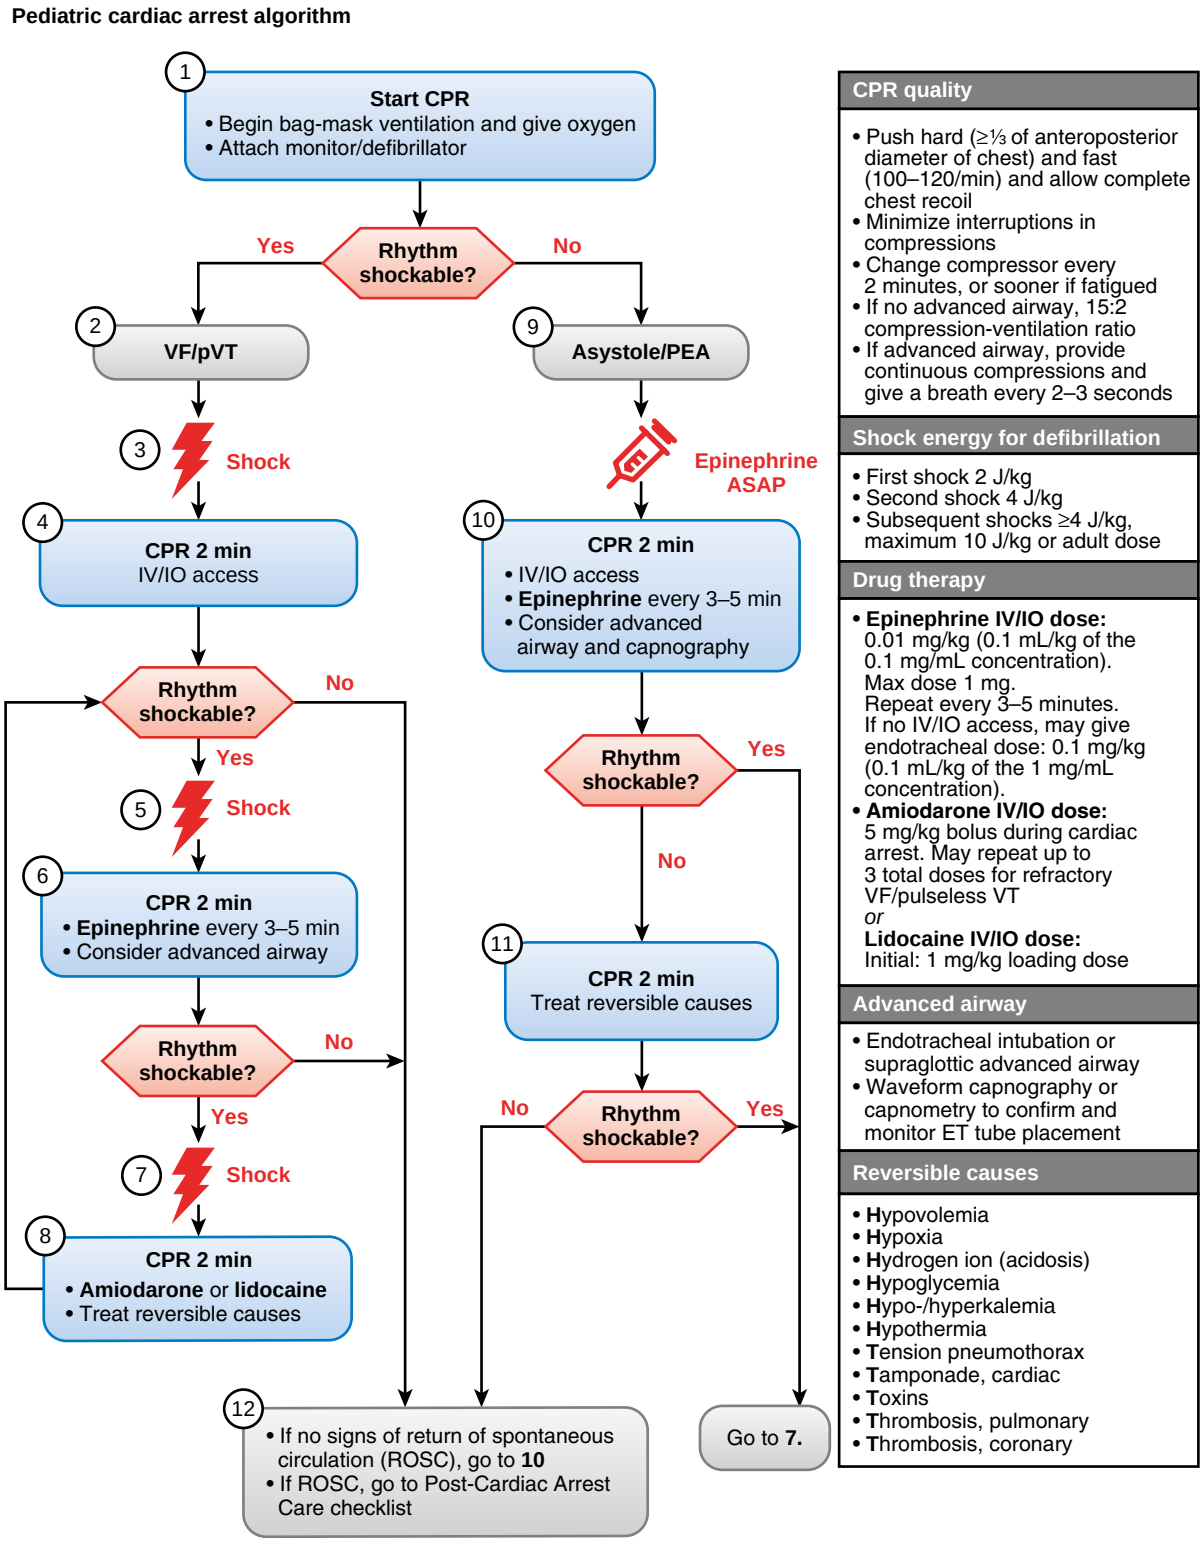

Fig. 79.16 Pediatric advanced life support cardiac arrest algorithm. CPR, Cardiopulmonary resuscitation; IO/IV, intraosseous/intravenous; PEA, pulseless electrical activity; VF/VT, ventricular fibrillation/tachycardia. (*From Topjian AA, Raymond TT, Atkins D, et al. Part 4: Pediatric Basic and Advanced Life Support: 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation. 2020;142[16 Suppl 2]:S469-S523.*)

that CPR >20 minutes in duration was futile have been disproven. More than 15% of children who received >35 minutes of CPR for IHCA survived to hospital discharge in one large registry study. Therefore decisions regarding futility and when to cease resuscitation efforts should take into account patient factors, goals of care, arrest etiology and characteristics, and a host of other factors, rather than CPR duration alone.

Extracorporeal Membrane Oxygenation and Extracorporeal Cardiopulmonary Resuscitation

Extracorporeal membrane oxygenation (ECMO) is a modified form of cardiopulmonary bypass that can be employed in children with severe cardiac or respiratory failure. Blood is removed from a large central vein, carried through tubing to an oxygenator for gas

Table 79.6 Potentially Reversible Causes of Cardiac Arrest

CONDITION	COMMON CLINICAL SETTINGS	TREATMENT
THE H'S		
Hypovolemia	Dehydration, hemorrhage, major burns, diabetes, gastrointestinal losses, shock, and trauma	Administer fluids For hemorrhage, administer packed red blood cells and other blood products
Hypoxemia	Upper airway obstruction (croup, anaphylaxis, foreign body) Lower airway obstruction (asthma, bronchiolitis) Parenchymal lung disease (pneumonia) Restrictive lung disease (pleural effusion)	Provide supplemental oxygen Confirm endotracheal tube placement and chest rise
Hydrogen ion (acidosis)	Preexisting acidosis, diabetes, diarrhea, drugs and toxins, prolonged resuscitation, renal disease, and shock	Reassess the adequacy of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement Ensure adequate ventilation and avoid concomitant respiratory acidosis Administer IV fluids May consider bicarbonate administration with documented severe acidosis
Hypoglycemia	Starvation, toxin, diabetes medications, metabolic disease	Administer dextrose (glucagon if dextrose not available) Discontinue causative medications
Hyperkalemia	Metabolic acidosis, excessive administration of potassium, renal failure, drugs and toxins, vigorous exercise, hemolysis, rhabdomyolysis, tumor lysis syndrome, and clinically significant tissue injury	Stop potassium-containing fluids Stabilize cardiac membrane: calcium Treat acidosis: sodium bicarbonate Shift potassium intracellularly: sodium bicarbonate, insulin (with glucose to prevent hypoglycemia), and albuterol Promote potassium excretion: loop diuretics, Kayexalate Removal of potassium: dialysis
Hypokalemia	Diabetes, diuretic use, drugs and toxins, profound gastrointestinal losses	If profound hypokalemia is accompanied by cardiac arrest, initiate urgent IV potassium replacement
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated patient, drowning, drugs and toxins, endocrine disease, history of exposure, homelessness, extensive skin disease, spinal cord disease, and trauma	If hypothermia is severe (temperature <30°C [86°F]), defibrillation may be ineffective; initiate active internal rewarming with cardiopulmonary support; can consider extracorporeal rewarming If hypothermia is moderate (temperature 30-34°C [86-93.2°F]), actively rewarm during CPR
THE T'S		
Tension pneumothorax	Procedural complication, mechanical ventilation complication, pulmonary disease with "air leak" (including asthma, chronic obstructive pulmonary disease, and necrotizing pneumonia), thoracentesis, and trauma	Needle decompression followed by chest tube insertion or primary chest tube insertion
Cardiac tamponade	Hemorrhage, malignancy, pericarditis, trauma, cardiac surgery, post–myocardial infarction	Administer fluids to increase cardiac preload (temporizing only); obtain bedside echocardiogram, if available Perform pericardiocentesis; immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected
Toxins	Alcohol abuse, behavioral or metabolic presentation, classic toxicologic syndrome, psychiatric disease, depressed mental status of unclear etiology, medications in the home, history of depression/suicidality	Supportive care and toxin-directed therapies in consultation with a toxicologist
Thrombosis, pulmonary	Hospitalized patient, recent surgical procedure, peripartum, known risk factors for venous thromboembolism, history of venous thromboembolism, or prearrest presentation consistent with a diagnosis of acute pulmonary embolism, recent immobility or fractures	Administer fluids; augment with vasoactive medications as necessary Consider pulmonary vasodilators (e.g., inhaled nitric oxide) Consider systemic or site-directed thrombolytic therapy Consider mechanical thrombectomy Consider ECMO
Thrombosis, coronary	Known risk factors for myocardial infarction (congenital heart disease, family history of sudden cardiac death)	Consider fibrinolytic therapy Consider percutaneous coronary intervention

Adapted from Kleinman ME, Chameides L, Schexnayder SM, et al. Part 14: Pediatric advanced life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2010;122(18 Suppl 3):S876-S908.

exchange, and then returned to the body via either a vein (venovenous or VV-ECMO) or an artery (venoarterial or VA-ECMO). VV-ECMO is typically used in patients with refractory respiratory failure who require ECMO for gas exchange but continue to rely on their native cardiac function for cardiac output. VA-ECMO is used for patients with shock or cardiac failure, with or without concomitant respiratory failure, with the ECMO pump and circuit augmenting or replacing native cardiac output. The processes of determining ECMO candidacy, performing ECMO cannulation, maintaining ECMO circuit integrity, and caring for critically ill children on ECMO are

Table 79.7 Medications to Maintain Cardiac Output and for Postarrest Stabilization*

MEDICATION	DOSE RANGE	COMMENT
Dobutamine	2-20 µg/kg/min IV/IO	Inotrope, chronotrope, vasodilator
Dopamine	2-20 µg/kg/min IV/IO	Inotrope, chronotrope, vasodilator at low doses, vasoconstrictor at high doses
Epinephrine	0.01-1 µg/kg/min IV/IO	Inotrope, chronotrope, vasodilator at low doses, vasoconstrictor at medium and high doses
Milrinone	50 µg/kg IV/IO over 10-60 min then 0.25-0.75 µg/kg/min	Inodilator, lusitrope, vasodilator
Norepinephrine	0.01-1 µg/kg/min	Vasopressor; weak inotrope

*Alternative formula for calculating an infusion: Infusion rate (mL/hr) = [weight (kg) × dose (µg/kg/min) × 60 (min/hr)]/concentration µg/mL).
Data from Kleinman ME, Brennan EE, Goldberger ZD, et al. Part 5: Adult Basic Life Support and Cardiopulmonary Resuscitation Quality: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132(18 Suppl 2):S414-S435.

complex; ECMO is thus performed only at centers with appropriate expertise and equipment.

Extracorporeal support can be employed as a rescue therapy for refractory cardiac arrest. Extracorporeal CPR (ECPR), which involves cannulating and placing a patient on VA-ECMO while CPR is in progress, has been successfully used in children. Its efficacy has been best demonstrated in hospitalized children with underlying cardiac disease; AHA guidelines therefore state that it can be considered for children "with cardiac diagnoses who have IHCA in settings with existing ECMO protocols, expertise, and equipment." In addition, ECPR has been employed in patients with noncardiac etiologies of cardiopulmonary arrest who are not responding to standard resuscitation protocols.

Post–Cardiac Arrest Care

After resuscitation from cardiac arrest, patients are at risk for developing **post-cardiac arrest syndrome (PCAS)**. PCAS is composed of post–cardiac arrest brain injury, myocardial dysfunction, systemic ischemia-reperfusion response, and persistence of preexisting pathophysiology and can last for days to weeks after the cardiac arrest. Primary brain injury occurs due to hypoxia and ischemia during the no-flow (pre-CPR) and low-flow (during CPR) periods. Secondary brain injury occurs during the postarrest period. Signs and symptoms of brain injury are encephalopathy, seizures, cerebral edema, and autonomic dysfunction. Myocardial dysfunction can present as hypotension, depressed left or right ventricular systolic or diastolic function, arrhythmias, or pulmonary edema. The systemic ischemia-reperfusion response is a "sepsis-like" syndrome and has clinical findings of hyperglycemia, coagulopathy, hypovolemia, fever, and multisystem organ dysfunction. These three components combined with the precipitant that caused the arrest (e.g., septic shock or PARDS) result in varied severity of PCAS ranging from minimal symptoms, with patients returning quickly to their neurologic baseline, to severe multisystem organ failure with high risk of repeat cardiac arrest.

To address this clinical spectrum, it is important to be deliberate and vigilant in caring for the postarrest patient. Thus close postarrest observation in an intensive care unit, where the child can receive ongoing multiorgan system assessments and support, is critical. To prevent secondary brain injury, which occurs during the postarrest period, clinicians should monitor for, prevent, and treat PCAS. Hypotension is common and can lead to organ hypoperfusion. Clinicians should frequently monitor blood pressure and should do so continuously with an arterial catheter if appropriate resources are available. IV fluids and vasoactive agents such as epinephrine or norepinephrine should be used to maintain a blood pressure greater than the fifth percentile for age. Clinicians should be proactive and not wait for hypotension to occur. Rather, they should be prepared with fluids, vasoactive infusions, and clearly defined postarrest blood pressure targets. Continuous arterial blood pressure monitoring can help the provider determine the need for, and response to, inotropic and chronotropic medications (Table 79.7).

Hyperoxia (Pao_2 >300) and hypoxemia after cardiac arrest should be prevented because both can worsen secondary brain injury. Clinicians should wean supplemental oxygen after ROSC, targeting a saturation of 94–99%. In most cases, weaning supplemental oxygen when patients are saturating 100% is not harmful. For patients with hypoxemia, clinicians may need to try alternative ventilator strategies if supplemental oxygen is insufficient to achieve a saturation above 94% or higher.

Fever is common after cardiac arrest and may worsen secondary brain injury. **Targeted temperature management (TTM)** is performed with an active temperature control device and should be used for children postarrest who do not return to their neurologic baseline. Because there is no difference in survival or neurologic outcomes between patients who receive TTM 33°C (32-34°C [89.6-91.4°F]) and patients who receive TTM 36.8°C (98.2°F) (36-37.5°C [96.8-99.5°F]), either can be selected. Patients should have continuous core temperature monitoring and receive sedation and analgesics to prevent discomfort. If shivering occurs, patients should be treated with a sedative or neuromuscular blockade. Hyperthermia must be avoided.

Seizures are common after cardiac arrest and often are nonconvulsive and therefore can only be detected on an EEG. It is unclear if treatment improves outcomes; however, antiseizure medications can be administered for convulsive and nonconvulsive seizures.

Most care is supportive, but close monitoring for organ injury that can be treated (e.g., coagulopathy or adrenal insufficiency) or that may require modification of therapies (e.g., medication dose adjusting in patients with acute kidney injury) should be considered. Survivors of cardiac arrest can have long-standing neurologic, cognitive, physical, and quality-of-life deficits. Clinicians should refer children for ongoing evaluation and assessments.

Communication with the patient's family is an essential element of postarrest care, as it is for the care of any acutely ill or injured child. The family should be thoroughly briefed on the elements of the resuscitation performed, the child's condition, and ongoing medical concerns, uncertainties, or issues. The provider should be available to answer the family's questions, clarify information, and provide comfort. Other support staff, including social workers and chaplains, should be contacted, as the family wishes, to provide additional support and comfort. For situations in which the resuscitation is ongoing, it is recommended that the provider make every effort possible to have the family present at the bedside, if they wish. Family presence during CPR or other emergency resuscitative efforts, even if the child dies, is associated with a more positive medical experience than if they are excluded. In situations where the child is critically ill but stable, the family should be brought to the bedside as soon as the healthcare team deems it safe and appropriate (see Chapter 8).

PROCEDURES

Vascular Access

Venous Access

Veins suitable for cannulation are numerous, but there is considerable anatomic variation from patient to patient. In the upper extremities, the *median antecubital vein,* located in the antecubital fossa, is often the largest and easiest to access. Many veins on the dorsum of the hand are also suitable for cannulation because they are often large and easily located, and their cannulation is generally well tolerated. The *cephalic vein* is usually cannulated at the wrist, along the forearm, or at the elbow. The *median vein* of the forearm is also suitable as it lies along a flat surface of the forearm. In the lower extremity, the *great saphenous vein,* located just anterior to the medial malleolus, is accessible in most patients. The dorsum of the foot usually has a large vein in the midline, passing across the ankle joint, but catheters are difficult to maintain in

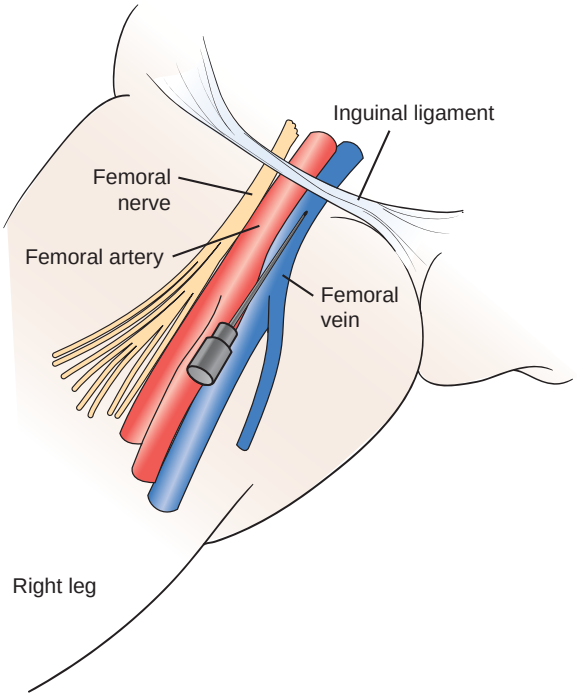

Fig. 79.17 Approach to the femoral vein. The patient is flat and supine, with the thigh slightly abducted and externally rotated. The introducer needle enters the skin 1-2 cm distal to the inguinal ligament and 0.5-1 cm medial to the pulse of the femoral artery. Remember the lateral to medial mnemonic NAVEL for nerve, artery, vein, empty space, and lymphatics. (*From Edwards LR, Malone MP, Prodham P, Schexnayder SM. Pediatric vascular access and centeses. In: Zimmerman JJ, Rotta AT, eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Philadelphia: Elsevier; 2022: Fig. 14.6, p. 102.*)

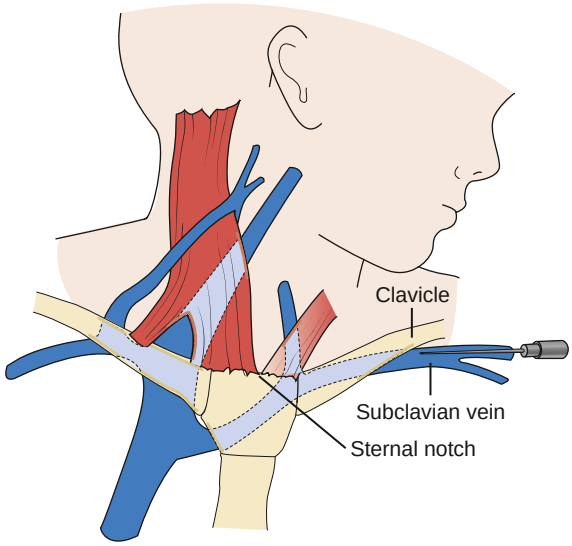

Fig. 79.19 Approach to the subclavian vein. The patient is supine, in slight Trendelenburg position, with a small roll along the spine between the shoulders. The needle enters the skin at the junction of the lateral and middle thirds of the inferior clavicle and is directed toward the suprasternal notch, passing along the inferior edge of the clavicle. (*From Edwards LR, Malone MP, Prodham P, Schexnayder SM. Pediatric vascular access and centeses. In: Zimmerman JJ, Rotta AT, eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Philadelphia: Elsevier: 2022: Fig. 14.5, p. 102.*)

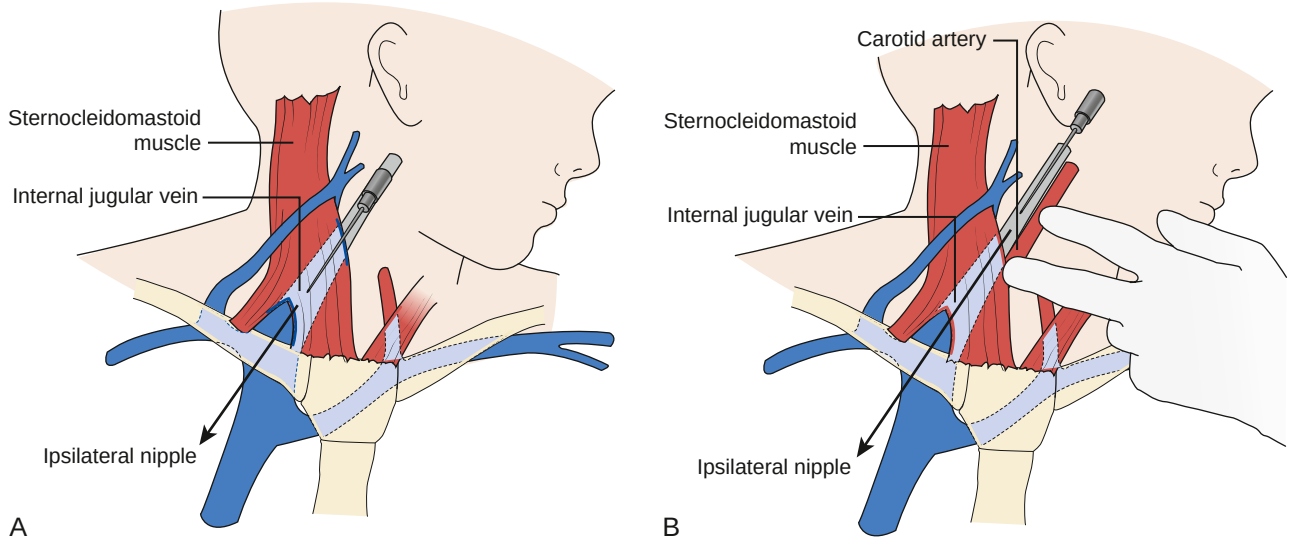

Fig. 79.18 Approaches to the internal jugular vein. The patient is supine, in slight Trendelenburg position, with the neck extended over a shoulder roll and the head rotated to the contralateral side. **A,** Middle approach: The introducer needle enters the skin at a 30-degree angle at the apex of the triangle formed by the heads of the sternocleidomastoid muscle and clavicle, directing it toward the ipsilateral nipple. **B,** Anterior approach: The carotid pulse is palpated and may be slightly retracted medially. The introducer needle enters along the anterior margin of the sternocleidomastoid, about halfway between the suprasternal notch and mastoid process, while being directed toward the ipsilateral nipple. (*Modified from Edwards LR, Malone MP, Prodham P, Schexnayder SM. Pediatric vascular access and centeses. In: Zimmerman JJ, Rotta AT, eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Philadelphia: Elsevier; 2022: Fig. 14.4, p. 101.*)

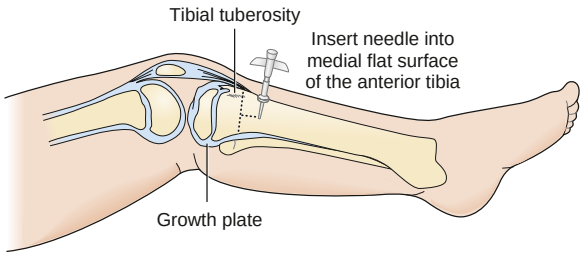

Fig 79.20 Insertion of the intraosseous needle into the anterior tibia. *(From Edwards LR, Malone MP, Prodham P, Schexnayder SM. Pediatric vascular access and centeses. In: Zimmerman JJ, Rotta AT, eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Philadelphia: Elsevier; 2022: Fig. 14.2, p. 95.)*

this vein because dorsiflexion tends to dislodge them. A second large vein on the lateral side of the foot, running in the horizontal plane, usually 1-2 cm dorsal to the lower margin of the foot, is preferable. The most notable scalp veins are the *superficial temporal* (just anterior to the ear) and *posterior auricular* (just behind the ear).

Deeper and larger central veins can provide more reliable access for medications, nutritive solutions, and blood sampling than peripheral venous lines. Placement of central access should be considered in the patient with difficult peripheral access where IVs may be challenging to obtain or may last for brief periods with increased risk of infiltration; when a patient is critically ill requiring numerous medications and needs stable access; when a patient requires IV vasoactive medications for more than a brief period; if long-term medications need to be administered in the hospital or at home; or if administered agents are vascular irritants (IV nutrition, electrolyte infusions, certain antibiotics). Central veins may be reached by percutaneous cannulation or surgical exposure. In infants and young children, the *femoral vein* or *internal jugular vein* are often the easiest to access and cannulate, but the subclavian veins may also be used (Figs. 79.17, 79.18, and 79.19). Peripherally inserted central catheters (PICCs) can be placed for longer-term access through the upper or lower extremity to administer medications or IV nutrition and can be used at home. With the expansion of bedside ultrasound availability and expertise, central venous catheters should be placed under ultrasound guidance to improve first-pass success and minimize the risk of complications.

Intraosseous Access

IO needles (for intramedullary venous plexus access) are specialized, rigid, large-bore needles. IO cannulation is recommended for patients in whom IV access proves difficult or unattainable in an emergent setting, even in older children. If venous access is not available within approximately 1 minute in a child with cardiopulmonary arrest, an IO needle should be placed in the anterior proximal tibia (with care taken to avoid traversing the epiphyseal plate) or other approved site. The needle should penetrate the anterior layer of compact bone, and its tip is advanced into the spongy interior of the bone (Fig. 79.20). Commercially available IO kits frequently include drills that mitigate the complications of needle placement associated with manual placement. All medications, blood products, and fluids may be administered through the IO route, including medications required for emergency resuscitation. Laboratory values can be sampled, although a complete blood count will be unreliable. Complications are uncommon but may include osteomyelitis with prolonged infusions, tibial fracture, and infiltration of fluids with dislodgement.

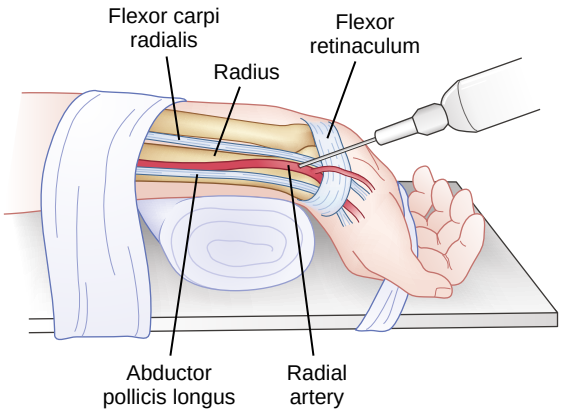

Fig. 79.21 Radial artery anatomy and cannulation.

Arterial Access

Arterial access is indicated when care providers need frequent blood sampling, particularly to assess adequacy of oxygenation, ventilation, or acid-base balance, or continuous blood pressure monitoring. The *radial artery,* the most commonly cannulated artery, lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius (Fig. 79.21). The *ulnar artery,* just lateral to the tendon of the flexor carpi ulnaris, is used less often because of its proximity to the ulnar nerve. Useful sites in the lower extremity, particularly in neonates and infants, are the *dorsalis pedis artery,* on the dorsum of the foot between the tendons of the tibialis anterior and the extensor hallucis longus, and the *posterior tibial artery,* posterior to the medial malleolus. Arterial catheters require special care for insertion and subsequent management. Clinicians should monitor for signs of decreased perfusion distal to catheter placement.

NONVASCULAR EMERGENCY PROCEDURES

Thoracentesis and Chest Tube Placement

Thoracentesis is the placement of a needle or catheter into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in one of the intercostal spaces between the fourth and sixth ribs in the plane of the midaxillary line. After appropriate systemic and local anesthesia/sedation, a needle (and later the chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. Ideally, the chest tube should lie *anterior* in the pleural space for air accumulation and *posterior* for fluid accumulation. A radiograph must be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis

When fluid, blood, or gas accumulates in the pericardial sac, the heart may become compressed and may be unable to fill/empty with normal volumes of blood, leading to diminished cardiac output (i.e., pericardial tamponade with obstructive shock). The cardinal signs of such a restrictive pericardial effusion are tachycardia and hypotension, generally with a narrowed pulse pressure. Pericardiocentesis includes needle aspiration of the pericardial sac, often followed by the placement of a catheter for continuous drainage. As with thoracentesis, chest radiography should be done to confirm catheter location and to evaluate for any complications, such as pneumothorax or hemothorax. Pericardiocentesis may be performed with echocardiography.

Chapter 80

Acute Care of Multiple Trauma

Courtney W. Mangus, Howard I. Pryor II, and Bruce L. Klein

EPIDEMIOLOGY

Injury is a leading cause of death and disability in children throughout the world (see Chapter 14). Deaths represent only a small fraction of the total trauma burden. Approximately 140,000 children were treated in U.S. trauma centers in 2016 for serious injury. Many survivors of trauma have permanent or temporary functional limitations. Motor vehicle–related injuries and falls rank among the top 15 causes of disability-adjusted life years in children worldwide. In childhood, blunt trauma predominates, accounting for the majority of injuries. In adolescence, penetrating trauma increases in frequency, accounting for approximately 13% of injuries, and penetrating trauma secondary to a firearm is associated with a high case fatality rate of 11%.

REGIONALIZATION AND TRAUMA TEAMS

Morbidity and mortality rates have decreased in geographic regions with comprehensive, coordinated trauma systems. Treatment at designated trauma centers is associated with decreased mortality. At the scene of injury, paramedics should administer necessary advanced life support and perform **triage** (Fig. 80.1). It is usually preferable to bypass local hospitals and rapidly transport a seriously injured child directly to a pediatric trauma center (or a trauma center with pediatric commitment). *Children have lower mortality rates, lower complication rates, and fewer operative interventions after severe blunt trauma when they are treated in designated pediatric trauma centers or in hospitals with pediatric intensive care units.*

When the receiving emergency department (ED) is notified before the child's arrival, the trauma team should be mobilized in advance. Each member has defined tasks. A senior surgeon (surgical coordinator) or an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; Figure 80.2 shows the model used at the Johns Hopkins Hospital Bloomberg Children's Center (Baltimore, MD). Consultants, especially neurosurgeons and orthopedic surgeons, must be promptly available, and the operating room staff should be alerted.

Physiologic status and mechanism of injury are used for field triage and to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales such as the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS), Pediatric Trauma Score (Table 80.1), and Revised Trauma Score use these parameters to predict patient outcome. The AIS and ISS are used together. First, the AIS is used to numerically score injuries—as 1 minor, 2 moderate, 3 serious, 4 severe, 5 critical, or 6 probably lethal—in each of six ISS body regions: head/neck, face, thorax, abdomen and pelvic contents, extremities/bony pelvis, and external. The ISS is the sum of the squares of the highest three AIS region scores.

ATLS: SYSTEMATIC EVALUATION OF THE INJURED PATIENT

The American College of Surgeons (ACS) endorses a systematic approach to trauma patients known as **Advanced Trauma Life Support** (ATLS). ATLS is accepted as the standard of care for the initial assessment of injured patients and is used internationally. The approach is centered on a standardized patient evaluation that prioritizes identification and management of injuries in a specific order that addresses their immediate risk to life. ATLS principles are detailed here and include performance of the primary survey with initial adjuncts followed by the secondary survey.

PRIMARY SURVEY

During the primary survey, the trauma team quickly assesses and treats life-threatening injuries (see also Chapter 79). The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, shock from hemorrhage, and central nervous system (CNS) injury. The primary survey addresses the **ABCDEs**: Airway, Breathing, Circulation, Disability/Neurologic Deficit, and Exposure of the patient and control of the Environment.

Airway

Optimizing oxygenation and ventilation, while protecting the cervical spine (C-spine) from potential further injury, is of paramount importance. Airway obstruction manifests as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds even with apparently good respiratory effort. Children are more likely than adults to have airway obstruction because of their smaller oral and nasal cavities, proportionately larger tongues, more tonsillar and adenoidal tissue, higher and more anterior glottic opening, and narrower larynx and trachea. Obstruction is common in patients with severe head injuries, partly because of decreased muscle tone, which allows the tongue to fall posteriorly and occlude the airway. With trauma, obstruction can also result from fractures of the mandible or facial bones, secretions such as blood or vomit, crush injuries of the larynx or trachea, and foreign body aspiration.

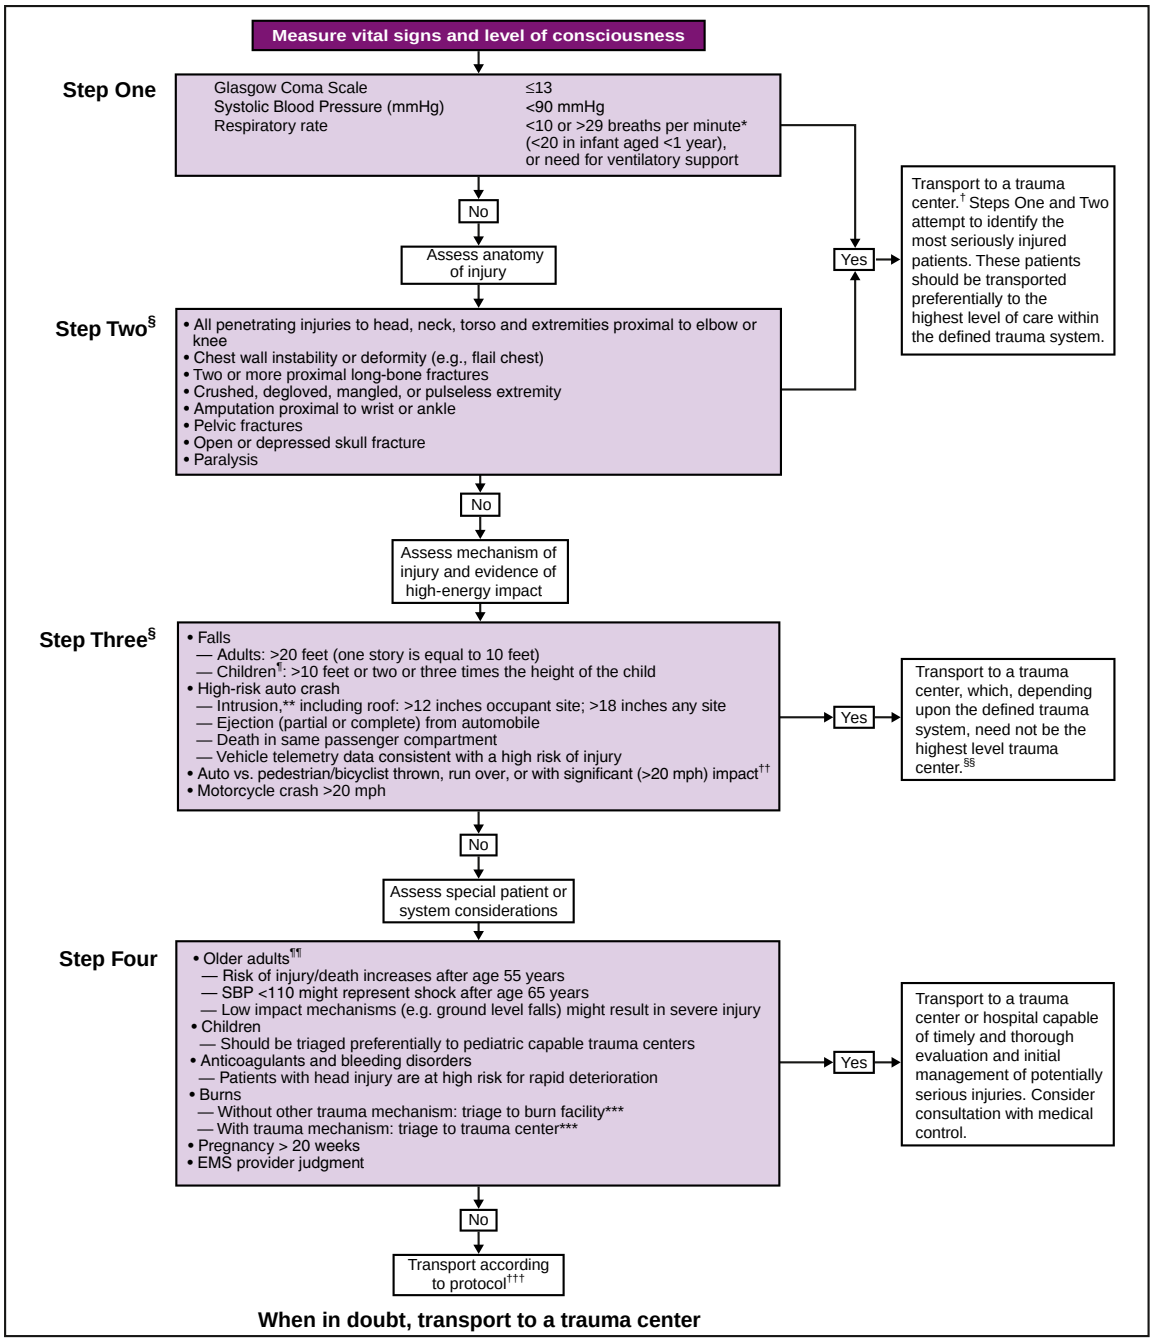
If it is necessary to open the airway, a jaw thrust without head tilt is recommended. This procedure minimizes cervical spine motion. In an unconscious child, an oropharyngeal airway may be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. A nasopharyngeal airway is contraindicated when there is significant nasal trauma or possibility of cribriform plate fracture. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated. When endotracheal intubation proves difficult, a laryngeal mask airway can be used as a temporary alternative. A laryngeal mask airway consists of a tube with an inflatable cuff that rests above the larynx and thus does not require placement of the tube into the trachea. Other extraglottic devices that can be blindly inserted in a difficult airway scenario include the Combitube and King laryngeal airway tube; these devices are considered temporary and should be exchanged for a definitive airway as soon as possible. Video-assisted laryngoscopy or the use of a bougie can also be particularly helpful in the management of a difficult airway. Emergency cricothyrotomy is needed in <1% of trauma victims.

Breathing

The physician assesses breathing by counting the respiratory rate; visualizing chest wall motion for symmetry, expansion, and accessory muscle use; and auscultating breath sounds in both axillae. Pulse oximetry and continuous waveform capnography monitoring should also be used; however, they may be less reliable in patients with shock. If ventilation is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory carbon dioxide (CO_2) detectors or capnography help verify accurate tube placement.

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with severe head injury may have a variety of breathing abnormalities, including Cheyne-Stokes respiration, slow irregular breaths, and apnea. A child with significant neurologic impairment will require endotracheal intubation and mechanical ventilation.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemothorax are immediately life threatening (Tables 80.2 and 80.3). A **tension pneumothorax** occurs when air accumulates under pressure in the pleural space. The adjacent lung is compacted; the mediastinum is pushed toward the opposite hemithorax; and the heart, great vessels, and contralateral lung are compressed



* The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.
† Trauma centers are designated Level I-IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in continuous availability of certain subspecialties or sufficient prevention, education, and research activities for Level I designation; Level II facilities are not required to be resident or fellow education centers. A Level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.
§ Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.
¶ Age <15 years.
** Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.
†† Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.
§§ Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.
¶¶ Age >55 years.
*** Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.
††† Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

Fig. 80.1 Algorithm showing guidelines for field triage of injured patients—United States, 2011. (*From Guidelines for Field Triage of Injured Patients: Recommendations of the National Expert Panel on Field Triage. MMWR. 2012;61:6.*)

Table 80.1 Pediatric Trauma Score*

COMPONENT	+2	+1	−1
Size	≥20 kg	10-20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic BP	≥90 mm Hg	50-90 mm Hg	<50 mm Hg
CNS	Awake	Obtunded/ LOC	Coma/ decerebrate
Open wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures
Sum total points			

*Children with a Pediatric Trauma Score ≤6 are at increased risk of mortality and morbidity.
BP, Blood pressure; CNS, central nervous system; LOC, loss of consciousness.
From Tepas JJ 3rd, Mollitt DL, Talbert JL, et al. The Pediatric Trauma Score as a predictor of injury severity in the injured child. *J Pediatr Surg.* 1987;22:14-18, Table 1, p. 15.

(see Chapter 461). Both ventilation and cardiac output are impaired. Characteristic findings include cyanosis, tachypnea, retractions, asymmetric chest rise, contralateral tracheal deviation, diminished breath sounds on the ipsilateral (more than contralateral) side, and signs of shock. When suspected, a tension pneumothorax should be treated before obtaining chest radiographs. Needle thoracentesis, followed by thoracostomy tube insertion, is diagnostic and lifesaving. **Hemothorax** results from injury to the intercostal vessels, lungs, heart, or great vessels. When ventilation is adequate, volume resuscitation should begin before evacuation, because a large volume of blood may drain through the chest tube, resulting in shock.

Circulation

Signs of **shock** include tachycardia; weak pulse; delayed capillary refill; altered mental status; and cool, mottled, or pale skin (see Chapter 85). The most common type of shock in trauma is *hypovolemic shock* caused by hemorrhage. Cardiac tamponade, which is a form of *obstructive shock,* occurs when blood or fluid accumulates in the pericardium. It may be suspected clinically with the classic findings of jugular venous distension, muffled heart sounds, and low blood pressure—collectively known as **Beck's triad**. Cardiac tamponade may be definitively diagnosed by ultrasound during a **focused assessment with sonography in**

Table 80.2 Differential Diagnosis of Immediately Life-Threatening Cardiopulmonary Injuries

	TENSION PNEUMOTHORAX	MASSIVE HEMOTHORAX	CARDIAC TAMPONADE
Breath sounds	Ipsilaterally decreased more than contralaterally	Ipsilaterally decreased	Normal
Percussion note	Hyperresonant	Dull	Normal
Tracheal location	Contralaterally shifted	Midline or shifted	Midline
Neck veins	Distended	Flat	Distended
Heart tones	Normal	Normal	Muffled

Modified from Cooper A, Foltin GL. Thoracic trauma. In: Barkin RM, ed. *Pediatric Emergency Medicine*, 2nd ed. St Louis: Mosby; 1997:325.

Table 80.3 Life-Threatening Chest Injuries

TENSION PNEUMOTHORAX
One-way valve leak from the lung parenchyma or tracheobronchial tree
Lung collapse with mediastinal and tracheal shift to the side opposite the leak
Compromises venous return and decreases ventilation of the other lung
Clinically, manifests as respiratory distress, unilateral absence of breath sounds, tracheal deviation, distended neck veins, tympany to percussion of the involved side, and cyanosis
Relieve first with needle aspiration, then with chest tube drainage

OPEN PNEUMOTHORAX (SUCKING CHEST WOUND)
Effect on ventilation depends on size

MAJOR FLAIL CHEST
Usually caused by blunt injury resulting in multiple rib fractures
Loss of bone stability of the thoracic cage
Major disruption of synchronous chest wall motion
Mechanical ventilation and positive end-expiratory pressure required

MASSIVE HEMOTHORAX
Must be drained with a large-bore tube
Initiate drainage only with concurrent vascular volume replacement

CARDIAC TAMPONADE
Beck's triad:
1. Decreased or muffled heart sounds
2. Jugular venous distention
3. Hypotension (with narrow pulse pressure)

Must be drained

Modified from Krug SE. The acutely ill or injured child. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics*, 4th ed. Philadelphia: Saunders; 2002:97.

trauma (FAST) examination or echocardiography. Cardiac tamponade is best managed by thoracotomy or pericardial window, although pericardiocentesis may be a necessary temporizing maneuver (see Table 80.3).

Early in shock, blood pressure remains normal because of compensatory increases in heart rate and peripheral vascular resistance (Table 80.4). Some individuals can lose up to 30% of blood volume before blood pressure declines. Notably, 25% of blood volume equals 20 mL/kg, which is only 200 mL in a 10-kg child. Loss of >40% of blood volume causes severe hypotension that, if prolonged, may be irreversible. Direct pressure should be applied to control external hemorrhage. When direct pressure does not control hemorrhage, a tourniquet should be applied to a proximal pressure point. Blind clamping of bleeding vessels, which risks damaging adjacent structures, is not advisable.

Cannulating a larger vein, such as an antecubital vein, is usually the quickest way to achieve intravenous (IV) access (see Chapter 79). A short, large-bore catheter offers less resistance to flow, allowing for more rapid fluid administration. Ideally, a second catheter should be placed within the first few minutes of resuscitation in a severely injured child. If IV access is not rapidly obtainable, an intraosseous (IO) needle should be inserted; all medications and fluids can be administered intraosseously (see Chapter 79). Other alternatives are central venous access using the Seldinger technique (e.g., in the femoral vein) and, rarely, surgical cutdown (e.g., in the saphenous vein). Ultrasonography may be employed to safely facilitate both peripheral IV placement and central venous catheter placement.

Traditionally, fluids are administered aggressively early in hemorrhagic shock to reverse and prevent further clinical deterioration. Isotonic crystalloid solution, such as lactated Ringer's or normal saline (20 mL/kg), should be infused rapidly. When necessary, repeated crystalloid boluses may be given. Most children are stabilized with administration of crystalloid solution alone; however, if the patient remains in shock after boluses totaling 40 mL/kg of crystalloid, packed red blood cells should be transfused. Massive transfusion protocols (including fresh-frozen plasma) should be initiated early to prevent coagulopathy, and tranexamic acid (TXA) should be considered. When shock persists despite these measures, exploratory surgery to stop internal hemorrhage is usually indicated. Emerging literature suggests modern trauma techniques for adults, including permissive hypotension, hemostatic resuscitation, and damage control surgery, confer similar benefits in children.

Disability/Neurologic Deficit

Neurologic status is briefly assessed by determining the level of consciousness and evaluating pupil size and reactivity. The level of consciousness can be classified using the mnemonic **AVPU**: Alert, responsive to Verbal commands, responsive to Painful stimuli, or Unresponsive. A **Glasgow Coma Scale** (GCS) or Pediatric GCS score (see Chapters 79 and 82) should be assigned to every child with significant head trauma or neurologic impairment. This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS helps categorize neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with GCS ≤8 should undergo endotracheal intubation and supportive mechanical ventilation. Importantly, the patient's pupil size/reactivity and ability to move extremities should be quickly assessed before administration of anticholinergics, sedatives, and paralytics in preparation for intubation.

The majority of pediatric blunt trauma deaths are accounted for by head injuries. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. *The goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion and by maintaining normal cerebral perfusion pressure.* Focal hemorrhagic lesions (e.g., epidural or subdural hematomas) are less common but may require immediate neurosurgical intervention (Fig. 80.3).

Signs of increased intracranial pressure (ICP), including progressive neurologic deterioration and evidence of transtentorial herniation, must be treated immediately (see Chapter 82). Hyperventilation lowers the arterial partial pressure of carbon dioxide ($Paco_2$), resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased

Table 80.4 Systemic Responses to Blood Loss in Pediatric Patients

SYSTEM	MILD BLOOD LOSS (<30%)	MODERATE BLOOD LOSS (30–45%)	SEVERE BLOOD LOSS (>45%)
Cardiovascular	Increased heart rate; weak, thready peripheral pulses; normal systolic blood pressure; normal pulse pressure	Markedly increased heart rate; weak, thready central pulses; peripheral pulses absent; low normal systolic blood pressure; narrowed pulse pressure	Tachycardia followed by bradycardia; central pulses very weak or absent; peripheral pulses absent; hypotension; narrowed pulse pressure (or undetectable diastolic blood pressure)
Central nervous	Anxiety; irritability; confusion	Lethargy; dulled response to pain	Coma
Skin	Cool, mottled; capillary refill prolonged	Cyanotic; capillary refill markedly prolonged	Pale and cold
Urine output	Low to very low	Minimal	None

Adapted from American College of Surgeons Committee on Trauma. *Advanced Trauma Life Support: Student Course Manual,* 10th ed. Chicago: American College of Surgeons; 2018:196.

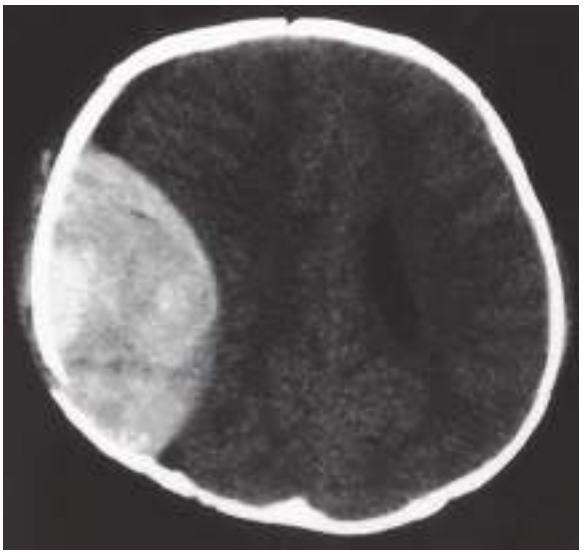

Fig. 80.3 Epidural hematoma. CT head scan from 7-mo-old female who, according to the history provided, did not wake up for her nightly feeding and began vomiting in the morning. The mother's friend reported that the infant had fallen from a chair the previous day. The CT scan shows a large epidural hematoma on the right and marked shift of the midline from right to left. The right lateral ventricle is compressed as a result of the mass effect, and the left lateral ventricle is slightly prominent. The infant underwent emergency surgical evacuation of the epidural hematoma and recovered uneventfully. (*From O'Neill JA Jr. Principles of Pediatric Surgery, 2nd ed. St Louis: Mosby; 2003:191.*)

ICP. Brief hyperventilation, targeting an end-tidal CO_2 goal of 30-35 mm Hg, remains an immediate option for patients with acute increases in ICP. Prophylactic hyperventilation, or vigorous or prolonged hyperventilation, is not recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion and oxygenation. Mannitol and hypertonic saline lower ICP and may improve survival. Because mannitol induces an osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Hypertonic saline may be a more useful agent for control of increased ICP in patients with severe head injury. Neurosurgical consultation is mandatory and will dictate further management, including ICP monitoring and emergent neurosurgical interventions.

Exposure and Environmental Control

Full exposure of the patient occurs during the primary survey. Using trauma shears, all clothing should be removed to reveal any injuries. Cutting clothing is fastest and minimizes unnecessary patient movement. Children often arrive in the ED mildly hypothermic because of their higher body surface area–to–mass ratios. They can be warmed with use of radiant heat and heated IV fluids, as necessary. After a thorough physical exam, the patient should be covered with warmed blankets with close monitoring of body temperature.

Initial Adjuncts

While the primary survey is being performed, the patient will simultaneously be placed on a cardiac monitor, vitals obtained, and vascular access established. Fluid resuscitation can be initiated as soon as access is established. Initial laboratory work generally includes a complete blood count, electrolytes, blood urea nitrogen, creatinine, liver function tests, lipase, lactate, blood gas, coagulation studies, type and cross match, and urinalysis. Per ATLS, portable (single, anterior-posterior view) radiographs of the chest and pelvis should be obtained to screen for life-threatening injury and identify potential causes of hemorrhage (e.g., pelvic fracture, hemothorax, great vessel injury as suggested by a widened mediastinum). Finally, a FAST exam should be performed at the bedside to assess for the presence of free fluid (blood) and guide resuscitation.

FAST Exam

The FAST exam and extended FAST (eFAST) are other adjuncts to the initial trauma survey. This bedside ultrasound can be performed by any trained member of the trauma team to assess for the presence of blood or free fluid in the intraperitoneal, pericardial, or pleural space. The exam assesses four windows: the right upper quadrant abdominal view, the left upper quadrant abdominal view, the suprapubic view, and the subxiphoid cardiac view. The eFAST adds additional views of bilateral lungs to assess for the absence of lung sliding, which is indicative of a pneumothorax. In addition to detection of hemoperitoneum, the eFAST can identify findings that may require emergent management in an unstable patient—such as a pneumothorax requiring needle decompression or a large pericardial effusion requiring pericardiocentesis.

Although the FAST examination helps detect hemoperitoneum, the variably low sensitivity of this test in children suggests that it should not be used alone to exclude intraabdominal injury in patients with a moderate to high pretest probability for injury (e.g., a patient with elevated serum lipase or transaminases). A positive FAST exam for hemoperitoneum requires further investigation. The FAST exam is most clinically useful in patients who have blunt trauma and are hemodynamically unstable or in patients who require immediate operative intervention for nonabdominal injuries, because in these cases the performance of a CT scan will delay emergency surgery.

SECONDARY SURVEY

During the secondary survey, the trauma team completes a thorough, head-to-toe physical examination to assess for additional injuries. In critically ill or hemodynamically unstable patients, emergent interventions may delay the secondary survey until the patient has been stabilized.

Head Trauma

Initial management of traumatic brain injuries is discussed earlier. The secondary survey of the head should identify and document injuries,

including scalp hematomas and lacerations. The skull and face should be carefully palpated to assess for possible fractures. Findings suggestive of basilar skull fractures include bruising around the eyes ("raccoon eyes"), bruising over the mastoid process (Battle sign), and blood behind the tympanic membrane (hemotympanum). The eyes should be assessed for conjunctival hemorrhages, hyphemas, and corneal injuries. Limitation in extraocular movements may suggest orbital fractures with muscle entrapment. The nares should be inspected for bleeding and presence of a nasal septal hematoma, which must be evacuated urgently to prevent permanent disfigurement. The mouth should be assessed for injuries to the tongue, teeth, gums, palate, and oropharynx; normal jaw mobility should be ensured. Patients with suspected head or facial injuries will typically undergo CT of the head, orbits, and/or maxillofacial region.

Spinal Trauma

Spinal Immobilization

Initially, spinal injury should be suspected in any child sustaining multiple blunt trauma. To prevent further spinal injury, paramedics have traditionally been taught to immobilize the C-spine in neutral position with a stiff collar, head blocks, and tape or cloth placed across the forehead. To immobilize the rest of the spine, the child is typically placed on a rigid backboard, and straps or tape are placed across the torso and thighs to restrain them. Care should be taken to continue spinal immobilization during initial evaluation and resuscitation until spinal injury can be excluded (see Chapter 81).

C-Spine Trauma

Cervical spine injuries occur in <3% of children with blunt trauma—with the risk being substantially higher in those with GCS scores ≤8—but they are associated with significant mortality and morbidity (see Chapter 81). Bony injuries occur mainly from C1 to C4 in children younger than 8 years. In older children, they occur equally in the upper and lower cervical spine. The mortality rate is significantly higher in patients with upper C-spine injuries, and ~30% of all patients with C-spine injuries have permanent neurologic deficits.

Evaluation

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps in estimating the likelihood of a spinal injury. Both the patient and the paramedic should be asked whether any neurologic symptoms or signs, such as weakness or abnormal sensation, were present before arrival in the ED. The spine should then be examined while maintaining immobilization. If no other distracting injuries are present (e.g., a displaced femur fracture), the collar can be carefully removed by one provider while a second provider manually stabilizes the neck. The C-spine should be palpated to assess for tenderness or step-offs. If the patient has neck pain, has neurologic symptoms, or is unable to participate in the exam, the collar should be replaced immediately. To assess the thoracic and lumbar spine, multiple providers are required to log-roll the patient and maintain spinal immobilization. A third provider will palpate the spine, assess for cutaneous injuries, and evaluate rectal tone. Before rolling the patient back to the supine position, the backboard must be removed to prevent further injury or patient discomfort.

Whenever the history, physical examination, or mechanism of injury suggests a spinal injury, imaging must be obtained after initial resuscitation. Depending on clinical suspicion, mechanism of injury, and the patient's symptoms and physiologic status, the provider may elect either radiography, CT, or MRI as the initial imaging modality.

The **National Emergency X-Radiography Utilization Study (NEXUS)** cervical spine rule helps identify low-risk patients who may not require radiographs (Table 80.5). The standard series of plain radiographs includes lateral, anteroposterior (AP), and odontoid views. Some centers use C-spine CT as the primary diagnostic tool, particularly in patients with abnormal GCS scores or significant injury mechanisms, recognizing that CT is more sensitive in detecting bony injury than plain radiographs. CT is also helpful if an odontoid fracture is suspected, because young children typically do not cooperate enough to obtain an open-mouth (odontoid) radiographic view. Use of cervical spine CT scan must be balanced with the knowledge that CT exposes thyroid tissue to 90-200 times the amount of radiation from plain films.

Table 80.5 National Emergency X-Radiography Utilization Study (NEXUS) to Rule Out Cervical Spine Injury After Blunt Trauma

*If **NONE** of the following is present, the patient is at very low risk for clinically significant cervical spine injury:*

- Midline cervical tenderness
- Evidence of intoxication
- Altered level of alertness
- Focal neurologic deficit
- Distracting painful injury

Data from Hoffman JR, Mower WR, Wolfson AB, et al. Validity of a set of clinical criteria to rule out injury to the cervical spine in patients with blunt trauma. *N Engl J Med.* 2000;343:94-99; and Viccellio P, Simon H, Pressman BD, et al. A prospective multicenter study of cervical spine injury in children. *Pediatrics.* 2001;108:e20.

SCIWORA

In a child with neurologic symptoms and normal findings on C-spine plain radiographs and CT scan, **spinal cord injury without radiographic abnormalities (SCIWORA)** must be considered. MRI of the spine is indicated in a child with suspected SCIWORA and in the evaluation of children who remain obtunded.

Thoracic Trauma

Pulmonary contusions occur frequently in young children with blunt chest trauma. A child's chest wall is relatively pliable; therefore less force is absorbed by the rib cage and more is transmitted to the lungs. Respiratory distress may be noted initially or may develop during the first 24 hours after injury.

Rib fractures result from significant external force. They are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. Table 80.6 lists indications for operative management in thoracic trauma. (See Table 80.2 for the differential diagnosis of immediately life-threatening cardiopulmonary injuries.) Thoracic trauma can be investigated via chest radiograph or CT, depending on the patient's symptoms, physical exam findings, mechanism of injury, and index of suspicion for injury.

Abdominal Trauma

Liver and spleen contusions, hematomas, and lacerations account for the majority of intraabdominal injuries from blunt trauma. The kidneys, pancreas, and duodenum are relatively spared because of their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen.

Although a thorough examination for intraabdominal injuries is essential, achieving it often proves difficult. Misleading findings can result from gastric distention after crying or in an uncooperative toddler. Calm reassurance, distraction, and gentle, persistent palpation help with the examination. Important findings include distention, bruises, and tenderness. Specific symptoms and signs give insight into the mechanism of injury and the potential for particular injuries. Pain in the left shoulder may signify splenic trauma. A lap belt mark across the abdomen raises concern for bowel or mesentery injury. The presence of certain other injuries, such as lumbar spinal fractures and femur fractures, increases the likelihood of intraabdominal injury.

An abdominal (and pelvic) CT scan with IV contrast medium enhancement rapidly identifies structural abnormalities and is the preferred study in a stable child. A negative abdominal CT scan has been shown to have a negative predictive value (NPV) of 99.6%. It has excellent sensitivity and specificity for splenic (Fig. 80.4), hepatic (Fig. 80.5), and renal injuries, but is less sensitive for diaphragmatic, pancreatic, or intestinal injuries. Small amounts of free fluid or air or a mesenteric

Table 80.6 Indications for Operation in Thoracic Trauma

THORACOTOMY IMMEDIATELY OR SHORTLY AFTER INJURY
Massive continuing pneumothorax or large air leak from tracheobronchial injury (cannot expand lung and ventilate)
Cardiac tamponade
Open pneumothorax
Esophageal injury
Aortic or other vascular injury
Acute rupture of the diaphragm
DELAYED THORACOTOMY OR THORACOSCOPY
Chronic rupture of the diaphragm
Clotted hemothorax
Persistent chylothorax
Traumatic intracardiac defects
Evacuation of large foreign bodies
Chronic atelectasis from traumatic bronchial stenosis

Modified from O'Neill JA Jr. *Principles of Pediatric Surgery,* 2nd ed. St Louis: Mosby; 2003:157.

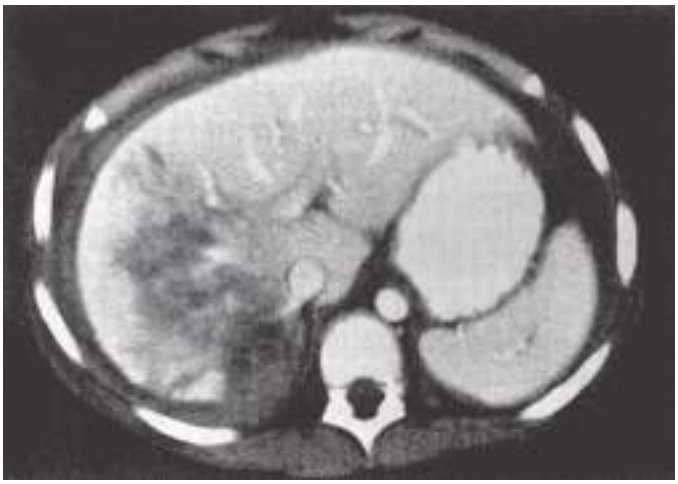

Fig. 80.5 Liver injury. CT scan performed after severe blunt injury of the abdomen shows a bursting injury of the liver. The patient was stable, and no operative intervention was required. The decision to perform surgery should be based on the patient's physiologic stability. (*From O'Neill JA Jr. Principles of Pediatric Surgery, 2nd ed. St Louis: Mosby; 2003:168.*)

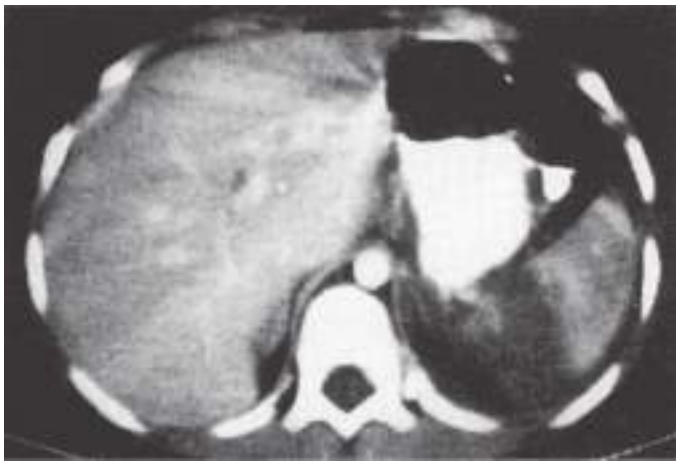

Fig. 80.4 Splenic rupture. CT scan with intravenous and gastrointestinal contrast enhancement shows an isolated splenic rupture that resulted from blunt trauma. This injury responded to nonoperative management, as do most splenic injuries. (*From O'Neill JA Jr. Principles of Pediatric Surgery, 2nd ed. St Louis: Mosby; 2003:166.*)

hematoma may be the only sign of an intestinal injury. Administration of an oral contrast agent is not routinely recommended for all abdominal CT scans, but it sometimes aids in identifying an intestinal, especially a duodenal, injury.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt trauma. The majority of such children can be treated nonsurgically. In addition to avoiding perioperative complications, nonoperative treatment decreases the need for blood transfusions and shortens hospital stay. When laparotomy is indicated, splenic repair is preferable to splenectomy.

Pelvic Trauma

Pelvic fractures in children are much less common than in adults, occurring in approximately 4% of children with more severe blunt trauma. Pelvic fractures are typically caused by high forces (e.g., high-speed motor vehicle crashes or pedestrian impacts) and are often associated with intraabdominal and/or vascular injuries. The pelvis itself forms a ring, and high-force impacts can lead to disruption of this ring. When the ring is disrupted in more than one location, such as the symphysis pubis and the sacroiliac joint, the ring can become unstable and displaced, potentially injuring large pelvic vessels and leading to massive blood loss. Catheter-directed embolization to control bleeding, performed by an interventional radiologist, may be required.

The pelvis should be assessed for stability by means of compression-distraction maneuvers. If instability is noted, immediate external fixation with a pelvis-stabilizing device or a sheet should be applied and orthopedic consultation sought. A trauma patient with a potential pelvic fracture should receive an AP pelvic radiograph in the trauma bay followed by a CT scan if there is still suspicion of injury. Children *without* a high-risk clinical finding (e.g., GCS <14; abdominal pain or tenderness; pelvic tenderness, laceration, ecchymosis, or abrasion; gross hematuria or >20 red blood cells/high-power field on urinalysis; or femur fracture) or a high-risk mechanism of injury (e.g., unrestrained motor vehicle collision, motor vehicle collision with ejection, motor vehicle collision rollover, auto vs pedestrian, or auto vs bicycle), however, are unlikely to have pelvic fractures.

Genitourinary Trauma

The perineum should be inspected and the stability of the bones of the pelvis assessed. Urethral injuries are more common in males. Findings suggestive of urethral injury include scrotal or labial ecchymosis, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate on rectal examination (in an adolescent male). Certain pelvic fractures also increase the risk for potential genitourinary injury. Any of these findings is a contraindication to urethral catheter insertion and warrants consultation with a urologist. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

Extremity Trauma

Thorough examination of the extremities is essential because extremity fractures are among the most frequently overlooked injuries in children with multiple traumas. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before radiographs are obtained, suspected fractures and dislocations should be immobilized and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon should be consulted immediately to evaluate children with compartment syndrome, neurovascular compromise, open fracture, or traumatic amputations.

An acute extremity compartment syndrome is a surgical emergency usually associated with extremity fractures (e.g., tibia, supracondylar humerus, distal radius) but has also been noted after thermal and electric injuries, rhabdomyolysis, coagulopathies, or nephrotic syndrome. Manifestations include pain out of proportion to the injury, pain with passive stretching of the muscles, poor distal pulses, pallor, paresthesia, and weakness. In children, escalating pain not relieved by pain medications, anxiety, and agitation are additional features. If needed, compartmental pressure should be measured (normal is 8 mm Hg in adults, 10-15 mm Hg in children). Absolute pressure ≥30 mm Hg is one indication for fasciotomy. Another indication for fasciotomy is a diastolic blood pressure minus compartment pressure <30 mm Hg.

Advanced Imaging

After completion of the primary survey, diagnostic adjuncts, and secondary survey, most stable trauma patients will require advanced imaging with CT or additional plain radiographs. As detailed earlier, injury mechanism, patient history, and clinical exam findings will help determine the specific imaging to be obtained. Additionally, clinical prediction rules have been developed to identify those at low risk of injury for whom specific imaging studies may not be necessary. The NEXUS C-spine rule is a sensitive, easily applicable rule that was validated for adults and children, although there were fewer young patients studied (see Table 80.5). Several clinical prediction rules have been developed to identify children at low risk of traumatic brain injury in whom head CT can be safely avoided (Table 80.7). Another clinical prediction rule has been developed to identify children at very low risk of clinically important intraabdominal injuries after blunt trauma (Table 80.8). Although this rule has an NPV of 99.9%, it needs to be externally validated before widespread implementation. One benefit of standardizing the evaluation of patients with major trauma is that fewer decisions need to be made on an individual basis, possibly expediting ED management.

DISPOSITION

Disposition from the ED trauma bay is determined by several factors. Patients who are critically unstable with suspected internal hemorrhage are emergently transferred to the operating room (OR) for exploratory surgery before advanced imaging. Up to 30% of children evaluated for trauma require hospitalization. Of the children admitted for trauma, 30% have operative injuries identified on the physical exam or advanced imaging and undergo surgery during that hospitalization. Of those requiring surgery, 25% will require surgery within 24 hours of admission, and of that group, 57% require emergent intervention. Nonoperative patients who are critically injured will ultimately benefit from continued management in an ICU capable of caring for children and in a facility with the necessary surgical subspecialists.

PSYCHOLOGIC AND SOCIAL SUPPORT

Serious multisystem trauma may result in significant long-term psychologic and social difficulties for the child and family, particularly when there is a major head injury. Like adults, children are at risk for depressive symptoms and posttraumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychologic symptoms. Psychologic and social support, during the resuscitation period and afterward, is extremely important. Parents often prefer to be offered the choice to be present during resuscitations. A member of the resuscitation team should be made responsible for answering the family's questions and supporting them in the trauma room.

Table 80.7 Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Brain Injuries After Head Trauma

*Children <2 yr old are at very low risk of clinically important traumatic brain injury if they have **NONE** of the following:*
Severe mechanism of injury
History of LOC >5 sec
GCS ≤14 or other signs of altered mental status
Not acting normally per parent
Palpable skull fracture
Occipital/parietal/temporal scalp hematoma
*Children 2-18 yr old are at very low risk of clinically important traumatic brain injury if they have **NONE** of the following:*
Severe mechanism of injury
History of LOC
History of vomiting
GCS ≤14 or other signs of altered mental status
Severe headache in the ED
Signs of basilar skull fracture

LOC, Loss of consciousness; GCS, Glasgow Coma Scale score; ED, emergency department.

Modified from Kuppermann N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically-important brain injuries after head trauma: A prospective cohort study. *Lancet.* 2009;374:1160-1170.

Table 80.8 Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Intraabdominal Injuries After Blunt Trauma

*If **NONE** of the following is present, the patient is at very low risk for clinically significant intraabdominal injury:*
Glasgow Coma Scale score <14
Vomiting
Evidence of thoracic wall trauma
Decreased breath sounds
Evidence of abdominal wall trauma or seatbelt sign
Abdominal pain
Abdominal tenderness

Modified from Holmes JF, Lillis K, Monroe D, et al. Identifying children at very low risk of clinically important blunt abdominal injuries. *Ann Emerg Med.* 2013;62:107-116, e2.

Chapter 81

Spinal Cord Injuries in Children

Katie P. Fehnel and Mark R. Proctor

See also Chapter 751.

Compared with adults, spine and spinal cord injuries are rare in children, particularly young children, because of both anatomic differences and etiologies of injury. The main mechanisms of injury to the spine are motor vehicle crashes, falls, sports, and violence, which affect young children less often (see Chapter 80).

Several anatomic differences affect the pediatric spine. The head of a young child is larger relative to body mass than in adults, and the neck muscles are still underdeveloped, which places the fulcrum of movement higher in the spine. Therefore children <9 years old have a higher percentage of injuries in the upper cervical spine (C-spine) than do older children and adults. The spine of a small child also is very mobile, with pliable bones and ligaments, so fractures of the spine are exceedingly rare. However, this increased mobility is not always a positive feature. Transfer of energy leading to spinal distortion may not affect the structural integrity of the bones and ligaments of the spine but can still lead to significant injuries of the spinal cord. This phenomenon of **spinal cord injury without radiographic abnormalities (SCIWORA)** is more common in children than in adults (see Chapter 80). The term is relatively outdated, because almost all injuries are detectable by MRI, but is still clinically useful when referring to spinal cord injuries evaluated by plain radiographs or CT. There seem to be two distinct forms of SCIWORA. The **infantile** form involves severe injury of the cervical or thoracic spinal cord; these patients have a poor chance of complete recovery. In older children and adolescents, SCIWORA is more likely to be a less severe injury, with a high likelihood of complete recovery over time. The **adolescent** form, also called *transient neurapraxia,* is assumed to be a spinal cord concussion or mild contusion, as opposed to the severe spinal cord injury related to the mobility of the spine in small children.

Although the mechanisms of spinal cord injury in children include birth trauma, falls, and child abuse, the major cause of morbidity and mortality across all ages remains **motor vehicle injuries**. Adolescents incur spinal cord injuries with epidemiology similar to that of adults, including significant male predominance and a high likelihood of fracture dislocations of the lower cervical spine or thoracolumbar region. In infants and children <5 years old, fractures and mechanical disruption of spinal elements are more likely to occur in the upper cervical spine between the occiput and C3. Certain conditions predispose to C-spine injury (Table 81.1).

Table 81.1 Conditions that Predispose Patients to a Cervical Spine Injury

CATEGORY	CONDITIONS
Abnormal development of the cervical spine	Trisomy 21 Larsen syndrome Mucopolysaccharidosis IV/Morquio syndrome Klippel-Feil syndrome Achondroplasia Chiari malformation Syringomyelia
Abnormal bone and soft tissue	Marfan syndrome Ehlers-Danlos syndrome Osteogenesis imperfecta
Arthritis	Ankylosing spondylitis Rheumatoid arthritis
History of cervical spine injury or surgery	

Modified from McCollum M, Guse S. Neck trauma: Cervical spine, seatbelt sign and penetrating palate injuries. *Emerg Med Clin N Am.* 2021;39:573-588, Table 1, p. 574.

CLINICAL MANIFESTATIONS

One in three patients with significant trauma to the spine and spinal cord will have a concomitant severe head injury, which makes early diagnosis challenging. For these patients, clinical evaluation may be difficult. Patients with a potential spine injury need to be maintained in a protective environment, such as a collar, until the spine can be cleared by clinical and/or radiographic means. A careful neurologic examination is necessary for infants with suspected spinal cord injuries. Complete spinal cord injury will lead to **spinal shock** with early areflexia (see Chapter 751). Severe C-spine injuries will usually lead to paradoxical respiration in patients who are breathing spontaneously. **Paradoxical respiration** occurs when the diaphragm, which is innervated by the phrenic nerves with contributions from C3, C4, and C5, is functioning normally, but the intercostal musculature innervated by the thoracic spinal cord is paralyzed. In this situation, inspiration fails to expand the chest wall but distends the abdomen. Other complications during the acute (2-48 hours) phase include autonomic dysfunction (bradyarrhythmias and tachyarrhythmias, orthostatic hypotension, hypertension), temperature instability, thromboembolism, dysphagia, and bowel/bladder dysfunction.

The *mildest* injury to the spinal cord is **transient quadriparesis** evident for seconds or minutes with complete recovery in 24 hours. This injury follows a concussion of the cord and is most frequently seen in adolescent athletes. If their imaging is normal, these children can generally return to normal activities after a period of rest from days to weeks, depending on the initial severity, similar to cerebral concussion management.

Significant spinal cord injury in the cervical region is characterized by flaccid quadriparesis, loss of sphincter function, and a sensory level corresponding to the level of injury. An injury at the high cervical level (C1-C2) can cause respiratory arrest and death in the absence of ventilatory support. Injuries in the thoracic region are generally the result of fracture dislocations. They may produce paraplegia when at T10 or above or the **conus medullaris syndrome** if at the T12-L1 level. This includes a loss of urinary and rectal sphincter control, flaccid weakness, and sensory disturbances of the legs. A **central cord lesion** may result from contusion and hemorrhage in the center of the spinal cord (Fig. 81.1). It typically involves the upper extremities to a greater degree than the legs because the motor fibers to the cervical and thoracic region are more centrally located in the spinal cord. There are lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs, bladder dysfunction, and loss of sensation caudal to the lesion. There may be considerable recovery, particularly in the lower extremities, although sequelae are common (see Chapter 751).

CLEARING THE CERVICAL SPINE IN CHILDREN

The management of children after major trauma is challenging. For older children, the clearance is similar to a lucid adult, and the National Emergency X-Radiography Utilization Study (NEXUS) criteria are appropriate (see Chapter 80, Table 80.5). Clearing the cervical spine in younger and uncooperative children involves similar issues as in adults with an altered level of consciousness

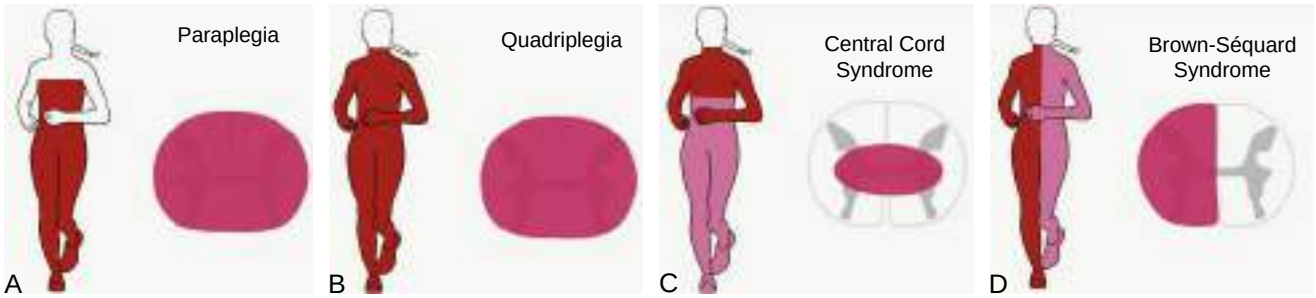

Fig 81.1 Patterns of spinal cord injury. Note the contrast between these syndromes and peripheral nerve/radicular injuries based on the distribution of motor and/or sensory loss beyond the affected extremity. *Paraplegia* (A) and *quadriplegia* (B): Complete loss of motor and sensory function below the level of injury resulting in loss of function of the legs only or arms and legs, respectively. *Central cord syndrome* (C): Injury of the central spinal cord resulting in functional greater impact of arm motor function than legs. Sensory deficits in this injury are variable. *Brown-Séquard syndrome* (D): Injury to one-half of the spinal cord resulting in ipsilateral motor weakness with contralateral sensory loss below the level of the lesion. (*From Jea A, Belal A, Zaazoue MA, Martin J. Cervical spine injury in children and adolescents. Pediatr Clin N Am. 2021;68:875-894: Fig. 11, p. 886.*)

Table 81.2 Risk Factors that Preclude Clinical Clearance of the C-Spine

HISTORY	PHYSICAL EXAMINATION
Child or parent reports persistent neck pain, abnormal head posture, or difficulty with neck movement	Visible known substantial injury to chest, abdomen, or pelvis (injury that is life-threatening, warrants surgical intervention or inpatient admission)
History of focal sensory abnormality or motor deficit	GCS of <14
High-risk injury*	Torticollis/abnormal head position
	Posterior midline neck tenderness
	Limited cervical range of motion
	Inability to maintain focus due to other injuries

*Diving, high speed motor vehicle crash, bike crash, motorized all-terrain vehicle.
GCS, Glasgow Coma Scale.
Modified from McCollum M, Guse S. Neck trauma: Cervical spine, seatbelt sign and penetrating palate injuries. *Emerg Med Clin N Am.* 2021;39:573-588, Table 2, p. 575.

(Table 81.2). Small children generally have a difficult-to-assess physical examination, and it is difficult to determine if they have cervical pain. Plain radiography remains a mainstay for assessing the spine because it is easy to obtain. There has been increasing emphasis on MRI for evaluation of potential C-spine instability, but in small children MRI requires sedation and in most centers the presence of an anesthesiologist (Fig. 81.2). CT scan is another important study with high sensitivity and specificity, but the risk of radiation exposure must be considered.

In addition to C-spine injury, neck trauma may also produce a radiculopathy or neuropathy (Table 81.3).

TREATMENT

The cervical spine should be immobilized in the field by the emergency medical technicians. In cases of acute spinal cord injury, weak data suggest acute infusion of a bolus of high-dose (30 mg/kg) methylprednisolone, followed by a 23-hour infusion (5.4 mg/kg/hr). The data for this treatment are controversial; the current neurosurgical guidelines for management of adult spine trauma do not recommend methylprednisolone; corticosteroids have not been specifically tested in children. *As such, many centers no longer use them routinely.*

Fig. 81.2 T2-weighted MRI performed the day after the accident showed cervical spinal cord swelling combined with high signal intensity (C1-C3) *(arrow)* and dislocation of C5-C6 *(arrowhead)*. (*From Inoue K, Kumada T, Fujii T, Kimura N. Progressive cervical spinal cord atrophy after a traffic accident. J Pediatr. 2017;180:287: Fig. 1, p. 287.*)

Maintenance of euvolemia and normotension is important, and vasopressors might be needed if the sympathetic nervous system has been compromised.

Surgical management of spinal injuries must be tailored to the patient's age but can be a crucial step in management. Any compression of the spinal cord must be surgically relieved to afford the best chance of a favorable outcome. In addition, spinal cord injury can be worsened by instability, so surgical stabilization can prevent further injury (Fig. 81.3). In general, younger children have a higher healing capacity for bones and ligaments, and external immobilization might be considered for injuries that require surgery in older children and adults. However, some injuries are highly unstable and always require surgery. **Occipitocervical dislocation** is one such highly unstable injury, and early surgery with fusion from the occiput to C2 or C3 should be performed, even in very young children. Fixation of the subaxial spine must be tailored to the size of the pedicles and other osseous structures of the developing axial skeleton.

Table 81.3 History and Examination Features Allowing for Discrimination of Myelopathy, Radiculopathy, and Peripheral Neuropathy

FINDING	PERIPHERAL NEUROPATHY	RADICULOPATHY	MYELOPATHY
Pain • Quality • Location	"Electric" Radiates either proximally or distally from injury site	Sharp, aching Radiates distally from the neck	Typically painless
Weakness	Variable, usually present	Variable, usually present	Variable, may be present
Sensory loss	Sharply demarcated borders	Indistinct borders	Indistinct borders, typically extends beyond single extremity
Tone/reflexes	Decreased	Decreased	Increased

From Jea A, Belal A, Zaazoue MA, Martin J. Cervical spine injury in children and adolescents. *Pediatr Clin N Am.* 2021;68:875-894, Table 4, p. 883.

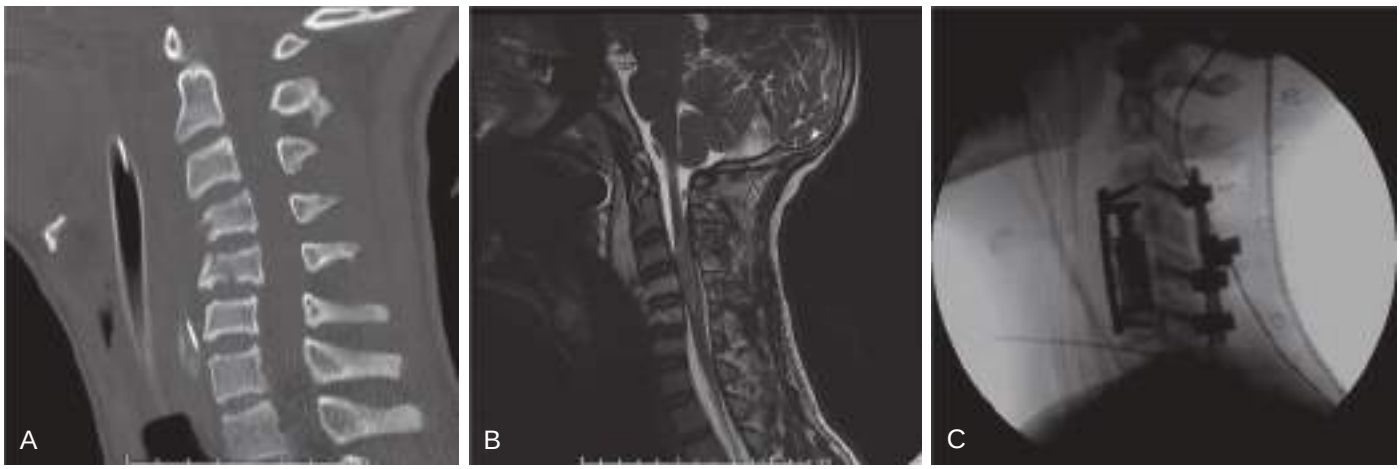

Fig. 81.3 A 15-year-old hockey player suffered acute paraplegia after his head struck the boards during a hockey game. **A,** CT scan shows compression fractures of C4 and C5. **B,** MRI shows severe spinal cord contusion. **C,** Because of the need to decompress the spinal cord and stabilize the spine, anterior and posterior surgery was performed. No meaningful recovery was obtained.

PREVENTION

The most important aspect of the care of spinal cord injuries in children is injury prevention. Use of appropriate child restraints in automobiles is the most important precaution. In older children and adolescents, rules against "spear tackling" in American football and the *Feet First, First Time* aimed at adolescents diving into swimming pools and natural water areas are important ways to help prevent severe cervical spinal cord injuries. Safe driving practices, such as using safety belts, avoiding distracted driving, and following the speed limit, can have substantial beneficial effects on injury rates.

Chapter 82

Neurologic Emergencies and Stabilization

Patrick M. Kochanek and Michael J. Bell

NEUROCRITICAL CARE PRINCIPLES

The brain has high metabolic demands, which are further increased during growth and development. Preservation of nutrient supply to the brain is the mainstay of care for children with evolving brain injuries. *Intracranial dynamics* describes the physics of the interactions of the contents—brain parenchyma, blood (arterial, venous, capillary), and cerebrospinal fluid (CSF)—within the cranium. Normally, brain parenchyma accounts for up to 85% of the contents of the cranial vault, and the remaining portion is divided between CSF and blood. The brain resides in a relatively rigid cranial vault, and cranial compliance decreases with age as the skull ossification centers gradually replace cartilage with bone. The **intracranial pressure (ICP)** is derived from the volume of its components and the bony compliance. The **perfusion pressure** of the brain (cerebral perfusion pressure [CPP]) is equal to the pressure of blood entering the cranium (mean arterial pressure [MAP]) minus the ICP, in most cases.

Increases in intracranial volume can result from swelling, masses, or increases in blood and CSF volumes. As these volumes increase, compensatory mechanisms prevent increases in ICP by (1) decreasing CSF volume (CSF is displaced into the spinal canal or absorbed by arachnoid villi), (2) decreasing cerebral blood volume (venous blood return to the thorax is augmented), and/or (3) increasing cranial volume (sutures pathologically expand or bone is remodeled). Once compensatory mechanisms are exhausted (the increase in cranial volume is too large), small increases in volume lead to clinically meaningful increases in ICP or intracranial hypertension (Fig. 82.1). As ICP continues to increase, brain ischemia can occur as CPP falls. Further increases in ICP can ultimately displace the brain downward into the foramen magnum—a process called **cerebral herniation**, which can become irreversible in minutes and may lead to severe disability or death; Figure 82.2 notes other sites of brain herniation.

Oxygen and glucose are required by brain cells for normal functioning, and these nutrients must be constantly supplied by cerebral blood flow (CBF). Normally, CBF is constant over a wide range of blood pressures (blood pressure autoregulation of CBF) via actions mainly within

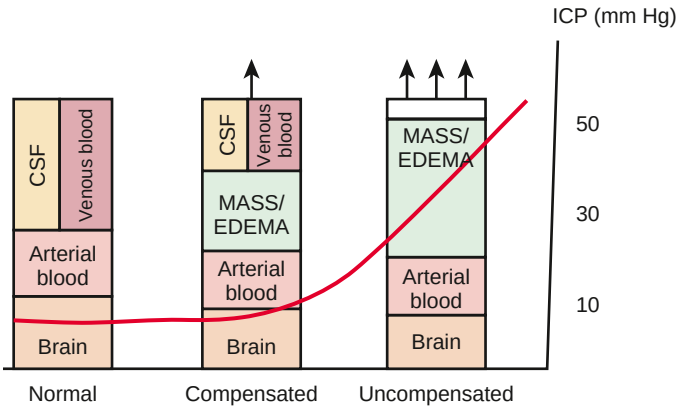

Fig. 82.1 The Munro-Kellie doctrine describes intracranial dynamics in the setting of an expanding mass lesion (i.e., hemorrhage, tumor) or brain edema. In the normal state, the brain parenchyma, arterial blood, CSF, and venous blood occupy the cranial vault at a low pressure, generally <10 mm Hg. With an expanding mass lesion or brain edema, initially there is a compensated state as a result of reduced CSF and venous blood volumes, and ICP remains low. Further expansion of the lesion, however, leads to an uncompensated state when compensatory mechanisms are exhausted and intracranial hypertension results.

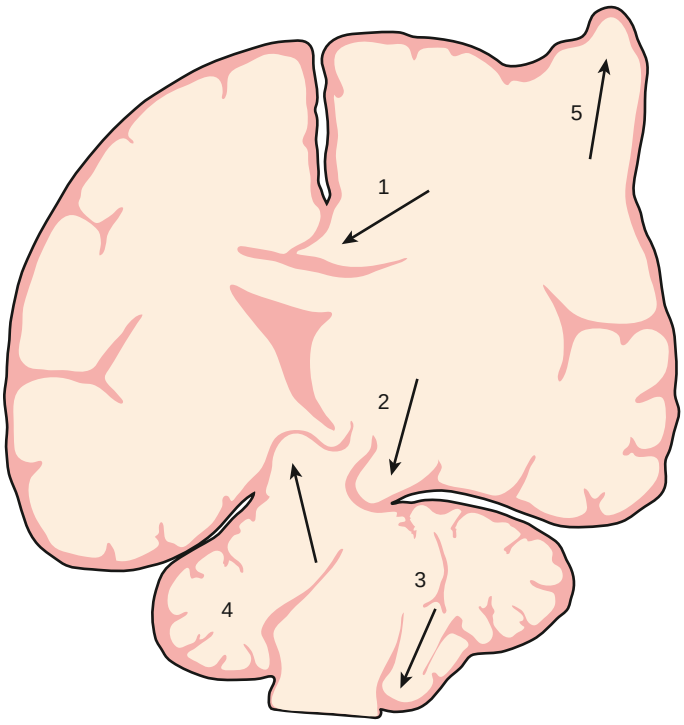

Fig. 82.2 Different forms of brain herniation. *1*, Cingulate. *2*, Uncal. *3*, Cerebellar tonsillar. *4*, Upward cerebellar. *5*, Transcalvarial. *(From Fishman RA. Cerebrospinal Fluid in Diseases of the Nervous System. Philadelphia: Saunders; 1980.)*

the cerebral arterioles. Cerebral arterioles are maximally dilated at lower blood pressures and maximally constricted at higher pressures so that CBF does not vary during normal fluctuations (Fig. 82.3). Above the upper limit of autoregulation, breakthrough dilation occurs that, if severe, can produce hypertensive encephalopathy. Acid-base balance of the CSF (often reflected by acute changes in arterial partial pressure of carbon dioxide [$Paco_2$]), body/brain temperature, glucose utilization,

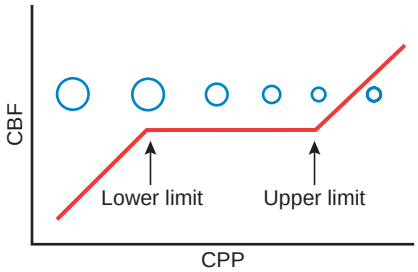

Fig. 82.3 Schematic of the relationship between CBF and CPP. The diameter of a representative cerebral arteriole is also shown across the center of the *y* axis to facilitate understanding of the vascular response across CPP that underlies blood pressure autoregulation of CBF. CPP is generally defined as the mean arterial pressure (MAP) minus the ICP. At normal values for ICP, this generally represents MAP. Thus, normally, CBF is kept constant between the lower limit and upper limit of autoregulation; in normal adults, these values are ≈50 mm Hg and 150 mm Hg, respectively. In children, the upper limit of autoregulation is likely proportionally lower than the adult value relative to normal MAP for age. However, according to the work of Vavilala et al. (2003), lower limit values are surprisingly similar in infants and older children. Thus infants and young children may have less reserve for adequate CPP. See text for details.

blood viscosity, and other vasoactive mediators (i.e., adenosine, nitric oxide, prostanoids) can also affect the cerebral vasculature.

Knowledge of these concepts is instrumental to preventing secondary brain injury. Increases in CSF pH that occur because of inadvertent hyperventilation (decreased $Paco_2$) can produce cerebral ischemia. Hyperthermia-mediated increases in cerebral metabolic demands may damage vulnerable brain regions after injury. Hypoglycemia can produce neuronal death when CBF fails to compensate. Prolonged seizures can lead to permanent injuries if hypoxemia occurs from loss of airway control.

Attention to detail and constant reassessment are paramount in managing children with critical neurologic insults. Among the most valuable tools for serial, objective assessments of neurologic condition is the **Glasgow Coma Scale (GCS)** (Table 82.1 and see Table 79.3). Originally developed to assess level of consciousness after traumatic brain injury (TBI) in adults, the GCS is also valuable in pediatrics. Modifications to the GCS have been made for nonverbal children and are available for infants and toddlers (see Table 79.3 in Chapter 79). Serial assessments of the GCS score along with a focused neurologic examination are invaluable to detect injuries before permanent damage occurs in the vulnerable brain. The **FOUR (full outline of unresponsiveness) score** (see Table 82.1) is a modification of the GCS, which eliminates the patient's verbal response but adds functional assessments of the brainstem (pupil, corneal, and cough reflexes) and respiratory pattern.

The most-studied monitoring device in clinical practice is the **ICP monitor**. Monitoring is accomplished by a catheter inserted either into the cerebral ventricle (externalized ventricular drain) or into brain parenchyma (parenchymal transducer). ICP-directed therapies are standard of care in TBI and are used in other conditions, such as intracranial hemorrhage, Reye syndrome, and some cases of encephalopathy, meningitis, and encephalitis. Other devices being used include catheters that measure brain tissue oxygen concentration, external probes that noninvasively assess brain oxygenation by absorbance of near-infrared light (near-infrared spectroscopy [NIRS]), monitors of brain electrical activity (continuous electroencephalography [EEG] or somatosensory, visual, or auditory evoked potentials), and CBF monitors (transcranial Doppler, xenon CT, perfusion MRI, or tissue probes). In the severe TBI guidelines, brain tissue oxygen concentration monitoring received level III support and thus may be considered as an adjunct to ICP-directed therapy.

Table 82.1 Commonly Used Coma Scores

GLASGOW COMA SCALE

Eye Opening
1 = does not open eyes
2 = opens eyes in response to noxious stimuli
3 = opens eyes in response to voice
4 = opens eyes spontaneously

Verbal Output
1 = makes no sounds
2 = makes incomprehensible sounds
3 = utters inappropriate words
4 = confused and disoriented
5 = speaks normally and oriented

Motor Response (Best)
1 = makes no movements
2 = extension to painful stimuli
3 = abnormal flexion to painful stimuli
4 = flexion/withdrawal to painful stimuli
5 = localized to painful stimuli
6 = obeys commands

FULL OUTLINE OF UNRESPONSIVENESS (FOUR) SCORE

Eye Response
4 = eyelids open or opened, tracking, or blinking to command
3 = eyelids open but not tracking
2 = eyelids closed but open to loud voice
1 = eyelids closed but open to pain
0 = eyelids remain closed with pain

Motor Response
4 = thumbs-up, fist, or peace sign
3 = localizing to pain
2 = flexion response to pain
1 = extension response to pain
0 = no response to pain or generalized myoclonus status

Brainstem Reflexes
4 = pupil and corneal reflexes present
3 = one pupil wide and fixed
2 = pupil or corneal reflexes absent
1 = pupil and corneal reflexes absent
0 = absent pupil, corneal, and cough reflex

Respiration
4 = not intubated, regular breathing pattern
3 = not intubated, Cheyne-Stokes breathing pattern
2 = not intubated, irregular breathing
1 = breathes above ventilatory rate
0 = breathes at ventilator rate or apnea

TRAUMATIC BRAIN INJURY

Etiology

Mechanisms of TBI include motor vehicle crashes, falls, assaults, and abusive head trauma. Most TBIs in children are from closed-head injuries.

Epidemiology

TBI is an important pediatric public health problem, with over 800,000 emergency department visits, 23,000 hospitalizations, and over 2,500 deaths in children annually in the United States. It is also 1 of the top 10 causes of years lost to disability throughout infancy, childhood, and adolescence.

Pathology

Epidural, subdural, and parenchymal intracranial hemorrhages can result. Injury to gray or white matter is also commonly seen and includes focal cerebral contusions, diffuse cerebral swelling, axonal injury, and injury to the cerebellum or brainstem. Patients with severe TBI often have multiple findings; diffuse and potentially delayed cerebral swelling is common.

Pathogenesis

TBI results in primary and secondary injury. Primary injury from the impact produces irreversible tissue disruption. In contrast, two types of secondary injury are targets of neurointensive care. First, some of the ultimate damage seen in the injured brain evolves over hours or days, and the underlying mechanisms involved (including edema, apoptosis, programmed necrosis, and secondary axotomy) are therapeutic targets. Second, the injured brain is vulnerable to additional insults because injury disrupts normal autoregulatory defense mechanisms; disruption of autoregulation of CBF can lead to ischemia from hypotension that would otherwise be tolerated by the uninjured brain.

Clinical Manifestations

The hallmark of **severe TBI** is coma **(GCS score 3-8)**. Coma is often seen immediately after the injury and is sustained. In some cases, such as with an epidural hematoma, a child may be initially alert on presentation but may deteriorate after a period of hours. A similar picture can be seen in children with diffuse swelling in whom a *talk-and-die* scenario has been described. Clinicians should also not be lulled into underappreciating the potential for deterioration of a child with **moderate TBI (GCS score 9-12)** with a significant contusion, because progressive swelling can potentially lead to devastating complications. In the comatose child with severe TBI, the second key clinical manifestation is the development of *intracranial hypertension*. The development of increased ICP with impending herniation may be heralded by new-onset or worsening headache, depressed level of consciousness, vital sign changes (hypertension, bradycardia, irregular respirations), and signs of sixth (lateral rectus palsy) or third (anisocoria [dilated pupil], ptosis, down-and-out position of globe as a result of rectus muscle palsies) cranial nerve compression. Increased ICP is managed with continuous ICP monitoring, as well as monitoring for clinical signs of increased ICP or impending herniation. The development of brain swelling is progressive. Significantly raised ICP (>20 mm Hg) can occur early after severe TBI, but peak ICP generally is seen at 48-72 hours. Need for ICP-directed therapy may persist for longer than a week. A few children have coma without increased ICP resulting from axonal injury or brainstem injury. *In addition to head trauma, it is critical to identify potential cervical spine injury* (see Chapter 81).

Laboratory Findings

Cranial CT should be obtained immediately after resuscitation and cardiopulmonary stabilization (Figs. 82.4-82.10). In some cases, MRI can be diagnostic (Fig. 82.11). An approach to CT scanning is noted in Figure 82.12. Generally, other laboratory findings are normal in isolated TBI, although occasionally coagulopathy or the development of the syndrome of inappropriate antidiuretic hormone (SIADH) secretion or cerebral salt wasting (CSW) is seen. In the setting of TBI with polytrauma, other injuries can result in laboratory and/or radiographic abnormalities, and a **full trauma survey** is important in all patients with severe TBI (see Chapter 80).

Diagnosis and Differential Diagnosis

In severe TBI, the diagnosis is generally obvious from the history and clinical presentation. Occasionally, TBI severity can be overestimated because of concurrent alcohol or drug intoxication. The diagnosis of TBI can be problematic in cases of abusive head trauma or after an anoxic event such as drowning or smoke inhalation.

Treatment

Infants and children with severe or moderate TBI (GCS score 3-8 or 9-12, respectively) receive intensive care unit (ICU) monitoring. Evidence-based guidelines for the management of severe TBI have been published (Fig. 82.13 and Fig. 82.14). This approach to ICP-directed therapy is also reasonable for other conditions in which ICP is monitored. Care involves a multidisciplinary team comprising pediatric caregivers from neurologic surgery, critical care medicine, surgery, and rehabilitation, among other services, and is directed at

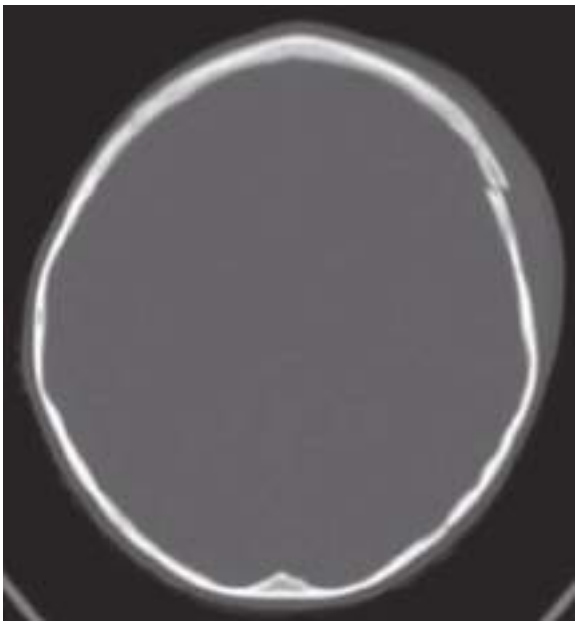

Fig. 82.4 Skull fracture. Mildly displaced skull fracture seen on CT imaging (bone window view) in a 4-year-old who fell and hit her head on a curb.

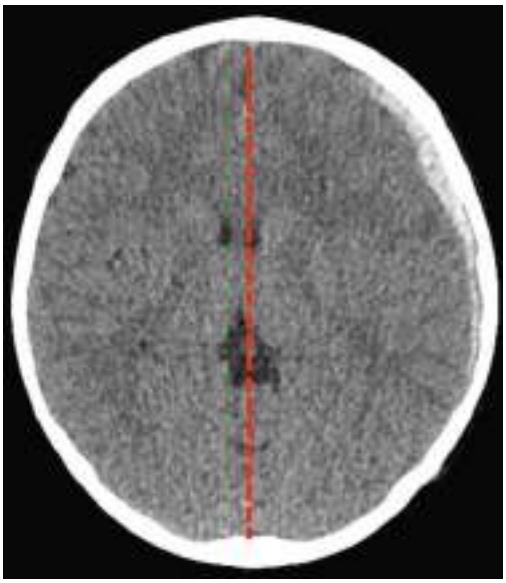

Fig. 82.6 Subdural hematoma. Left subdural hematoma observed on CT imaging in a 10-year-old child after a motor vehicle accident. Note effacement of the left lateral ventricle and midline shift (see *dashed line* for midline reference).

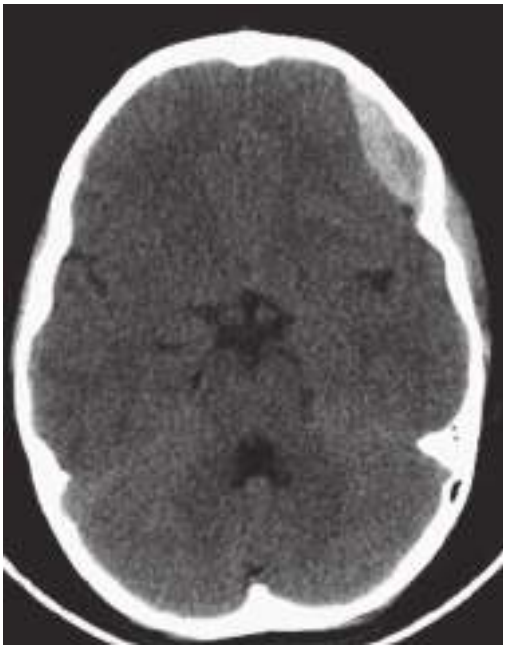

Fig. 82.5 Epidural hematoma. Left frontal epidural hematoma observed on CT imaging in a 12-year-old child who fell off his bike onto a concrete surface.

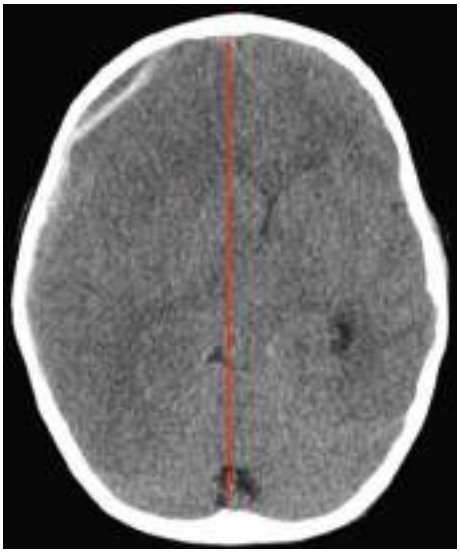

Fig. 82.7 Subdural hematoma. Hyperacute right frontal subdural hematoma observed on CT imaging in a 5-year-old after a motor vehicle accident. Note that the hyperacute aspect of the subdural hematoma is dark on CT imaging in the early stage after injury. Also, note that there is marked midline shift of intracranial contents, as both lateral ventricles are displaced into the left side of the skull.

preventing secondary insults and managing raised ICP. Initial stabilization of infants and children with severe TBI includes rapid sequence tracheal intubation with spine precautions along with maintenance of normal extracerebral hemodynamics, including blood gas values (Pao_2 and $Paco_2$), MAP, and temperature. Intravenous fluid boluses may be required to treat hypotension. Euvolemia is the target, and hypotonic fluids must be rigorously avoided; *normal saline is the fluid of choice*. Pressors may be needed as guided by monitoring of central venous pressure, with avoidance of both fluid overload and exacerbation of brain edema. A trauma survey should be performed. Once stabilized, the patient should be taken for CT scanning to rule out the need for emergency neurosurgical intervention. If surgery is not required, an ICP monitor should be inserted to guide the treatment of intracranial hypertension. Repeat CT scan may help determine whether a new lesion requiring surgical intervention has developed; this should be obtained if there is a change in examination or for refractory intracranial hypertension.

During stabilization or at any time during the treatment course, patients can present with signs and symptoms of *cerebral herniation* (pupillary dilation, systemic hypertension, bradycardia, extensor posturing). Because herniation and its devastating consequences can sometimes be reversed if promptly addressed, it should be treated as a medical emergency, with use of hyperventilation with a fraction of inspired oxygen of 1.0 titrated to reversal of pupillary dilation and

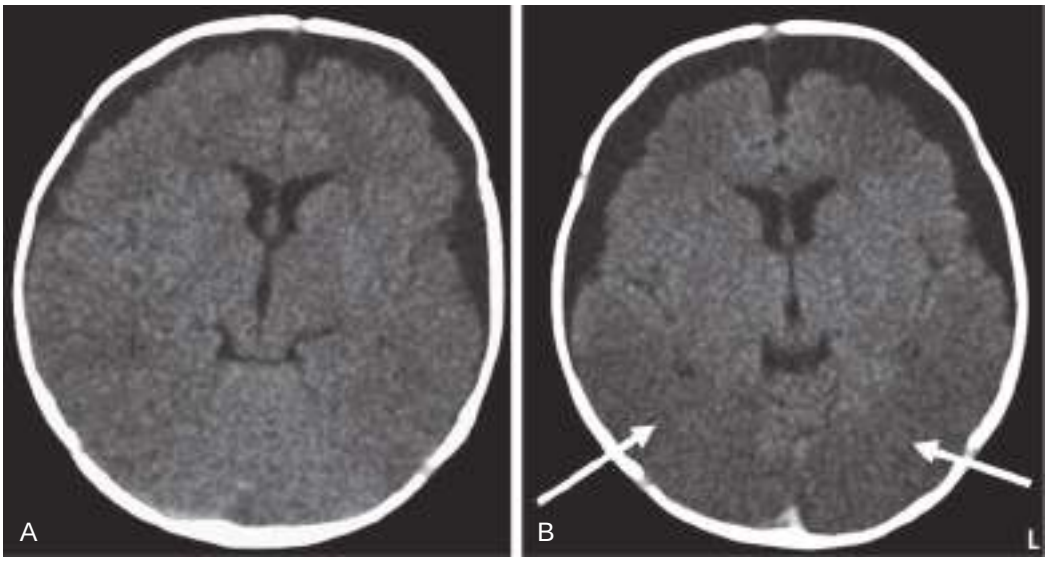

Fig. 82.8 Subdural hematoma. In a 3-month-old child who suffered from abusive head trauma, initial CT imaging (A) demonstrates chronic subdural hematoma bilaterally. Three days after hospitalization (B), the subdural hematomas are slightly larger but infarctions are noted in the posterior areas of brain parenchyma (*arrows*).

Fig. 82.9 Hemorrhage and edema. In a 16-year-old who fell from his dirt bike, CT imaging demonstrates intraparenchymal hemorrhage and significant surrounding edema *(arrow).*

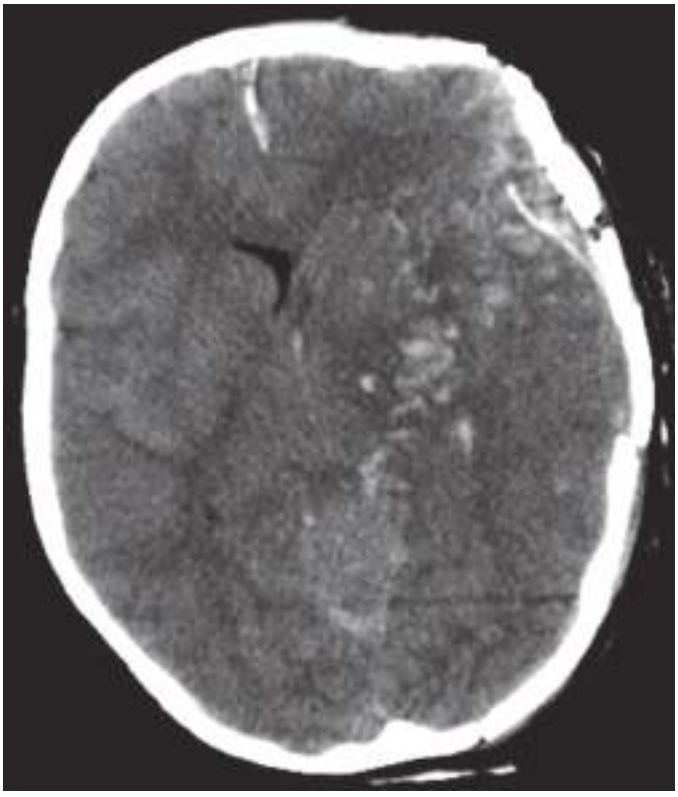

Fig. 82.10 Skull fractures and hemorrhage. An 11-year-old child was hit in the head by a horse, and CT imaging demonstrates multiple comminuted skull fractures with fragments of bone within the brain parenchyma, multifocal areas of intraparenchymal hemorrhage, and obliteration of the left lateral ventricle.

administration of either hypertonic saline (3% solution, 5-10 mL/kg IV) or mannitol (0.25-1.0 g/kg IV). If an external ventricular drain is in place, it should be opened to continuous drainage. Pentobarbital administration can also be considered if a prompt clinical response has not been observed.

ICP should be maintained at <20 mm Hg; age-dependent CPP targets are approximately 50 mm Hg for children 2-6 years of age, 55 mm Hg for those 7-10 years of age, and 65 mm Hg for those 11-16 years of age. **First-tier** therapy includes elevation of the head of the bed, ensuring midline positioning of the head, controlled mechanical ventilation, and analgesia and sedation (i.e., narcotics and benzodiazepines). If neuromuscular blockade is needed, it may be desirable to monitor EEG continuously because *status epilepticus* can occur; this complication will not be recognized in a paralyzed patient and is associated with raised ICP and unfavorable outcome. If a ventricular rather than parenchymal catheter is used to monitor ICP, therapeutic CSF drainage is available and can be provided either continuously (often targeting an ICP >5 mm Hg) or intermittently in response to ICP spikes, generally >20

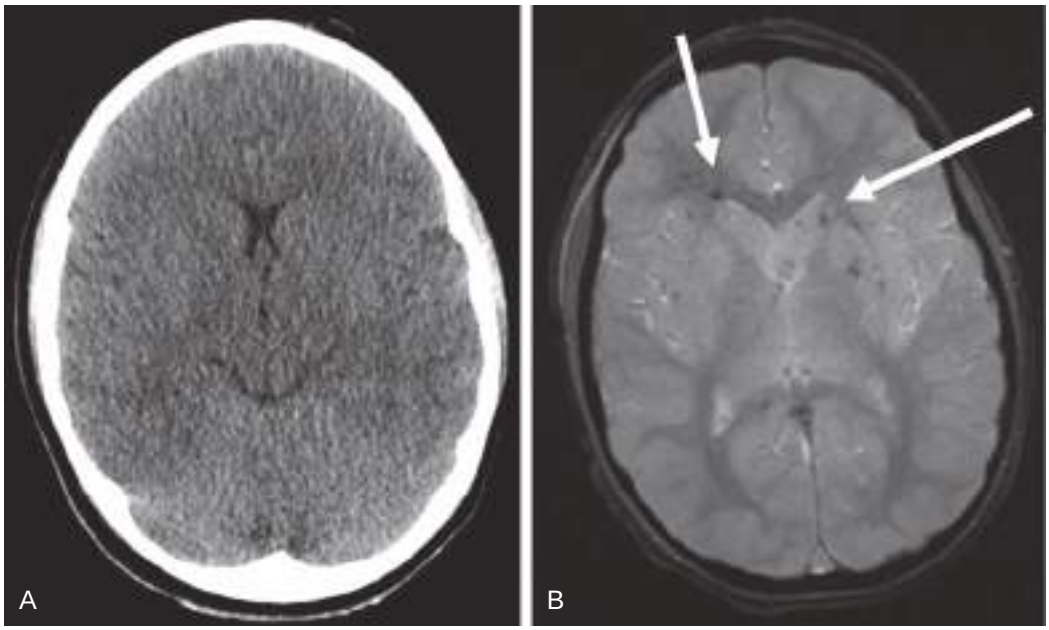

Fig. 82.11 Hemorrhages and axonal injury. In a 6-year-old child who was hit by a car while riding his bike, initial CT imaging demonstrates no obvious abnormality (**A**). However, immediate MRI demonstrates multiple areas of punctate hemorrhages (lucencies) consistent with diffuse axonal injury (**B**, *arrows*).

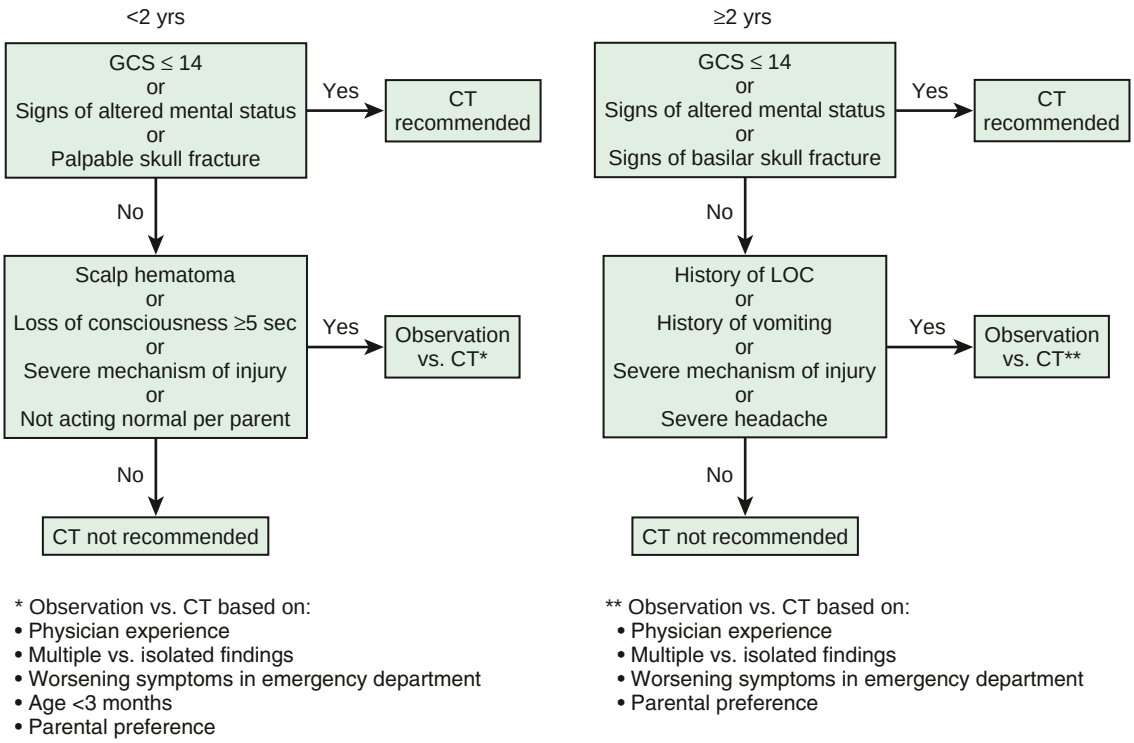

Fig. 82.12 Algorithm for head computed tomography (CT) scan using predictive rules. GCS, Glasgow Coma Scale; LOC, level of consciousness. *(Modified from Kupperman N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically important brain injuries after head trauma: A prospective cohort study.* Lancet. *2009;374:1160-1170.)*

mm Hg. Other first-tier therapies include the osmolar agents hypertonic saline or mannitol. Bolus administration of 3% **hypertonic saline** (between 2 and 5 mL/kg over 10-20 minutes) has guideline-based level II evidence supporting its use to treat ICP spikes >20 mm Hg or using a fixed (q4-q6h) dosing interval. It can also be given as a continuous infusion of 3% saline at 0.1-1.0 mL/kg/hr. **Mannitol** (0.25-1.0 g/kg IV over 20 minutes) represents an alternative. These agents can be used concurrently. It is recommended to avoid serum osmolality >320 mOsm/L. A Foley urinary catheter should be placed to monitor urine output.

If increased ICP remains refractory to treatment, careful reassessment of the patient is needed to rule out unrecognized hypercarbia, hypoxemia, fever, hypotension, hypoglycemia, pain, and seizures. Repeat imaging should be considered to rule out a surgical lesion. Guideline-based **second-tier** therapies for refractory raised ICP are available, but evidence favoring a given second-tier therapy is limited.

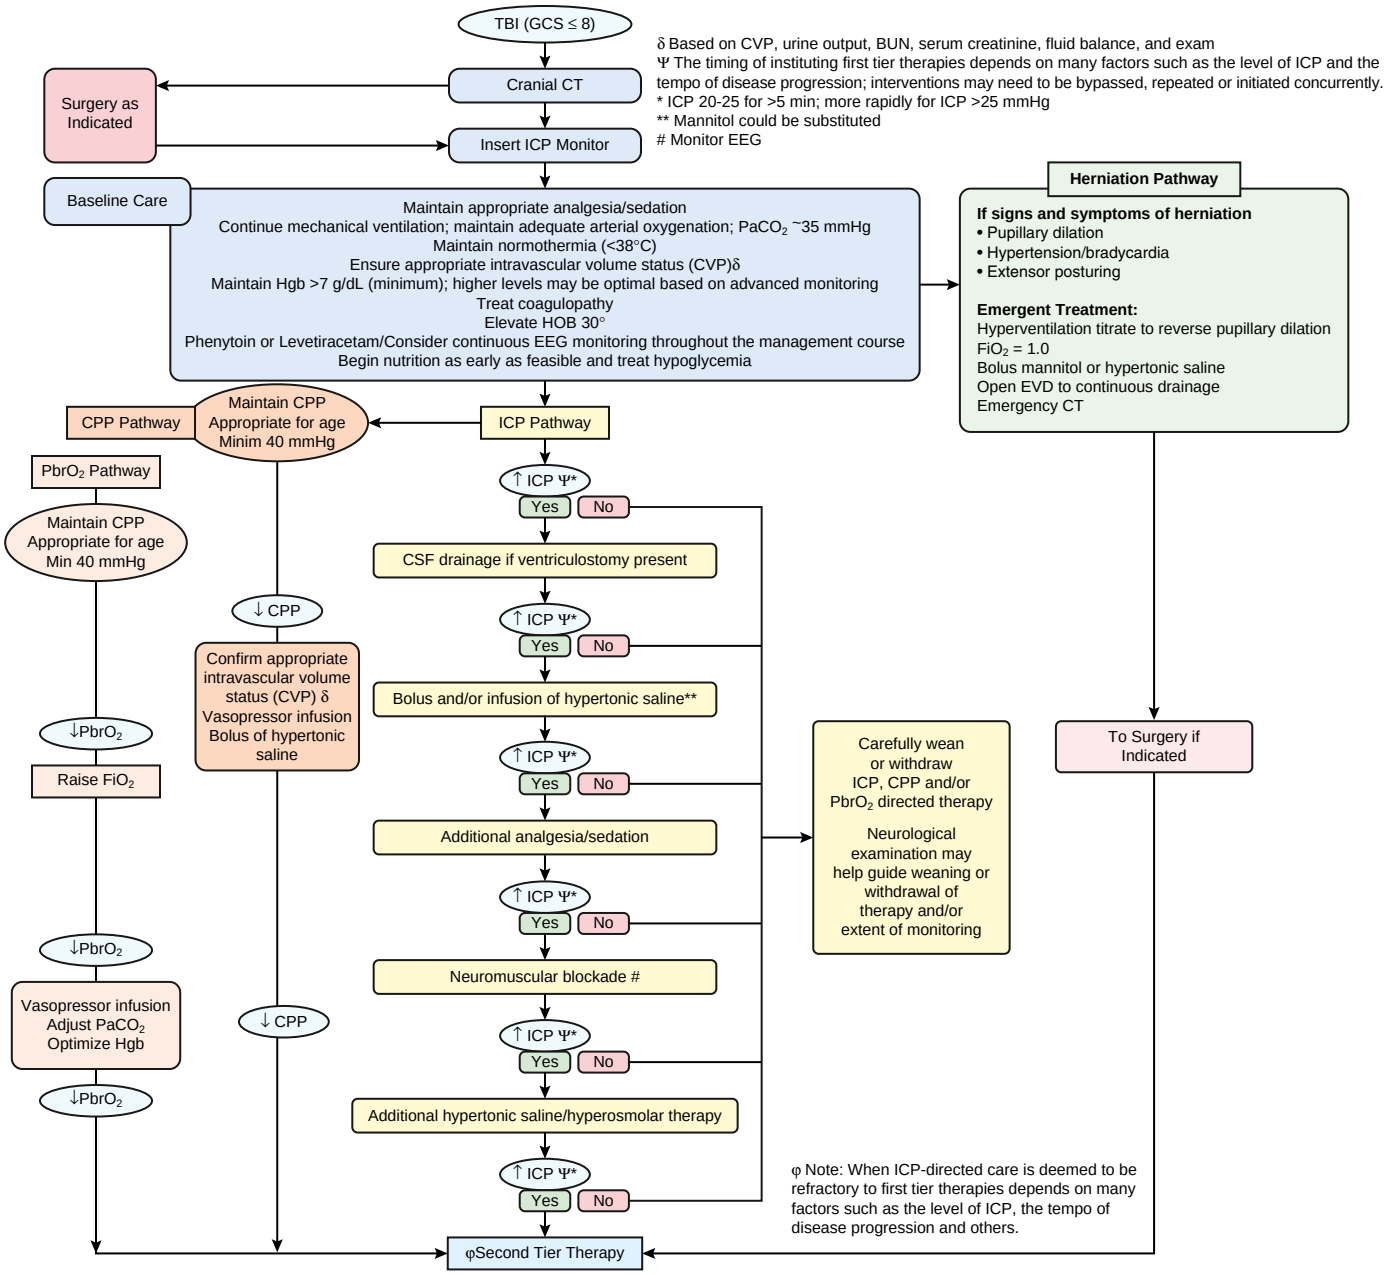

Fig. 82.13 Algorithm for use at the bedside to guide first-tier therapies to treat severe pediatric traumatic brain injury (TBI). This evidence- and consensus-based document that accompanied the third edition of the guidelines includes baseline care *(gray)*, an intracranial pressure (ICP) pathway *(yellow)*, a herniation pathway *(green)*, a cerebral perfusion pressure (CPP) pathway *(orange)*, a brain tissue partial pressure of oxygen ($PbrO_2$) pathway (purple), and surgical intervention (red). The caregiver should integrate all the available information and implement the evidence in the guidelines in the context of each patient's unique response to therapies to craft the most optimal treatment regimen. Although a linear approach in each pathway is provided, variations in tempo and timing during which therapies are implemented will vary from case to case. In some cases, a single intervention for raised ICP may suffice, whereas in others, multiple simultaneous interventions may be required. The *blue box* indicates the need for second-tier therapy (see Fig. 82.14). BUN, Blood urea nitrogen; CSF, cerebrospinal fluid; CT, computed tomography; CVP, central venous pressure; EEG, electroencephalogram; EVD, external ventricular drain; FiO_2, fraction of inspired oxygen concentration; GCS, Glasgow Coma Scale; Hgb, hemoglobin; HOB, head of bed; $PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen. *(From Kochanek PM, Bell MJ, Simon DW, et al. Traumatic brain injury. In: Zimmerman JJ, Totta AT, eds. Fuhrman & Zimmerman's Pediatric Critical Care, 6th ed. Philadelphia: Elsevier; 2022: Fig. 118.11, p. 1391.)*

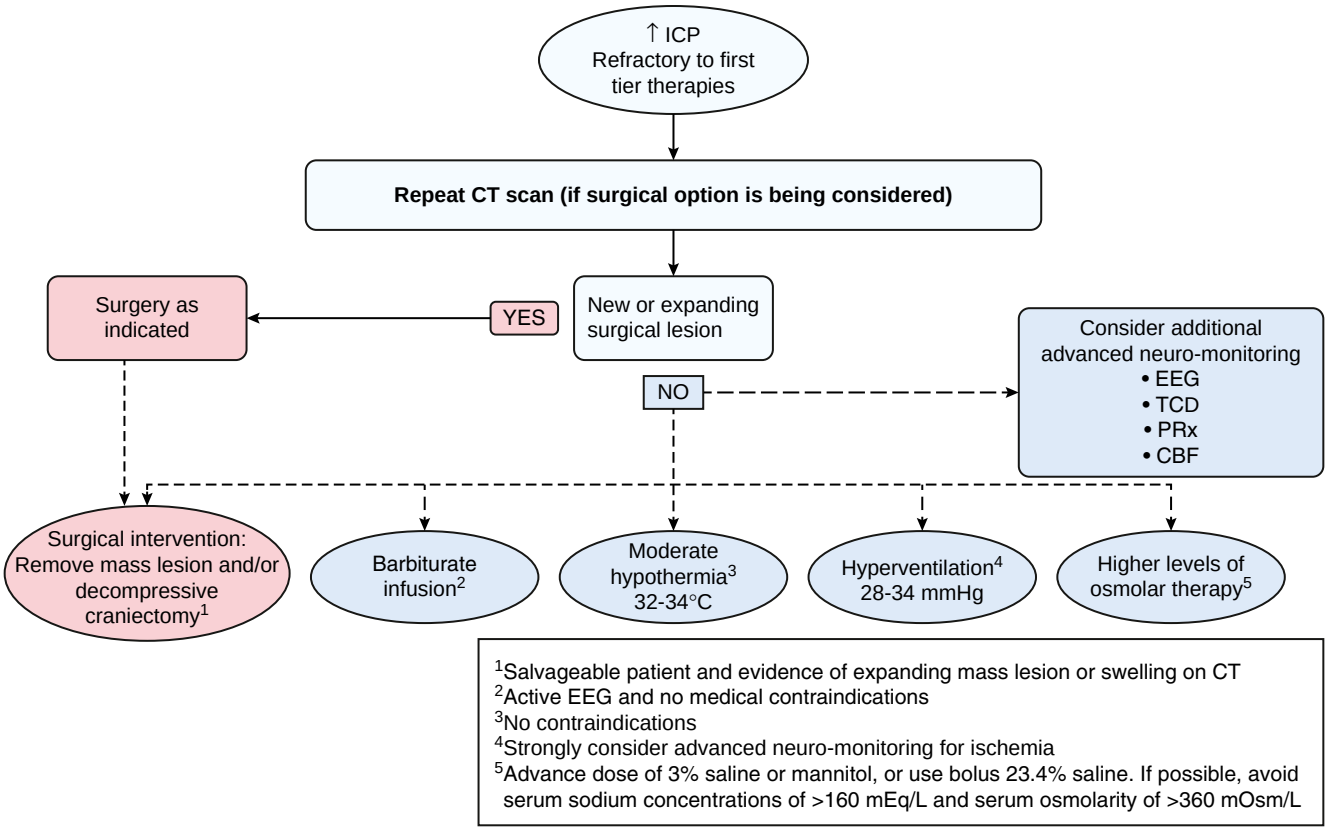

Fig. 82.14 Bedside algorithm to guide second-tier therapies to treat refractory intracranial hypertension in severe pediatric traumatic brain injury (TBI). This evidence- and consensus-based document that accompanied the third edition of the guidelines represents the treatment options when tier 1 approaches are inadequate. These therapies may be applied singly, serially, or in combination. In addition, as shown, management of refractory intracranial hypertension in the second-tier phase may be aided by advanced monitoring. CBF, Cerebral blood flow; CT, computed tomography; EEG, electroencephalogram; ICP, intracranial pressure; PRx, pressure reactivity index; TCD, transcranial Doppler ultrasonography. (*From Kochanek PM, Bell MJ, Simon DW, et al. Traumatic brain injury. In: Zimmerman JJ, Totta AT, eds.* Fuhrman & Zimmerman's Pediatric Critical Care, *6th ed. Philadelphia: Elsevier; 2022: Fig. 118.12, p. 1394.*)

In some centers, decompressive **craniectomy** is used. Others use a **pentobarbital infusion**, with a loading dose of 5-10 mg/kg over 30 minutes followed by 5 mg/kg every hour for 3 doses and then maintenance with an infusion of 1 mg/kg/hr. Careful blood pressure monitoring is required because of the possibility of drug-induced hypotension and the frequent need for support with fluids and/or pressors. Mild hypothermia (32–34°C [89.6–93.2°F]) to control refractory ICP is controversial but can be induced and maintained by means of surface cooling. Sedation and neuromuscular blockade are used to prevent shivering, and rewarming should be slow. Hypotension should be prevented during rewarming. Refractory raised ICP can also be treated with hyperventilation ($Paco_2$ = 25-30 mm Hg). Combinations of these second-tier therapies are often required.

Supportive Care

Euvolemia should be maintained, and isotonic fluids are recommended throughout the ICU stay. Either SIADH or CSW can develop and are important to differentiate, because management of SIADH is fluid restriction and that of CSW is sodium replacement. Severe hyperglycemia (blood glucose level >200 mg/dL) should be avoided and treated. The blood glucose level should be monitored frequently. Early nutrition with enteral feedings is advocated. Corticosteroids should generally not be used unless adrenal insufficiency is documented. Tracheal suctioning can exacerbate raised ICP. Timing of the use of analgesics or sedatives around suctioning events and/or use of tracheal or IV lidocaine can be helpful. Seizures are common after severe acute TBI. Early posttraumatic seizures (within 1 week) will complicate management of TBI and are often difficult to treat. Anticonvulsant prophylaxis with fosphenytoin or levetiracetam is recommended. Late posttraumatic seizures (≥7 days after TBI) and, if recurrent, late posttraumatic epilepsy are not prevented by prophylactic anticonvulsants, whereas early posttraumatic seizures are prevented by initiating anticonvulsants soon after TBI. Antifibrinolytic agents (tranexamic acid) reduce hemorrhage size, as well as the development of new focal ischemic cerebral lesions and improve survival in adults with severe TBI.

Prognosis

Mortality rates for children with severe TBI who reach the pediatric ICU range between 10% and 30%. Ability to control ICP is related to patient survival, and the extent of cranial and systemic injuries correlates with quality of life. Motor and cognitive sequelae resulting from severe TBI generally benefit from rehabilitation to minimize long-term disabilities. Recovery from TBI may take months or years to achieve. Physical therapy, and in some centers methylphenidate or amantadine, helps with motor and behavioral recovery. Pituitary insufficiency may be an uncommon but significant complication of severe TBI.

Chapter 83

Brain Death: Death by Neurologic Criteria

Matthew P. Kirschen and Wynne Morrison

Brain death, also known as **death by neurologic criteria**, is legally and culturally accepted as death in most of the world. In the United States, the **Uniform Determination of Death Act (UDDA)** defines brain death as the irreversible (some use "permanent") cessation of all functions of the entire brain, including the brainstem. The UDDA or a similar statute has been adopted in all states. Guidelines for the declaration of brain death in infants and children were published jointly by the Society of Critical Care Medicine (SCCM), American Academy of Pediatrics (AAP), and Child Neurology Society (CNS) in 2011. In 2020, the World Brain Death Project published a consensus statement with recommendations for the minimum clinical standards for determination of brain death in adults and children.

EPIDEMIOLOGY

Brain death by definition must occur as a result of catastrophic permanent global brain injury. Approximately 20% of children who die in pediatric intensive care units (PICUs) are declared brain dead. The most common etiologies of brain injury leading to brain death are hypoxic-ischemic injury from cardiac arrest, shock and/or respiratory failure without cardiac arrest, traumatic brain injury, intracranial infections, toxic ingestions, and causes of malignant cerebral edema. Mimics of brain death include botulism, Guillain-Barré syndrome, and high cervical cord injuries.

CLINICAL EVALUATION AND DIAGNOSIS

Brain death is determined by a careful, thorough clinical evaluation. The fundamental components of brain death are **coma**, **absence of brainstem reflexes**, and **apnea**. The first step in the brain death evaluation is to confirm that the catastrophic brain injury occurred because of an etiology known to lead to brain death. The next step is to ensure that there are no confounding conditions that could mimic or falsely suggest brain death. This is done by meticulously ensuring the patient is not hypotensive or hypothermic; does not have severe metabolic abnormalities like hypoglycemia, hyponatremia, or acidosis; and that sufficient time has passed to allow for clearance of all sedating medication or other toxins that could confound the examination. This involves review of the medical history, neuroimaging, electroencephalography (EEG), and laboratory data to rule out reversible causes of coma. Additionally, the patient should be observed for a sufficient amount of time (typically at least 24 hours after CPR or from their severe acute brain injury) to ensure there is no recovery of neurologic function. Checklists are very helpful in ensuring no prerequisites are missed (Fig. 83.1). Confounding factors must be corrected, if feasible, before initiation of the brain death evaluation. If all confounders are unable to be adequately corrected, ancillary testing is required to diagnose brain death. Brain death evaluation should not be performed in infants <37 weeks corrected gestational age.

Brain Death Neurologic Examination

The clinical examination evaluates for coma; absence of motor responses of the head, neck, and extremities; and brainstem areflexia including apnea in a setting of an adequate respiratory stimulus. The patient must be unresponsive to tactile, auditory, and visual stimulation other than spinally mediated reflexes. If it is unclear if motor movements are spinally mediated, ancillary testing may be necessary before brain death can be diagnosed. Brainstem reflexes must be absent. Table 83.1 lists the components of the neurologic examination, including brainstem reflexes to be tested, the brainstem location of each reflex, and the exam finding that is consistent with brain death. Several injuries and conditions can preclude completion or interpretation of the clinical examination. These include spinal cord injury, orbital/facial trauma, and severe neuromuscular disorders. In these situations, an ancillary test must be performed before declaring brain death. It is still necessary to perform all examination components that can be completed, and every component assessed must be consistent with brain death to allow declaration.

Apnea Test

Apnea is the absence of respiratory effort. The purpose of the required apnea test is to evaluate whether the chemoreceptors in the brainstem's medulla, which stimulate respiration when exposed to hypercarbia and acidosis, are functional. The patient should be euvolemic, normotensive, and euthermic before beginning the apnea test. The apnea test can result in cardiopulmonary decompensation and should only be performed in a PICU by clinicians with skills to stabilize or resuscitate the patient if needed. Before the apnea test, the patient is preoxygenated with 100% oxygen for approximately 10 minutes, and ventilation is adjusted to achieve a $Paco_2$ of approximately 40 mm Hg. A baseline arterial blood gas (ABG) documents the starting $Paco_2$ value. The patient is then removed from intermittent mechanical ventilation and provided apneic oxygenation by delivering 100% oxygen via continuous positive airway pressure (CPAP) on the ventilator or via flow-inflating resuscitation bag with a functioning peak end-expiratory pressure (PEEP) valve. The patient's hemodynamics and pulse oximetry oxygen-hemoglobin saturation (Spo_2) are monitored continuously while the physician observes for respiratory effort. An ABG sample is obtained approximately 5-10 minutes into the test and every 2 minutes thereafter until the target $Paco_2$ is surpassed; ventilatory support is resumed at that time. Absence of respiratory effort with a $Paco_2$ ≥60 mm Hg *and* >20 mm Hg above baseline is consistent with brain death. If at any point during the test the patient becomes hypoxic (Spo_2 <85%) or hypotensive, the test is aborted and ventilatory support resumed.

OBSERVATION PERIODS

To determine brain death in the United States, current guidelines recommend the neurologic examination and apnea test be performed by different attending physicians separated by an observation period. The examination determines that the child has met criteria for brain death. An observation period before the examination is based on the patient's age: For infants (≥37 weeks corrected gestational age) and children <24 months, observe for at least 48 hours. For patients >2 years, observe for at least 24 hours. Before testing, core body temperature should be maintained ≥36° C. In addition in adults, systolic blood pressure (SBP) should be ≥100 mm Hg and mean arterial blood pressure (MAP) should be ≥75 mm Hg; in children SBP and MAP should be ≥5th percentile for age.

Similar MAPs are recommended for patients on venoarterial ECMO. Furthermore, before treating metabolic disorders, intoxication and effects of therapeutic medications that depress the CNS and peripheral nervous system (paralytics) must be excluded. In children, two different clinicians must perform independent neurological and apnea examinations separated by a minimal interval of 12 hours.

ANCILLARY STUDIES

Ancillary studies are not required for the diagnosis of brain death and should only be used to assist the clinician in declaring brain death (1) when components of the neurologic examination or apnea test cannot be completed safely because of the underlying medical condition of the patient; (2) if there is uncertainty about the results of the neurologic examination; (3) if a medication effect may be present; or (4) to reduce the observation period between examinations. If an ancillary test is used to shorten the observation period, the physician is still required to complete two clinical examinations and apnea tests, along with the ancillary study.

The most common ancillary tests are EEG and radionuclide perfusion scintigraphy (or cerebral blood flow) studies. Other tests are available (Table 83.2); however, these have not been incorporated into clinical practice in the United States, although they are used outside of the United States in some practice settings. A valid **electroencephalogram** to support a diagnosis of brain death must be performed according to the American EEG Society standards and technical requirements. Confounders should be excluded, and the EEG must demonstrate

Checklist for Documentation of Brain Death

Brain Death Examination for Infants and Children[a]

Age of Patient	Timing of First Examination	Interexamination Interval
Term newborn 37 weeks gestational age and up to 30 days old	☐ First examination may be performed 24 hours after birth OR following cardiopulmonary resuscitation or other severe brain injury	☐ At least 24 hours ☐ Interval shortened because ancillary study (Section 4) is consistent with brain death
31 days to 18 years old	☐ First examination may be performed 24 hours following cardiopulmonary resuscitation or other severe brain injury	☐ At least 12 hours OR ☐ Interval shortened because ancillary study (Section 4) is consistent with brain death

Section 1. Prerequisites for Brain Death Examination and Apnea Test

A. Irreversible and Identifiable Cause of Coma (please check)

☐ Traumatic brain injury ☐ Anoxic brain injury ☐ Known metabolic disorder ☐ Other (specify) _____

B. Correction of Contributing Factors That Can Interfere with the Neurologic Examination

	Examination 1		Examination 2	
a. Core body temperature is >95°F (35°C)	☐ Yes	☐ No	☐ Yes	☐ No
b. Systolic blood pressure or MAP in acceptable range (Systolic BP not less than 2 standard deviations below age-appropriate norm) based on age	☐ Yes	☐ No	☐ Yes	☐ No
c. Sedative/analgesic drug effect excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
d. Metabolic intoxication excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
e. Neuromuscular blockade excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No

☐ If ALL prerequisites are marked YES, then proceed to section 2, OR

☐ _____ confounding variable was present. Ancillary study was therefore performed to document brain death (Section 4).

Section 2. Physical Examination (please check); Note: Spinal Cord Reflexes Are Acceptable

	Examination 1, Date/Time: _____		Examination 2, Date/Time: _____	
a. Flaccid tone, patient unresponsive to deep painful stimuli	☐ Yes	☐ No	☐ Yes	☐ No
b. Pupils are midposition or fully dilated and light reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
c. Corneal, cough, gag reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
d. Sucking and rooting reflexes are absent (in neonates and infants)	☐ Yes	☐ No	☐ Yes	☐ No
e. Oculovestibular reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
f. Spontaneous respiratory effort while on mechanical ventilation is absent	☐ Yes	☐ No	☐ Yes	☐ No

☐ The _____ (specify) element of the examination could not be performed because _____.
Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death (Section 4).

Section 3. Apnea Test

	Examination 1, Date/Time: _____	Examination 2, Date/Time: _____
No spontaneous respiratory efforts were observed despite final $PaCO_2$ ≥60mmHg and a ≥20mmHg increase above baseline (Examination 1). No spontaneous respiratory efforts were observed despite final $PaCO_2$ ≥60mmHg and a ≥20mmHg increase above baseline (Examination 2).	Pretest $PaCO_2$: _____ Apnea duration: _____ min Post-test $PaCO_2$: _____	Pretest $PaCO_2$: _____ Apnea duration: _____ min Post-test $PaCO_2$: _____

Apnea test is contraindicated or could not be performed to completion because _____.
Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death (Section 4).

Section 4. Ancillary Testing

Ancillary testing is required (1) when any components of the examination or apnea testing cannot be completed; (2) if there is uncertainty about the results of the neurologic examination; or (3) if a medication effect may be present. Ancillary testing can be performed to reduce the interexamination period; however, a second neurologic examination is required. Components of the neurologic examination that can be performed safely should be completed in close proximity to the ancillary test.

Date/Time:_____

☐ EEG report documents electrocerebral silence OR ☐ Yes ☐ No

☐ CBF study report documents no cerebral perfusion ☐ Yes ☐ No

Section 5. Signatures

Examiner 1
I certify that my examination is consistent with cessation of function of the brain and brainstem. Confirmatory examination to follow.

Fig. 83.1 Checklist for documentation of brain death. *(From Nakagawa TA, Ashwal S, Mathur M, et al. Guidelines for the determination of brain death in infants and children: An update of the 1987 Task Force recommendations—executive summary.* Ann Neurol. *2012;71:573-585, Table 2.)*

Table 83.1 Neurologic Examination to Evaluate a Patient for Brain Death

EXAM COMPONENT	HOW TO PERFORM	RESPONSE CONSISTENT WITH BRAIN DEATH
Coma	Visual response: blink to visual threat Auditory response: clapping and yelling the child's name loudly Tactile response: apply deep pressure to the condyles at the level of the temporomandibular joints, the supraorbital notch bilaterally, the sternum, and all four extremities proximally and distally	No response to visual or auditory stimuli; noxious stimuli do not produce grimacing, facial or body muscle movement, or any motor response other than spinally mediated reflexes
Pupillary light reflex (CNs II and III)	Shine a bright light into each eye while closely observing pupillary size and reactivity	Absence of ipsilateral and contralateral pupillary response, with pupils fixed in a midsize or dilated position (4-6 mm) in both eyes
Corneal reflex (CNs III, V, VII)	Touch the cornea of each eye with a cotton swab at the external border of the iris, applying light pressure and observing for any eyelid movement	Absence of eyelid movement
Oculocephalic reflex (CNs III, VI, and VIII)	Confirm integrity of the cervical spine. Secure the endotracheal tube to prevent dislodgement; briskly rotate the head horizontally to both sides and observe for movement of the eyes	Absence of movement of the eyes relative to head movement; eyes follow the head movement, staying in mid-position
Oculovestibular reflex (CNs III, IV, VI, and VIII)	Irrigate the ear canal with 50-60 mL of ice water for at least 60 sec while observing for eye movement; test each side separately and with a 5-min interval in between	Absence of eye movement
Gag and cough reflex (CNs IX and X)	Touch the posterior pharynx with a tongue depressor or a rigid suction catheter to stimulate a gag; touch the tracheobronchial wall at the level of the carina with placement of a suction catheter through the endotracheal tube to stimulate a cough	Absence of both cough and gag
Sucking and rooting reflexes	Place a gloved finger inside the baby's mouth to stimulate sucking; stroke the external surface of both cheeks and corners of the mouth to stimulate rooting	Absence of sucking and rooting

CN, Cranial nerve.

Table 83.2 Ancillary Tests for Determining Brain Death

TEST	CONFOUNDER/LIMITATION*	SENSITIVITY/ SPECIFICITY
BRAIN BLOOD FLOW		
Computed tomography angiography	Requires transport to the scanner Image variability based on injection technique Potential to miss a slow flow state Risk of nephrotoxicity Not recommended by AAN 2023 Guidelines[#]	52–97% / 100%
Digital subtraction angiography[†]	Requires transport to angiography suite Risk of nephrotoxicity Image variability based on injection technique	100% / 100%
Magnetic resonance angiography	Requires transport to the scanner Image variability based on injection technique	93–100% / 100%
Radionuclide angiography[†]	Limited evaluation of brainstem	99% / 56%
Radionuclide scintigraphy[†]	Requires transport to the scanner Planar imaging may have limited evaluation of brainstem	Planar: 78% / 100% SPECT: 88% / 100%
Transcranial Doppler ultrasonography[†]	Potential for technical difficulties in performance Potential for lack of windows	90% / 98%
ELECTROPHYSIOLOGIC FUNCTION		
Electroencephalography	Risk of environmental artifact Confounded by sedation, hypothermia and toxic-metabolic derangements Predominantly provides information about cortical function	53–80% / 97%
Evoked potentials-auditory	Can be absent in comatose patients with other intact brainstem reflexes Confounded by sedation, hypothermia, isolated eighth nerve and brainstem lesions Only evaluates auditory pathways Performance/interpretation may be limited by experience	NA / NA
Evoked potentials-somatosensory	Can be absent in comatose patients with ongoing brain function Confounded by cervical spine injury, isolated brainstem lesions, sedation, and hypothermia Only evaluates somatosensory pathways Performance/interpretation may be limited by experience	100% / 78%
Evoked potentials-visual	Can be absent in comatose patients with ongoing brain function Confounded by sedation, retinal or optic nerve lesions Only evaluates visual pathways Performance/interpretation may be limited by experience	NA / NA

*Performance/interpretation of all ancillary tests may be limited by experience

electrocerebral silence. A **radionuclide cerebral blood flow study** consists of intravenous injection of a radiopharmaceutical agent followed by imaging of the brain by planar or single-photon emission computed tomography (SPECT) imaging. A study that demonstrates absence of intracranial blood flow and cerebral perfusion is supportive of brain death. CT and MR angiography are not recommended.

Interpretation of both EEG and cerebral blood flow studies should only be performed by trained and qualified individuals. If the study shows any evidence of electrical activity or cerebral blood flow, brain death cannot be declared. A 24-hour waiting period is recommended before repeating the brain death evaluation.

DOCUMENTATION

Documentation is an important aspect of the brain death evaluation and determination and should follow a checklist, including the following points:

1. Etiology of brain injury
2. Absence of confounding factors, including hypothermia, hypotension, metabolic abnormalities, and recent doses of sedative or neuromuscular blocking agents
3. Absence of motor response to tactile, auditory, and visual stimuli
4. Absence of brainstem reflexes, including pupillary light reflex, oculocephalic/oculovestibular reflex, corneal reflex, cough reflex, and gag reflex
5. ABG values during the apnea test and statement about respiratory effort
6. Results of ancillary testing (if indicated)

AFTER DECLARATION OF BRAIN DEATH

After brain death has been declared, the child is legally dead. The time of death is the time the final required component of the evaluation is completed: either ABG results or ancillary test. Families may be approached by representatives of organ procurement organizations to discuss options for organ donation after brain death. For families that choose not to donate organs, the next appropriate step in the care of the child is removal of technologic supports, including mechanical ventilation, after which the child's heart will become asystolic. It is important for care providers to be supportive of the family dealing with this difficult situation. Child life and palliative care specialists can be helpful in guiding families during this time. Technologic support is typically stopped within a few hours of declaring brain death, although in some situations it can be delayed at the discretion of the physician and in accordance with hospital protocols.

OBJECTIONS TO THE CONCEPT OF BRAIN DEATH

The concept of brain death may not be accepted by families for personal, religious, or cultural reasons. Some families have difficulty comprehending the fact that their child meets criteria for legal death despite having a heartbeat, blood pressure, and being warm to the touch. Other families maintain hope for recovery, and some have religious views that death can only be declared after cessation of cardiorespiratory function. Some individuals have challenged the brain death guidelines claiming that they do not sufficiently evaluate "all functions of the entire brain, including the brainstem," as mandated by the UDDA, particularly as some patients who meet brain death criteria continue to show evidence of *integrative functioning,* such as control over free water homeostasis (absence of diabetes insipidus), control of temperature regulation, and capacity for growth and wound healing. Others argue that the intent of the UDDA is met by the current clinical evaluation. Objections to performing the brain death evaluation or declaration of death should be handled by a multidisciplinary team with experience in these situations. These teams often include physicians, social workers, ethicists, chaplains, hospital administrators, and lawyers as appropriate.

Chapter 84

Syncope

Aarti S. Dalal and George F. Van Hare

Syncope is defined as a sudden transient loss of consciousness with inability to maintain postural tone. The most common cause of syncope in the normal pediatric population is **neurocardiogenic syncope** (vasovagal syncope, fainting). **Vasovagal syncope** is classically associated with a prodrome that includes diaphoresis, warmth, pallor, or feeling lightheaded and is often triggered by acute position changes or by a specific situation or event such as pain, medical procedures, or emotional distress (Table 84.1). This type of syncope is characterized by hypotension and bradycardia. Approximately 30–50% of children will have had a **fainting** episode before 18 years of age. The symptoms of vasovagal syncope can overlap with those of postural orthostatic tachycardia syndrome (POTS), a constellation of symptoms characterized by symptoms of rapid heart rate and supported by a positional increase in heart rate by 40 beats per minute with normal blood pressure (see Chapter 84.1).

Most patients with a vasovagal syncope episode will have prodromal features followed by loss of motor tone. Once in a horizontal position, consciousness returns rapidly, usually in 1-2 minutes; some patients may have a brief period of stiffening or jerking, which should not be confused with a **seizure** (Table 84.2). Syncope must also be distinguished from **vertigo** and **ataxia** (Table 84.3).

Although this type of syncope is very common in adolescence and has an excellent prognosis, other causes for loss of consciousness are more dangerous; thus syncope may be the first sign of more serious conditions (Table 84.4). Indeed, the occurrence of syncope may well be the pediatrician's best opportunity to diagnose a life-threatening condition before the patient subsequently succumbs. The task of the clinician therefore is not only to counsel the family and the patient concerning the common form but also to rule out a number of important life-threatening cardiac problems.

MECHANISMS

Syncope by whatever mechanism is caused by a lack of adequate cerebral blood flow with loss of consciousness and inability to remain upright.

Primary **cardiac causes** of syncope (see Table 84.4) include conditions that predispose a patient to arrhythmias or conditions such as congenital or acquired structural heart disease. Arrhythmic causes of syncope include Wolff-Parkinson-White syndrome (particularly with atrial fibrillation), ventricular tachycardia (VT), and occasionally supraventricular tachycardia (see Chapter 484). VT may be associated with hypertrophic cardiomyopathy (HCM), arrhythmogenic cardiomyopathy, repaired congenital heart disease, or an inherited arrhythmia syndrome such as catecholaminergic polymorphous ventricular tachycardia (CPVT) or long QT syndrome (LQTS) (Table 84.5). Other arrhythmias that may lead to syncope are bradyarrhythmias such as sinus node dysfunction and high-grade second- or third-degree atrioventricular (AV) block. Syncope may also be caused by cardiac obstructive lesions, such as critical aortic stenosis, or coronary artery anomalies, such as an aberrant left coronary artery arising from the right sinus of Valsalva. Patients with primary pulmonary hypertension or Eisenmenger syndrome may also experience syncope. In all the obstructive forms of syncope, exercise increases the likelihood of an episode because the obstruction interferes with the ability of the heart to increase cardiac output in response to exercise.

Noncardiac causes of loss of consciousness include epilepsy, basilar artery migraine, hysterical syncope, and psychogenic nonepileptic seizures (see Table 84.1). Occasionally, patients with narcolepsy may present with syncope. Hypoglycemia and hyperventilation may also present as syncope.

Table 84.1 Noncardiac Causes of Syncope

REFLEX VASODEPRESSOR SYNCOPE
Neurocardiogenic (vasovagal)
Emotion (seeing blood)
Pain (needle phobia)
Reflex asystolic syncope (pallid breath-holding)

MISCELLANEOUS SITUATIONAL REFLEX
Tussive
Sneeze
Exercise, after exercise
Swallowing
Stretching
Defecation
Micturition
Hair grooming
Valsalva (increased intrathoracic pressure)
Trumpet playing

Conversion disorder

Table 84.2 Comparison of Clinical Features of Syncope and Seizures

FEATURES	SYNCOPE	SEIZURES
Relation to posture	Common	No
Time of day	Diurnal	Diurnal or nocturnal
Precipitating factors	Emotion, injury, pain, crowds, heat, exercise, fear, dehydration, coughing, micturition, venipuncture, prolonged standing	Sleep loss, drug/alcohol withdrawal, illness, medication nonadherence
Skin color	Pallor	Cyanosis or normal
Diaphoresis	Common	Rare
Aura or premonitory symptoms	Often minutes or longer, but can be very brief	Brief
Convulsion	Rare	Common
Other abnormal movements	Minor irregular twitching	Rhythmic jerks
Injury	Rare	Common (with convulsive seizures)
Urinary incontinence	Rare	Common
Tongue biting	No	Common with convulsive seizures
Postictal confusion	Rare	Common
Postictal headache	No	Common
Focal neurologic signs	No	Occasional
Cardiovascular signs	Common to have low blood pressure and heart rate during event; cardiovascular exam may be completely normal after event unless there is an underlying cardiac disorder	Rare
Abnormal findings on EEG	Rare (generalized slowing may occur during the event)	Common

Table 84.4 Causes of Cardiovascular Syncope: Potentially Fatal If Unrecognized

ARRHYTHMIAS

Bradyarrhythmias

1. Sinus node dysfunction (especially in patients with congenital heart defects)
2. Atrioventricular block (congenital or acquired; Lyme, Fabry, Chagas diseases)
3. Kearns-Sayre syndrome
4. Pacemaker malfunction

Tachyarrhythmias

1. Supraventricular
   a. Wolff-Parkinson-White syndrome
   b. Supraventricular tachycardia/atrial arrhythmias (especially in patients with congenital heart defects)
2. Ventricular: ventricular tachycardia/torsades/ventricular fibrillation
   a. Channelopathies
      - Long QT syndromes
      - Catecholaminergic polymorphic ventricular tachycardia
      - Brugada syndrome
      - Short QT syndrome
   b. Drug induced
   c. Idiopathic
      - Ventricular fibrillation
      - Ventricular tachycardia from outflow tract

STRUCTURAL/FUNCTIONAL HEART DISEASE

Cardiomyopathy

1. Hypertrophic cardiomyopathy
2. Dilated cardiomyopathy
3. Arrhythmogenic right ventricular dysplasia
4. Left ventricular noncompaction

Coronary Anomalies

1. Anomalous origin
2. Kawasaki disease
3. Multisystemic inflammatory syndrome in children (MIS-C) secondary to SARS-CoV-2

Valvar Aortic Mitral or Pulmonary Stenosis

Takotsubo Disease

Acute Myocarditis

Congenital Heart Disease (Repaired and Unrepaired)

Pulmonary Hypertension, Pulmonary Embolus

Aortic Dissection (Marfan Syndrome)

Cardiac Masses (Myxoma, Rhabdomyoma, Thrombus)

Eisenmenger Syndrome

From MacNeill E, Vashist S. Approach to syncope and altered mental status. *Pediatr Clin N Am.* 2013;60:1083-1106.

EVALUATION

The most important goal in the evaluation of the new patient with syncope is to diagnose life-threatening causes of syncope so that these causes can be managed and more severe outcomes avoided. Many patients presenting with sudden cardiac arrest caused by conditions such as LQTS will have previously experienced an episode of syncope, so the presentation with syncope is an opportunity to prevent sudden death.

The most important tool in evaluation of syncope is a careful **personal** and **family history**. The characteristics of cardiac syncope differ significantly from benign causes of syncope such as neurocardiogenic syncope (Table 84.6). Several red flags can be identified that should lead the clinician to suspect that the mechanism is a life-threatening cardiac cause rather than simple fainting (Table 84.7). The occurrence *during* exercise suggests an arrhythmia or an outflow tract or coronary artery obstruction. Noncardiac (postexercise) syncope is seen in athletes *after* a strenuous workout or competition and has no associated cardiac features. The occurrence of syncope resulting in injury also suggests an arrhythmia, as it indicates a sudden onset with a lack of adequate prodromal symptoms. The occurrence of syncope while recumbent would be quite unusual in a patient with neurocardiogenic syncope and therefore suggests a cardiac or neurologic cause. Occasionally, a patient with syncope caused by a tachyarrhythmia will report the sensation of a racing heart before the event, but this is often not present.

A careful family history is essential in evaluation of syncope. Specifically, if there are first-degree relatives with inherited syndromes, such as LQTS, CPVT, or HCM, this should lead to more specific evaluation of the patient. If relatives died suddenly at a young age without a clear and convincing cause, inherited cardiac arrhythmias or cardiomyopathies should also be suspected. Other questions that may increase suspicion for an inherited arrhythmia include family history of congenital deafness, unexplained recurrent syncope, poorly controlled seizures, single-vehicle car accidents, or drowning events.

Patients with a history of heart disease requiring surgical repair may have causes of syncope that are specific to their repair. Sinus node dysfunction is common after the Senning or Mustard procedure for transposition of the great vessels or after the Fontan procedure for single-ventricle palliation. VT may be seen after repair of tetralogy of Fallot. A patient with a history of repair of a ventricular septal defect or an AV canal defect should be evaluated for the late occurrence of AV block. Patients with an implanted pacemaker should be evaluated for pacemaker lead failure.

The **physical examination** may also offer clues (see Table 84.7) that point toward cardiac syncope. Patients with HCM or aortic stenosis may have a prominent cardiac impulse and/or an ejection murmur. A patient with primary pulmonary hypertension will have a displaced apical impulse, with a loud and single second

Table 84.5 Primary Electrical Abnormalities: Features, ECG, and Treatment

PRIMARY ELECTRICAL ABNORMALITIES	FEATURES	ECG	TREATMENT
LQTS: Romano-Ward, Jervell–Lange-Nielsen, acquired	• Familial genetic or acquired disorders • Ion channel pathologic gene variant (~17 genes)* • Presents in torsades de pointes • Romano-Ward is most common inherited • LQTS Jervell–Lange-Nielsen has congenital deafness	• Prolonged QT measured from the onset of the Q wave to the end of the T wave in lead II • Varies with HR but >0.44 in men, >0.46 in children and women for HR 50-90 beats/min is prolonged • Torsades de pointes can occur • Can deteriorate from polymorphic ventricular tachycardia to ventricular fibrillation	• β-Blocker therapy • Recommendations on exercise intensity by a cardiologist • ICD if β blockers fail
Brugada syndrome	• Inherited autosomal dominant arrhythmogenic syndrome characterized by life-threatening ventricular arrhythmias • Pathologic gene variant in *SCN5A* and 13 other genes	• ECG abnormalities are from repolarization and depolarization abnormalities • Coved-type ST-segment elevations in the right precordial leads • J wave amplitude ≥2 mm followed by a negative T wave	• Placement of ICD
Wolff-Parkinson-White	• Owing to one or more reentrant pathways inducing SVT or atrial fibrillation • Up to 14% associated with malignant tachycardias • Malignant arrhythmias from short reentrant pathway repolarization or multiple pathways	• Short PR interval • Delta waves present	• Undergo EPS and ablation
Dilated cardiomyopathy: ventricular tachycardia/ fibrillation	• Cardiac dilation and systolic dysfunction • Inherited or acquired • Lamin AC pathologic gene variant a common cause of DCM and SCD	• Marked LVH • Poor R-wave progression • Left atrial enlargement • Right axis deviation	• Permanent pacemaker and ICD placement
Catecholamine-exercise: ventricular tachycardia	• Ventricular ectopy induced by exercise or emotional stress • Variant in gene that encodes Ca-mediated sarcoplasmic fibers • Lethal in 30–50% if left untreated	• Preexercise ECG is usually normal, stress testing recommended • ECG with exercise • Nonsustained wide ventricular tachycardia	• β-Blocker therapy • Recommendations on exercise intensity by a cardiologist • ICD if β blockers fail

DCM, Dilated cardiomyopathy; EPS, electrophysiology study; HR, heart rate; ICD, implantable cardioverter defibrillator; LQTS, long QT syndrome; LVH, left ventricular hypertrophy; SCD, sudden cardiac death; SVT, supraventricular tachycardia.

Table 84.6 Differentiating Features for Causes of Syncope

NEUROCARDIOGENIC
Symptoms after prolonged motionless standing, sudden unexpected pain, fear, or unpleasant sight, sound, or smell; pallor
Syncope in a well-trained athlete *after* exertion (without heart disease)
Situational syncope during or immediately after micturition, cough, swallowing, or defecation
Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)
ORGANIC HEART DISEASE (PRIMARY ARRHYTHMIA, OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY, PULMONARY HYPERTENSION)
Brief sudden loss of consciousness, no prodrome, history of heart disease
Syncope while sitting or supine
Syncope with exertion
History of palpitations
Family history of sudden death
NEUROLOGIC
Seizures: preceding aura, postevent symptoms lasting >5 min (includes postictal state of decreased level of consciousness, confusion, headache, or paralysis)
Migraine: syncope associated with antecedent headaches with or without aura
OTHER VASCULAR
Carotid sinus: syncope with head rotation or pressure on the carotid sinus (as in tumors, shaving, tight collars)
Orthostatic hypotension: syncope immediately on standing, especially after prolonged bed rest
DRUG INDUCED
Patient is taking a medication that may lead to long QT syndrome, orthostasis, or bradycardia
PSYCHIATRIC ILLNESS
Frequent syncope, somatic complaints, no heart disease

From Cohen G. Syncope and dizziness. In: Kliegman RM, Lye PS, Bordini BJ, et al., eds. *Nelson Pediatric Symptom-Based Diagnosis.* Philadelphia: Elsevier; 2018: Table 6.4.

Table 84.7 Red Flags in Evaluation of Patients with Syncope

Syncope with activity or exercise or supine
Syncope not associated with prolonged standing
Syncope precipitated by loud noise or extreme emotion
Absence of presyncope or lightheadedness
Family history of syncope, drowning, sudden death, familial ventricular arrhythmia syndromes,* cardiomyopathy
Syncope requiring CPR
Injury with syncope
Anemia
Other cardiac symptoms
Chest pain
Dyspnea
Palpitations
History of cardiac surgery
History of Kawasaki disease
Implanted pacemaker
Abnormal physical examination
Murmur
Gallop rhythm
Loud and single second heart sound
Systolic click
Increased apical impulse (tachycardia)
Irregular rhythm
Hypotension or hypertension
Digital clubbing
Cyanosis

*Long QT syndrome, Brugada syndrome, catecholamine polymorphic ventricular tachycardia, arrhythmogenic cardiomyopathy.

heart sound, with an ejection click or murmur of pulmonary insufficiency. Patients with repaired congenital heart disease will have obvious scars on their chest and abdomen from prior cardiac surgery or device implantation.

All patients presenting with syncope *should* have an **electrocardiogram**, looking primarily for QT interval prolongation, preexcitation, ventricular hypertrophy, T-wave abnormalities, and conduction abnormalities. Additional tests that may be needed include echocardiography, exercise testing, cardiac MRI, or 24-hour Holter monitoring. In patients for whom there is a strong suspicion of a paroxysmal arrhythmia, an insertable cardiac monitor (loop recorder) may offer the most effective means of diagnosis. Additional tests may be useful to look for anemia, hypoglycemia, drugs of abuse, and other etiologies noted in Table 84.1 as determined by the history and physical examination.

TREATMENT

Therapy for vasovagal syncope includes avoiding triggering events (if possible), fluid and salt supplementation, and if needed, specific therapies targeting the orthostatic hypotension (i.e., midodrine) (Table 84.8). Immediately after the event, the patient should remain supine until symptoms abate to avoid recurrence.

Treatment for cardiac causes of syncope will be determined by the diagnosis. If supraventricular tachycardia (SVT) is found, then a catheter ablation may be indicated. If bradycardia from sinus node dysfunction or AV block is the cause of the syncope, a pacemaker may be warranted. Patients with syncope from medically refractory malignant arrhythmias, as may be seen in HCM, LQTS, arrhythmogenic cardiomyopathy, or CPVT, require an implantable cardioverter-defibrillator. Patients with structural heart disease (valvular disease or coronary artery anomalies) should be referred for surgery.

Visit Elsevier eBooks+ at eBooks.Health.Elsevier.com for Bibliography.

Table 84.8 Treatment of Neurocardiogenic Syncope/Vasovagal Syncope (V-VS)

Patient education on the diagnosis and prognosis of V-VS is recommended. In all patents with the common faint or V-VS, an explanation of the diagnosis, education targeting awareness of and possible avoidance of triggers (prolonged standing, warm environments, coping with dental and medical settings), and reassurance about the benign nature of the condition should be provided.
Physical counterpressure maneuvers can be useful in patients with V-VS who have a sufficiently long prodromal period. Patients with a syncope prodrome should be instructed to assume a supine position to prevent a faint and minimize possible injury. In patients with a sufficiently long prodrome, physical counter-maneuvers (leg crossing, limb and/or abdominal contraction, squatting, isometric handgrip, arm tensing) are a core management strategy.
Midodrine is reasonable in patients with recurrent V-VS with no history of hypertension, heart failure, or urinary retention. Midodrine is a prodrug that is metabolized to desglymidodrine, which is a peripherally active α-agonist used to ameliorate the reduction in peripheral sympathetic neural outflow responsible for venous pooling and vasodepression in V-VS.
The usefulness of orthostatic training is uncertain in patients with frequent V-VS. There are 2 main methods of orthostatic training. Patients undergo repetitive tilt-table tests in a monitored setting until a negative tilt-table test occurs and then are encouraged to stand quietly against a wall for 30-60 min daily, or patients simply stand quietly against a wall at home for a prolonged period daily.
Fludrocortisone might be reasonable for patients with recurrent V-VS and inadequate response to salt and fluid intake, unless contraindicated. Fludrocortisone has mineralocorticoid activity resulting in sodium and water retention and potassium excretion, which results in increased blood volume. Serum potassium level should be monitored because of potential drug-induced hypokalemia. POST II (Prevention of Syncope Trial II) reported a marginally insignificant 31% risk of reduction in adults with moderately frequent V-VS, which was significant in patients after a 2-wk dose stabilization period.
Encouraging increases in salt and fluid intake may be reasonable in selected patients with V-VS, unless contraindicated. Evidence for the effectiveness of salt and fluid intake for patients with V-VS is limited. Nonetheless, in patients with recurrent V-VS and no clear contraindication, such as a history of hypertension, renal disease, heart failure, or cardiac dysfunction, it may be reasonable to encourage ingestion of 2-3 L of fluid per day and a total of 6-9 g (100-150 mmol) of salt per day, or about 1-2 heaping teaspoonfuls. The long-term balance of risks and benefits of a strategy of increasing salt and water intake is unknown.
In selected patients with V-VS, it may be reasonable to reduce or withdraw medications that cause hypotension when appropriate. A careful examination of the patient's history for medications that may lower blood pressure (hypotensive agents) should be performed. Care should be taken to withdraw or reduce medications only when safe to do so and in conjunction with the prescribing healthcare provider.
In patients with recurrent V-VS, a selective serotonin reuptake inhibitor might be considered. Serotonin has central neurophysiologic effects on blood pressure and heart rate and acutely induces syncope during tilt-table testing.

Modified from Shen WK, Sheldon RS, Benditt DG, et al. 2017 ACC/AHA/HRS guideline for the evaluation and management of patients with syncope: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society [published correction appears in *Circulation*. 2017 Oct 17;136(16):e271-e272]. *Circulation*. 2017;136(5):e60-e122.

84.1 Postural Tachycardia Syndrome

Gisela G. Chelimsky and Thomas Chelimsky

Several complex and interrelated mechanisms allow humans to stand despite the pull of gravity on the cerebral circulation. In the supine posture, most blood sits in the thoracic cavity, with 25–30% of total volume in the splanchnic vasculature. When an adult stands up, about 500 mL of blood shifts to the lower extremities and to the splanchnic vasculature. The decrease in hydrostatic pressure in the carotid sinuses produces vasoconstriction in the peripheral vessels mediated by sympathetic outflow and in the splanchnic vasculature. This action is mediated by norepinephrine, adenosine triphosphate (ATP), and neuropeptide Y. The muscles in the legs and gluteal area work as a pump when the individual is upright and during exercise to help return the blood to the heart.

Understanding postural tachycardia syndrome, or postural orthostatic tachycardia syndrome **(POTS)**, requires an understanding of other orthostatic conditions. Many adolescents have lightheadedness or tunnel vision in the first few seconds of assuming the upright posture. This phenomenon, termed **initial orthostatic hypotension (IOH)**, can lead to *syncope,* but usually is very short, perhaps 30-60 seconds, and occurs primarily with active standing. Blood pressure (BP) may drop 30% of baseline at 10-20 seconds of standing and may be associated with tachycardia. BP returns to baseline in 30-60 seconds, whereas heart rate (HR) typically returns to a new, higher value above the baseline when supine. Because of its transient rapidity, IOH escapes detection with standard BP machines and requires beat-to-beat monitoring of BP and HR. The clinical diagnosis requires a careful history. The symptoms usually happen after prolonged recumbence and when the individual stands. The person complains of lightheadedness and "blacking out" or tunnel vision 5-10 seconds after standing.

In contrast to IOH, **orthostatic hypotension (OH)** is defined as a *sustained* decrease in the systolic BP of >20 mm Hg or diastolic BP >10 mm Hg in the first 3 minutes of upright tilt. OH rarely occurs in children. The patient often has no orthostatic symptoms while upright despite very low pressures (Fig. 84.1). This distinguishes OH from POTS, which *requires* symptoms while upright. A third orthostatic disorder, **reflex syncope** (i.e., vasovagal or neurally mediated), is defined as relatively sudden change in autonomic nervous system activity that leads to a sudden decrease in BP, HR, and cerebral perfusion (Fig. 84.2).

In children, POTS is defined as a syndrome characterized by HR increase of >40 beats/min during the first 10 minutes of upright tilt test without associated hypotension, (>30 beats/min if >19 years old) while replicating orthostatic symptoms that occur when upright (Fig. 84.3). Improvement of symptoms in the supine position is expected. The diagnosis of POTS also requires *daily* orthostatic symptoms. In patients with POTS, the larger decline in cardiac stroke volume appears to be the primary trigger for the tachycardia, which may result from various pathophysiologic mechanisms, such as the following:

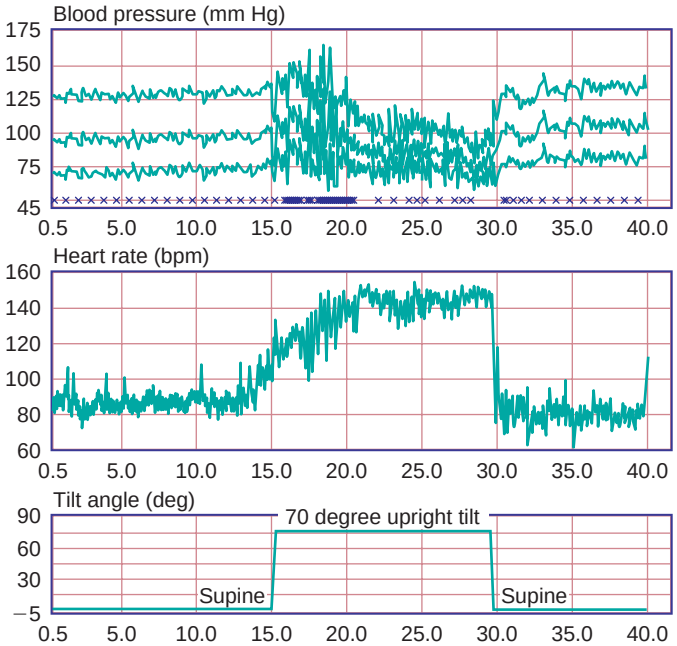

Fig. 84.1 Example of orthostatic hypotension.

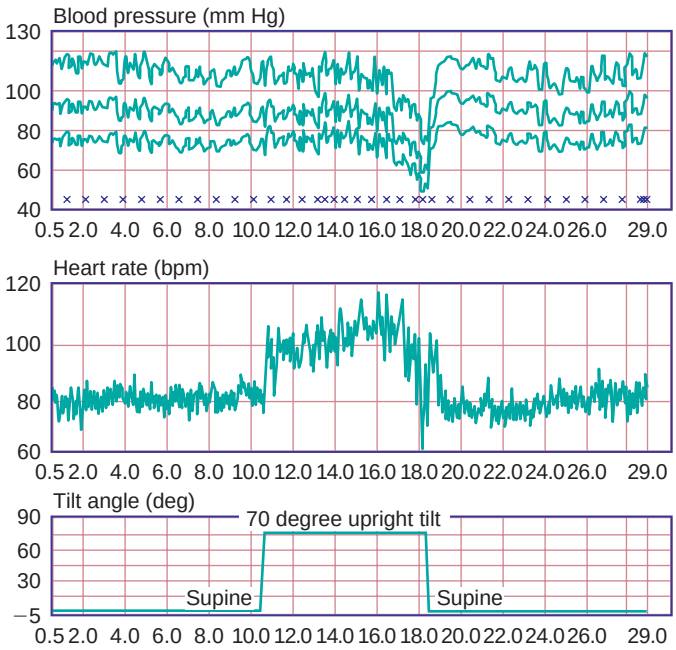

Fig. 84.2 Example of neurally mediated syncope.

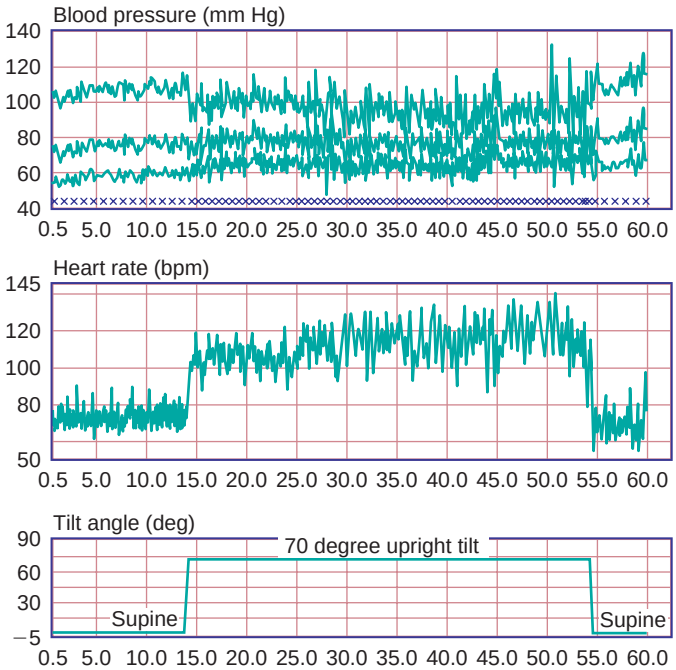

Fig. 84.3 Example of postural tachycardia syndrome.

- **Neuropathic** POTS, an autonomic neuropathy impairing sympathetic venoconstriction in the lower extremities or splanchnic circulation, decreasing stroke volume and consequently resulting in tachycardia.
- **Hypovolemic** POTS, a common contributor, often related to decreased aldosterone with reduced renin activity, resulting in tachycardia caused by decreased blood volume.
- **Hyperadrenergic** POTS, with norepinephrine levels rising threefold to fourfold in the standing position (norepinephrine normally doubles on standing), which may occur in norepinephrine transporter deficiency or strong stimulation of central baroreflex responses.
- **Autoimmune** POTS, typically assumed based on a postviral chronology, but seldom proven; such a form may or may not exist. The antiganglionic antibody is almost never elevated in these patients. Nonetheless, a group of patients report that intravenous immunoglobulin (IVIG) is helpful to them. Whether they benefit from the increase in intravascular volume or an actual immune effect is unknown.

Some patients have orthostatic symptoms while upright but do not meet criteria for syncope, OH, or POTS. This group has **orthostatic intolerance not otherwise specified (OI-NOS)**.

CLINICAL PRESENTATION

The symptoms that intrinsically relate to POTS are those that are replicated during upright tilt testing or standing. Many other symptoms also occur in patients with POTS, fitting the description of comorbid conditions, but not reproduced while upright. A patient may have nausea while upright associated with lightheadedness and have a diagnosis of POTS. Another patient may complain of nausea on awakening and have POTS, but have no nausea while upright. In the former patient the nausea is a symptom of POTS itself, whereas in the latter nausea is an associated condition. The symptoms that often directly relate to POTS include lightheadedness, orthostatic nausea, orthostatic headaches, fatigue, tunnel vision, and brain fog. About 20–30% of pediatric patients with POTS will also have syncope (Fig. 84.4). Other comorbid conditions frequently occur in these patients but are not caused by POTS (i.e., not an orthostatic phenomenon). These comorbidities include (1) sleep issues, usually delayed onset of sleep, frequent awakening, and not feeling refreshed in the morning; (2) joint hypermobility and aches in different parts of the body; (3) abdominal pain; (4) headaches and migraines; (5) nausea and vomiting; (6) depression and anxiety; and (7) Raynaud-like symptoms and other, less frequent problems (e.g., urinary symptoms).

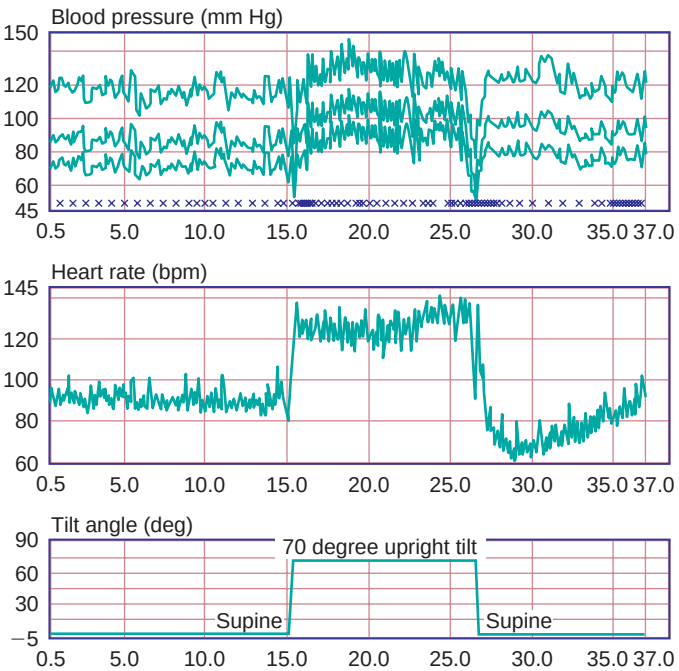

Fig. 84.4 Example of postural tachycardia syndrome (POTS) followed by a neurally mediated syncope.

The association between upper gastrointestinal (GI) symptoms and POTS is well described. Nausea, early satiety, and bloating are described in association with POTS. Such GI symptoms relate mechanistically to POTS only when they occur in the upright position. Many patients with POTS have comorbid GI symptoms that are not a consequence of the orthostatic challenge. Therefore only the GI symptoms replicated during tilt testing will improve with treatment aimed at orthostasis. Patients with POTS have changes in the electrical activity of the stomach while upright, which may explain the upright GI symptoms; they usually do not have delayed gastric emptying. The emptying is either normal or accelerated, implying that the cause of nausea is not gastroparesis.

Patients with **hypermobility Ehlers-Danlos syndrome** (h-EDS) may have POTS. Typically, such individuals have more migraines and syncope. Joint hypermobility itself in *adults* is associated with more autonomic complaints such as syncope, presyncope, palpitations, chest discomfort, fatigue, and heat intolerance. Those with hypermobility have more frequent positive tilt tests than healthy controls. Interestingly, in children, joint hypermobility does not influence the number of comorbidities or autonomic disorders. Similarly, those with pediatric chronic overlapping pain conditions with or without POTS have the same comorbidities, suggesting that neither POTS nor hypermobility are drivers of the comorbidities or the chronic overlapping pain condition, but rather another associated disorder (see Chapter 212).

DIAGNOSIS

Orthostatic intolerance is clinically diagnosed by detailed history attending specifically to symptoms as they relate to body position. Dizziness that begins in the supine position cannot be a manifestation of orthostatic intolerance. Furthermore, those symptoms that do develop while upright should improve or resolve when supine. Importantly, the history should include a detailed description of current physical exercise habits, with frequency, type, and endurance. One should also assess sleep, diet (mainly evaluating intake of salt), fluid intake, and other comorbidities. The physical examination is also important and should include a cardiac and neurologic evaluation with supine and standing BP and HR. Examination of the extremities may provide information about venous pooling, such as mild edema or reddish-purple discoloration when sitting or standing. Cold, clammy hands can signify excess sympathetic activity.

To diagnose POTS the patient needs to undergo a *head-up tilt test for at least 10 minutes*. It is important to have the patient supine for at least 20 minutes before the tilt test. POTS can also be assessed by a standing test, measuring BP and HR at 1, 3, 5, and 10 minutes standing, but to have a reliable test similar to the tilt test, the patient needs to be supine for 1 hour before standing. The HR increase with active standing is typically less than with tilt, because the lower-extremity muscle pump is less active in tilt. The diagnosis of POTS requires replication of the day-to-day symptoms while upright, not just the increased HR while upright. A small but significant proportion of healthy teenagers in school will have an increased HR that may be diagnosed as POTS but will not have associated symptoms.

Other tests may include electrocardiogram, echocardiogram, and Holter monitor when there is concern of a primary cardiac cause of tachycardia or if there is a need to determine if symptoms correlate with tachycardia (see Chapter 84). Supine and standing plasma catecholamines help confirm the diagnosis of POTS, as one expects to see either the normal doubling of norepinephrine levels from supine to standing or a tripling with hyperadrenergic POTS. Beyond tilt table testing, autonomic testing will also include cardiac response to deep breathing (checking cardiac parasympathetic function), Valsalva maneuver (checking cardiac sympathetic and parasympathetic functions and vasomotor sympathetic function), and quantitative axon reflex sudomotor test (to assess for an autonomic neuropathy and vasomotor sympathetic dysfunction).

Table 84.9 First-Line Medications in Treatment of Postural Tachycardia Syndrome (POTS)

DRUG	MECHANISM OF ACTION	SIDE EFFECTS	TREATMENT GUIDELINES
Fludrocortisone	Low dose: sensitizes α-receptors Higher doses: mineralocorticoid effect	Peripheral edema, headache, irritability, hypokalemia, hypomagnesemia, acne	Monitor basic metabolic panel and magnesium
Midodrine	α_1-Agonist; produces vasoconstriction	Scalp tingling, urinary retention, goosebumps, headache, supine hypertension	Monitor supine blood pressure 30-60 min after dose
Metoprolol succinate/ tartrate	β Blocker	Worsening of asthma, dizziness, fatigue	Use with caution in asthma If fatigue is severe, use at bedtime
Propranolol	Nonselective β blocker	Bradycardia, gastrointestinal symptoms, lightheadedness, sleepiness, hypotension, syncope	Use with caution in diabetes and asthma
Pyridostigmine	Peripheral acetylcholinesterase inhibitor that increases synaptic acetylcholine in autonomic ganglia and at peripheral muscarinic receptors	Symptoms of excessive cholinergic activity (diarrhea, urinary incontinence, salivation)	Very useful if patient has POTS and constipation Use with caution in asthma Contraindicated in urinary or bowel obstruction

Additional studies depend on the clinical symptoms and include morning cortisol (to rule out Addison disease) and thyroid studies if the patient has unusually severe fatigue or is not responsive to usual treatment. Serum tryptase and urine methylhistamine are tested if mast cell activation disorder is suspected, based on a history of flushing during the spells. If an autoimmune cause for the POTS is a concern, antibodies such as voltage-gated potassium channel and acetylcholine receptor antibodies could be checked, but this etiology for POTS is being questioned. Patients rarely (<5 in 1,000) benefit from IVIG; if this mechanism is really causing POTS, such patients should experience peak benefit at about 10 days after the infusion rather than immediately (which may simply reflect increasing intravascular volume). If the patient has hypertension, plasma and urine metanephrines should be measured to test for a pheochromocytoma. In addition, if symptoms are associated with perimenstrual timing, an assessment of sex hormone axis is helpful, with occult polycystic ovarian syndrome or low testosterone levels sometimes present.

MANAGEMENT

The core of POTS management is **nonpharmacologic**. Medications will be of little benefit without these measures being undertaken first. The best measure for treating POTS is a regular **aerobic exercise** program. Given the combination of orthostatic symptoms and severe deconditioning found in most patients, the exercise program must be introduced in a slow, progressive manner. Patients with POTS typically have moderate to severe exercise intolerance, and compared with sedentary healthy controls, have decreased peak oxygen uptake. After 3 months of exercise, POTS patients have an increase in cardiac mass and size, blood volume, and peak oxygen uptake, as reflected in a better exercise performance. The tachycardia in POTS is caused by a decrease in stroke volume and not an intrinsic circulatory problem. An exercise program should start with water exercises combined with recumbent aerobic activities (recumbent bike or rowing machine), slowly increasing the exercise time to 45 minutes at least 5 times per week. When tolerance increases, patients can advance to more upright aerobic activities. These aerobic activities need to be combined with light core- and limb-strengthening exercises.

Exercise usually cannot be performed without simultaneous expansion of the intravascular volume. To this end, encourage teenagers to drink >80 oz of fluids daily and to add 2 g of salt to their usual diet in both the morning and the early afternoon. **Salt supplementation** increases plasma and blood volume, improves orthostatic tolerance, and decreases baroreflex sensitivity. Salt also reduces nitric oxide production, resulting in less vasodilation. Trial and error of different salt formulations can help to identify the best method for each individual patient. Salt tablets are simple and inexpensive but may make some people nauseous. An alternative is simply to obtain empty capsules on the internet and fill them with table salt. A "0" size capsule contains about 400 mg of salt.

The content of sodium in the body determines the extracellular fluid volume that in turn dictates orthostatic tolerance. Patients with POTS who have lower urinary sodium excretion have more symptoms than those with higher urinary sodium (>123 mmol/24 hours), and they often respond less well to salt supplementation. Those with severe orthostatic symptoms either in the morning or before sports should drink 16 oz of plain water, which is known to increase sympathetic response mainly in individuals with baroreflex dysregulation. The effect starts soon after drinking the water and lasts for about 1 hour. Compression garments may also be useful. These can be thigh or waist high; the waist-high compression garments may not be tolerated.

Medications can be added when the nonpharmacologic interventions are not sufficient. Different centers use different strategies, and there is no single correct evidence-based approach. Table 84.9 addresses first-line medications that primary care physicians could use; only the most common side effects are included.

Chapter 85

Shock

Scott L. Weiss, Pierre Tissières, and Mark J. Peters

Shock is an acute, life-threatening process of cardiovascular insufficiency characterized by inadequate delivery of oxygen and nutrients (e.g., glucose) by the circulatory system to meet the metabolic demands of vital organs that results in cellular dysfunction and injury. The initial imbalance between oxygen/nutrient delivery through the circulation and oxygen/nutrient consumption within organ systems can be compensated for by increasing tissue oxygen extraction. However, with further limitations in delivery of oxygen and nutrients as the shock state progresses, energy production gradually shifts from aerobic metabolism to less efficient anaerobic metabolic pathways, and a cellular bioenergetic crisis can ensue. If this process is not corrected, numerous adverse vascular, inflammatory, metabolic, cellular, and endocrine responses contribute to a state of **multiple organ dysfunction syndrome (MODS)**, cardiovascular collapse, and death.

It is important to recognize that the shock state can be present *before* the onset of hypotension, especially in children, and that inadequate cellular metabolism of oxygen and nutrients (not just impaired delivery) contributes to the clinical manifestations and outcomes observed in patients with shock. Therefore it is necessary to recognize early symptoms and signs of impaired circulation, including tachycardia, altered mental status (e.g., irritability, confusion, lethargy), tachypnea (often secondary to acidemia), abnormal capillary refill time, diminished peripheral pulses, and oliguria, in combination with metabolic markers such as acidemia, hyperlactatemia, and low central venous oxygen saturation. Hypotension, when present, is also important to recognize, but children—especially infants and preschool-age children—with *compensated* shock may be able to maintain a normal blood pressure (BP) for age until the later phases of shock. When hypotension is present, the child has reached a state of *uncompensated shock* and is at risk of irreversible organ damage and death without immediate treatment.

EPIDEMIOLOGY

Shock occurs in approximately 2% of all hospitalized infants, children, and adults in developed countries, and the mortality rate varies substantially depending on the etiology and clinical circumstances. Of patients who do not survive, many do not die in the initial acute phase of shock, but rather because of associated complications and MODS. MODS is defined as dysfunction in two or more organ systems; the presence of MODS in patients with shock substantially increases the probability of death. In 2017, there were an estimated 20.3 million cases of sepsis, with 2.9 million deaths, worldwide among children younger than 5 years and 4.9 million cases of sepsis, with 454,000 deaths, among older children and adolescents. In the United States, over 70,000 children are hospitalized with sepsis each year at an annual healthcare cost of $7.31 billion. In pediatrics, educational efforts and the use of standardized management guidelines that emphasize early recognition and intervention, along with the rapid transfer of critically ill patients to a pediatric intensive care unit (PICU), have decreased mortality from shock.

TYPES OF SHOCK

Shock classification systems generally define five major types of shock: hypovolemic, cardiogenic, obstructive, distributive, and dissociative (Table 85.1 and Fig. 85.1). **Hypovolemic shock**, the most common cause of shock in children worldwide, is most frequently caused by acute fluid losses resulting from diarrhea, vomiting, or hemorrhage. A special cause of hypovolemic shock is hemorrhagic shock, which may be caused by traumatic injury or gastrointestinal (GI), peritoneal, vaginal, soft tissue, or other sources of severe bleeding. **Cardiogenic shock** is seen in patients with congenital heart disease (before or after surgery, including heart transplantation) or those with congenital or acquired cardiomyopathies, including acute myocarditis and multisystem inflammatory syndrome in children (MIS-C). **Obstructive shock** stems from any lesion that creates a mechanical impediment to ventricular blood outflow, which includes pericardial tamponade, tension pneumothorax, pulmonary embolism, and ductal-dependent left-sided heart lesions (hypertrophic left heart syndrome, aortic coarctation, interrupted aortic arch, and critical aortic valve stenosis). **Distributive shock** is caused by inappropriate vasodilation, pooling of blood in the peripheral vasculature, leakage of blood plasma into the interstitium through a compromised endothelial barrier, and microvascular shunting. Common causes of distributive shock in children include sepsis, anaphylaxis, and accidental or intentional drug overdose (e.g., calcium channel blockers, atypical antipsychotics). Neurogenic shock is a type of distributive shock caused by a sudden disruption of sympathetic nerve stimulation to the vascular smooth muscle leading to a profound decrease in vasomotor tone, typically with severe traumatic brain or cervical spine injury. Unlike other types of shock, the unopposed vagal activity classically results in bradycardia, or at least absence of the usual tachycardic response to hypotension. **Dissociative shock** is a special category of shock in which cellular oxygen delivery or utilization is severely impaired despite sustained or supranormal tissue perfusion and is typically caused by exposure to a toxic metabolite or drug, such as severe anemia, methemoglobinemia, carbon monoxide poisoning, or thiamine deficiency (beriberi).

Septic shock is life-threatening cardiovascular dysfunction in patients with suspected or confirmed infection and confers a high risk for mortality in children compared to those with uncomplicated infections or sepsis without shock. Sepsis in children is operationalized as a Phoenix Sepsis Score of at least 2 points from a composite four-organ system model that includes criteria for respiratory, neurologic, coagulation, and cardiovascular dysfunction, with septic shock requiring at least 1 point in the cardiovascular subscore (Table 85.2). Many children with septic shock also have MODS, including respiratory, kidney, hematologic (disseminated intravascular coagulation [DIC]), hepatobiliary, and neurologic dysfunction. Septic shock classically presents as a type of distributive shock with high cardiac output and low systemic vascular resistance (SVR). However, most children with sepsis also have features of hypovolemic shock from poor oral intake, GI fluid losses, and vascular leak as well as cardiogenic shock due to decreased myocardial contractility. In younger children, septic shock often presents with low cardiac output and high SVR in which features of cardiogenic and hypovolemic shock predominate.

PATHOPHYSIOLOGY

An initial insult triggers shock, leading to a decrease in effective cardiac output with inadequate oxygen delivery to organs and tissues. Compensatory mechanisms attempt to maintain BP by increasing cardiac output and SVR. The body also attempts to optimize oxygen delivery to the tissues by increasing oxygen extraction and redistributing blood flow to the brain, heart, and kidneys at the expense of the skin, skeletal muscles, and GI tract. These responses lead to an initial state of **compensated shock** in which BP is often maintained near normal levels for age. If resuscitative treatment is not initiated or is inadequate during this period, **uncompensated shock** develops, with hypotension and tissue damage that may lead to irreversible organ damage, MODS, and, ultimately, death.

In the early phases of shock, multiple compensatory physiologic mechanisms act to maintain BP and preserve tissue perfusion and oxygen delivery. Cardiovascular effects include increases in heart rate (HR), stroke volume, and vascular smooth muscle tone, which are regulated through sympathetic nervous system activation and neurohormonal responses. Respiratory compensation involves greater carbon dioxide (CO_2) elimination in response to the metabolic acidosis and increased CO_2 production from poor tissue perfusion. Renal excretion of hydrogen ions (H^+) and retention of bicarbonate (HCO_3^-) also increase in an effort to maintain normal body pH (see Chapter 73.7). Maintenance of intravascular volume is facilitated via renal sodium retention mediated by activation of the renin-angiotensin-aldosterone and atrial natriuretic factor axes, cortisol and catecholamine synthesis

Table 85.1 Types of Shock

TYPES OF SHOCK	PATHOPHYSIOLOGY	APPEARANCE	EXAMPLES	TREATMENTS
Hypovolemic*	Decreased cardiac output due to volume depletion → decreased preload	Tachycardia and vasoconstriction maintain adequate circulation up to 30% of circulating volume Narrowed pulse pressure, delayed capillary refill, orthostatic changes, late hypotension, AMS, and decreased UOP	Nonhemorrhagic (vomiting and diarrhea) Hemorrhagic (trauma)	IV fluid bolus Vasopressors Blood replacement
Cardiogenic	Decreased cardiac output due to myocardial dysfunction, increased afterload, and/or lack of ventricular filling	Tachycardia, vasoconstriction, cool extremities, narrow pulse pressure, delayed capillary refill, respiratory distress, rales or gallop rhythm, enlarged liver, JVD, cardiomegaly on chest radiograph Significant gradient between upper and lower extremity blood pressures	Cardiomyopathies, infectious myocarditis, and systemic inflammatory process, autoimmune disease, impaired coronary perfusion, cardiopulmonary bypass, acidosis, HIE, and dysrhythmias Infants: ductal-dependent lesions, tachydysrhythmias	Judicious IV fluid resuscitation, ionotropic agents to improve contractility, vasodilators to reduce afterload, and management of tachyarrhythmias PGE for infants <2 mo
Distributive	Decreased cardiac output and systemic vascular resistance due to peripheral vasodilation → decreased afterload and preload, redistribution of blood flow away from vital organs, and loss of sympathetic outflow	Tachycardic, vasodilated, flushed, warm extremities, wide pulse pressure, bounding pulses, flash capillary refill Anaphylaxis: rash; facial swelling; lip, tongue, or airway swelling; bronchospasm; hypotension Spinal shock: unable to raise HR, hypotension Neurogenic: Control ↑ ICP	Septic shock Toxic ingestions Anaphylaxis Spinal cord injuries	IV fluids, vasopressors, antibiotics Specific antidotes Remove triggers, IV fluids, IM epinephrine, antihistamines, vasopressors IV fluids, vasoconstrictors
Obstructive	Decreased cardiac output due to increased afterload of the right ventricle from an obstructive process	Tachycardia, delayed capillary refill, cool extremities, narrow pulse pressure, distended neck veins, distant heart tones, asymmetric breath sounds	Tension pneumothorax Pulmonary embolism Cardiac tamponade	Anticoagulants Drain pericardial effusion Evacuate pneumothorax
Dissociative	High cardiac output failure due to inadequate oxygen-releasing capacity	Tachycardia ± delayed capillary refill, cool extremities, weakened pulse, pallor or flushed cheeks	Anemia Carbon monoxide Methemoglobinemia Cyanide	Gradual fluid replacement and blood replacement 5 mL/dL Oxygen, hyperbaric chamber Methylene blue Hydroxocobalamin and cyanide antidote kit (sodium thiosulfate, sodium nitrate, amyl nitrite) plus oxygen

*Most common.
AMS, Altered mental status; HIE, hypoxic ischemic encephalopathies; HR, heart rate; IM, intramuscular; ICP, intracranial pressure; IV, intravenous; JVD, jugular venous distention; PGE, prostaglandin; UOP, urine output.
Modified from Baumer-Mouradian SH, Drendel AL. Shock. In: Kliegman RM, Toth H, Bordini BJ, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis,* 2nd ed. Philadelphia: Elsevier;2023: Table 10.4.

and release, and antidiuretic hormone secretion. Despite these compensatory mechanisms, the underlying shock and host response lead to vascular endothelial cell injury and loss of endothelial adhesion proteins that allow significant leakage of intravascular fluid into the interstitial extracellular space.

Another important aspect of the initial pathophysiology of shock is the impact on cardiac output. All forms of shock affect cardiac output through several mechanisms, with changes in HR, preload, afterload, and myocardial contractility occurring separately or in combination (see Fig. 85.1). **Hypovolemic shock** is characterized primarily by fluid loss and decreased preload. Tachycardia and an increase in SVR are the initial compensatory responses that seek to maintain cardiac output, systemic BP, and tissue perfusion. Without adequate volume replacement, hypotension inevitably develops, followed by tissue ischemia and further clinical deterioration. When there is preexisting low plasma oncotic pressure (caused by nephrotic syndrome, malnutrition, hepatic dysfunction, acute severe burns, etc.), further volume loss and exacerbation of shock may result from worsening vascular leak.

In contrast, the underlying pathophysiologic mechanism leading to **distributive shock** is a state of abnormal vasodilation and decreased SVR. In sepsis, loss of normal regulation of vasomotor tone is due to a combination of factors, including excessive nitric oxide (NO) produced from an increase in inducible NO synthase, altered sympathetic and parasympathetic tone, and diminished circulating levels and/or reduced responsiveness to vasopressin, endogenous catecholamines, and cortisol. In anaphylaxis, vasodilation is caused by an acute release of histamine and other mediators from mast cells. Irrespective of the inciting event, the sudden fall in SVR is accompanied initially by a maldistribution of blood flow away from vital organs and a compensatory increase in cardiac output caused by an increase in HR and, potentially, left ventricular stroke volume. This process leads to significant decreases in both preload and afterload. Therapies for distributive shock must address both these problems simultaneously.

Cardiogenic shock may be seen in patients with myocarditis, cardiomyopathy, arrhythmias, and congenital heart disease (generally after cardiac surgery) (see Chapter 483). In these patients, myocardial contractility is directly impaired, leading to systolic and/or diastolic dysfunction. The later phases of all forms of shock frequently have a negative impact on the myocardium, leading to development of a cardiogenic component to the initial shock state.

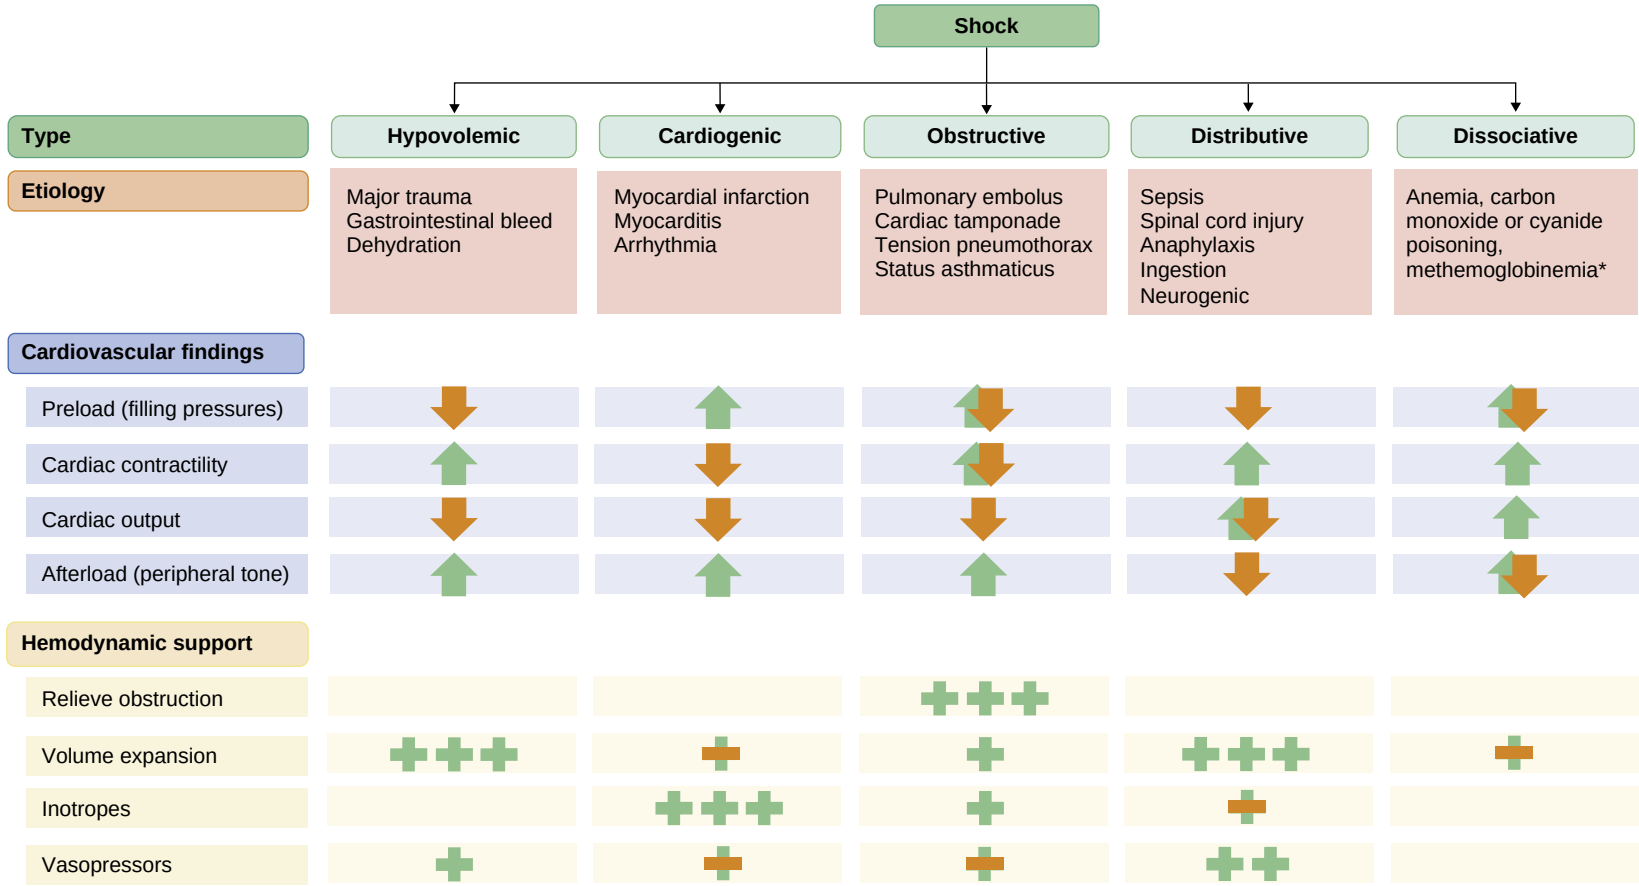

Fig. 85.1 The causes, cardiovascular findings, and hemodynamic support for different types of shock. Under cardiovascular findings, *bidirectional arrows* indicate variation in findings among patients with the particular type. Under hemodynamic support, the number of *+ signs* indicates the importance of therapy. A combined *+ and −* indicates that the intervention could help some patients but must be used with caution. *Treat specific etiology transfusion or specific antidotes. *(Modified from Angus DC. Approach to the patient with shock. In: Goldman L, Schafer AI, eds.* Goldman-Cecil Medicine, *26th ed. Philadelphia: Elsevier; 2020:642, Fig. 98-1.)*

Table 85.2 The Phoenix Sepsis Score[a]

VARIABLES	0 POINTS	1 POINT	2 POINTS	3 POINTS
RESPIRATORY, 0–3 POINTS				
	PaO_2:FIO_2 ≥400 or SpO_2:FIO_2 ≥292[b]	PaO_2:FIO_2 <400 on any respiratory support or SpO_2:FIO_2 <292 on any respiratory support[b,c]	PaO_2:FIO_2 100–200 and IMV or SpO_2:FIO_2 148–220 and IMV[b]	PaO_2:FIO_2<100 and IMV or SpO_2:FIO_2 <148 and IMV[b]
CARDIOVASCULAR, 0–6 POINTS		1 point each (up to 3)	2 points each (up to 6)	
	No vasoactive medications[d]	1 Vasoactive medication[d]	≥2 Vasoactive medications[d]	
	Lactate <5 mmol/L[e]	Lactate 5–10.9 mmol/L[e]	Lactate ≥11 mmol/L[e]	
AGE BASED[f]	Mean Arterial Pressure, mm Hg[g]			
<1 mo	>30	17–30	<17	
1 to 11 mo	>38	25–38	<25	
1 to <2 yr	>43	31–43	<31	
2 to <5 yr	>44	32–44	<32	
5 to <12 yr	>48	36–48	<36	
12 to 17 yr	>51	38–51	<38	
COAGULATION, 0–2 POINTS[H]		1 point each (maximum 2 points)		
	Platelets ≥100 × 10^3/μL	Platelets <100 × 10^3/μL		
	International normalized ratio ≤1.3	International normalized ratio >1.3		
	D-dimer ≤2 mg/L FEU	D-dimer >2 mg/L FEU		
	Fibrinogen ≥100 mg/dL	Fibrinogen <100 mg/dL		
NEUROLOGIC, 0–2 POINTS[i]				
	Glasgow Coma Scale score >10; pupils reactive[j]	Glasgow Coma Scale score ≤10[j]	Fixed pupils bilaterally	
PHOENIX SEPSIS CRITERIA				
Sepsis	Suspected infection and Phoenix Sepsis Score ≥2 points			
Septic shock	Sepsis with ≥1 cardiovascular point(s)			

[a]The score may be calculated in the absence of some variables (eg, even if lactate level is not measured and vasoactive medications are not used, a cardiovascular score can still be ascertained using blood pressure). It is expected that laboratory tests and other measurements will be obtained at the discretion of the medical team based on clinical judgment. Unmeasured variables contribute no points to the score. Ages are not adjusted for prematurity, and the criteria do not apply to birth hospitalizations, neonates whose postconceptional age is younger than 37 weeks, or those 18 years of age or older.

[b]SpO_2:FIO_2 ratio is only calculated if SpO_2 is 97% or less.

[c]The respiratory dysfunction of 1 point can be assessed in any patient receiving oxygen, high-flow, noninvasive positive pressure, or IMV respiratory support, and includes a PaO_2:FIO_2 ratio of less than 200 and a SpO_2:FIO_2 ratio of less than 220 in children who are not receiving IMV. For children receiving IMV with a PaO_2:FIO_2 less than 200 and SpO_2:FIO_2 less than 220, see criteria for 2 and 3 points.

[d]Vasoactive medications include any dose of epinephrine, norepinephrine, dopamine, dobutamine, milrinone, and/or vasopressin (for shock).

[e]Lactate reference range is 0.5 to 2.2 mmol/L. Lactate can be arterial or venous.

[f]Age is not adjusted for prematurity, and the criteria do not apply to birth hospitalizations, children whose postconceptional age is younger than 37 weeks, or those 18 years or older.

[g]Use measured MAP preferentially (invasive arterial if available or noninvasive oscillometric), and if measured MAP is not available, a calculated MAP (1/3 × systolic + 2/3 × diastolic) may be used as an alternative.

[h]Coagulation variable reference ranges: platelets, 150 to 450 × 103/μL; D-dimer, <0.5mg/L FEU; fibrinogen, 180 to 410mg/dL. The INR reference range is based on the local reference prothrombin time.

[i]The neurological dysfunction subscore was pragmatically validated in both sedated and nonsedated patients, and those receiving or not receiving IMV support.

[j]The Glasgow Coma Scale score measures level of consciousness based on verbal, eye, and motor response (range, 3–15, with a higher score indicating better neurological function).

FEU, fibrinogen equivalent units; IMV, invasive mechanical ventilation; INR, international normalized ratio of prothrombin time; MAP, mean arterial pressure; PaO_2:FIO_2, arterial partial pressure of oxygen to fraction of inspired oxygen ratio; SpO_2, oxygen saturation measured by pulse oximetry (only SpO_2 of ≤97%).

SI conversion factor: To convert lactate from mmol/L tomg/dL, divide by 0.111.

From Schlapbach LJ, Watson RS, Sorce LR, et al. International Consensus Criteria for Pediatric Sepsis and Septic Shock. *JAMA*. Published online January 21, 2024. https://doi.org/10.1001/jama.2024.0179.

Obstructive shock manifests as an acute increase in SVR typically in response to a sudden decrease in cardiac output that resembles a state of functional hypovolemia. A compensatory increase in HR and afterload provides temporary support, but compensation will soon fail without relief of the mechanical obstruction.

Dissociative shock is caused by the inability to deliver oxygen due to severe anemia or a congenital or acquired hemoglobinopathy, such as carbon monoxide intoxication. Alternatively, oxygen delivery may be preserved, but consumption can be impaired by a metabolic disorder or acquired state of mitochondrial dysfunction, such as cyanide

From Baumer-Mouradian SH, Drendel AL. Shock. In: Kliegman RM, Bordini BJ, Toth H, Basel D, eds. *Nelson Pediatric Symptom-Based Diagnosis*, 2nd ed. Elsevier: Philadelphia; 2022: Table 10.6.

toxicity. Notably, varying degrees of dissociative shock may also be present in other shock types, especially sepsis, in which acquired pyruvate dehydrogenase deficiency or mitochondrial dysfunction have been increasingly recognized.

Septic shock is generally a unique combination of distributive, hypovolemic, and cardiogenic shock, as well as dissociative shock. Hypovolemia from insufficient fluid intake, GI losses, and/or vascular leak is common. Cardiogenic shock results from the myocardial-depressant effects of sepsis, and distributive shock is the result of decreased SVR. The degree to which a patient exhibits each of these responses varies, but there are frequently alterations in preload, afterload, and myocardial contractility.

In septic shock, it is important to distinguish between the inciting infection and the host inflammatory response. Normally, host immunity prevents the development of sepsis through activation of the reticular endothelial system along with the cellular and humoral immune systems. This host immune response produces an *inflammatory cascade* mediated by hormones, cytokines, and chemokines. If this inflammatory cascade is uncontrolled, derangement of the microcirculatory system leads to subsequent organ and cellular dysfunction.

Systemic inflammatory response syndrome (SIRS) is an inflammatory cascade that is initiated by the host response to an infectious or noninfectious trigger (Table 85.3). This inflammatory cascade is triggered when the host defense system does not adequately recognize and/or eliminate the triggering event. The inflammatory cascade initiated by shock can lead to hypovolemia, cardiac and vascular failure, acute respiratory distress syndrome (ARDS), insulin resistance, decreased cytochrome P450 activity (decreased steroid synthesis), coagulopathy, and unresolved or secondary infection. Tumor necrosis factor (TNF) and other inflammatory mediators increase vascular permeability, causing diffuse vascular leak, decreased vascular tone, and an imbalance between perfusion and metabolic demands of the tissues. Early increases in TNF, interleukin (IL)-1, and IL-6 stimulate the release of both proinflammatory and antiinflammatory mediators, causing fever, vasodilation, and myocardial dysfunction. Simultaneous upregulation of antiinflammatory mediators (such as circulating levels of IL-4, IL-10, and transforming growth factor-β), downregulation of hematopoietic growth factors (such as IL-7), and increased expression of immune cell surface checkpoint proteins (such as programmed death [PD]-1 and its PD ligand [PD-L1/2]), as well as production of immature immune cells through emergency myelopoiesis contribute to a state of immune dysregulation that can impair pathogen clearance and allow for secondary infections.

The inflammatory cascade is initiated by toxins or superantigens through macrophage binding or lymphocyte activation. The vascular endothelium is both a target of tissue injury and a source of mediators that may cause further injury. Biochemical responses include the production of arachidonic acid metabolites, release of myocardial-depressant factors and endogenous opiates, activation of the complement system, and production and release of other mediators, which

Table 85.4 Signs of Decreased Perfusion

ORGAN SYSTEM	↓ PERFUSION	↓↓ PERFUSION	↓↓↓ PERFUSION
Central nervous system	—	Restless, apathetic, anxious	Agitated/confused, stuporous, coma
Respiratory	—	↑ Ventilation	↑↑ Ventilation
Metabolic	—	Compensated metabolic acidemia	Uncompensated metabolic acidemia
Gastrointestinal	—	↓ Motility	Ileus
Kidney	↓ Urine volume ↑ Urinary specific gravity	Oliguria (<0.5 mL/kg/hr)	Oliguria/anuria
Skin	Delayed capillary refill	Cool extremities	Mottled, cyanotic, cold extremities
Cardiovascular system	↑ Heart rate	↑↑ Heart rate ↓ Peripheral pulses	↑↑ Heart rate ↓ Blood pressure, central pulses only

may be proinflammatory or antiinflammatory. The balance among these mediator groups for an individual patient contributes to the progression (and resolution) of disease and affects the prognosis.

CLINICAL MANIFESTATIONS

Table 85.1 and Figure 85.1 show a classification system for shock. Categorization is important, but there may be significant overlap among these groups, especially in septic shock. The clinical presentation of shock depends in part on the underlying etiology, but if unrecognized and untreated, all forms of shock follow a common progression of clinical signs and pathophysiologic changes that may ultimately lead to irreversible organ injury and death. Among the first physiologic responses is sympathetic adrenergic system activation and its related signs and symptoms.

Shock may initially manifest as only tachycardia, with or without tachypnea. Progression leads to decreased urine output, poor peripheral perfusion, respiratory distress or failure, alteration of mental status, and low BP (Table 85.4). A significant misconception is that shock occurs only with low BP. Hypotension is often a late finding, especially in infants and young children, and is not a criterion for the diagnosis of shock because of a complex set of compensatory mechanisms that attempt to preserve BP and peripheral perfusion. Hypotension reflects an advanced state of uncompensated shock and is associated with increased morbidity and mortality.

Hypovolemic shock often manifests initially as tachycardia and orthostatic hypotension and is associated with dry mucous membranes, dry axillae, poor skin turgor, and decreased urine output. Depending on the degree of dehydration, the patient with hypovolemic shock may present with either normal or slightly cool distal extremities, and peripheral pulses may be normal, decreased, or absent depending on disease severity.

The presenting signs of **cardiogenic shock** are often tachypnea, cool extremities, delayed capillary filling time, poor peripheral and/or central pulses, reduced pulse pressure, declining mental status, and decreased urine output caused by the combination of decreased cardiac output and compensatory peripheral vasoconstriction (see Chapter 491.1).

Obstructive shock often also manifests as inadequate cardiac output because of a physical restriction of forward blood flow with tachycardia, delayed capillary refill, cool extremities, diminished peripheral pulses, and decreased pulse pressure (difference between systolic and diastolic BP) or presence of pulsus paradoxus. The acute presentation may quickly progress to cardiac arrest. Obstructive shock due to tension pneumothorax typically includes signs of respiratory distress, hypoxia, and diminished breath sounds. Pericardial tamponade includes Beck's triad of hypotension, jugular vein distention, and muffled heart sounds. A saddle pulmonary embolism often presents with a sudden cardiac arrest. Left-heart obstructive lesions may present in newborns with discrepant perfusion of the upper and lower extremities.

Distributive shock includes signs of vasodilation, including tachycardia, flash capillary refill, warm extremities, bounding peripheral pulses, and increased pulse pressure, often with diastolic hypotension. In neurogenic shock, tachycardia may be absent or frank bradycardia may be present. Similar to distributive shock, signs of vasodilation may be present, although in the immediate phase, the patient can feel cool peripherally with delayed capillary refill.

Septic shock can be difficult to diagnose because of the wide spectrum of presenting signs and symptoms. A key historical clue is the presence of fever (or hypothermia) along with evidence for either a *systemic* (e.g., bacteremia, rickettsial disease, fungemia, viremia) or *localized* (e.g., meningitis, pneumonia, pyelonephritis, peritonitis, necrotizing fasciitis) infection. Infants and young children most commonly present with "cold shock," with features of hypovolemic and cardiogenic shock predominating, including tachycardia, delayed capillary refill, cool extremities, diminished peripheral pulses, and decreased pulse pressure. Older children and adolescents, especially those with sepsis from indwelling central venous catheters, more commonly present with "warm shock" that resembles distributive shock, including tachycardia, flash capillary refill, warm extremities, bounding peripheral pulses, and increased pulse pressure. However, the pathobiology of sepsis can evolve over time and with treatment in children, such that "warm shock" may shift to "cold shock" or vice versa.

In addition to the traditional description of septic shock, a subgroup immunophenotype presents with **hyperferritinemia**. Ferritin levels >3,000 mg/mL often predict a poor prognosis and the need for intensive care unit (ICU) admission. Hyperferritinemic septic shock may be due to familial primary genetic hemophagocytic lymphohistiocytosis (HLH) (usually age <2 years; see Chapter 556.2) or, more often, secondary HLH initiated by an infectious agent or macrophage activation syndrome (MAS) (see Chapter 207) associated with autoimmune diseases (Table 85.6).

Regardless of etiology, uncompensated shock, with hypotension, high SVR, decreased cardiac output, respiratory failure, obtundation, and oliguria, occurs late in the progression of disease. Table 85.1 lists the hemodynamic findings in various shock states. Additional clinical findings in shock include cutaneous lesions such as petechiae, diffuse erythema, ecchymoses, ecthyma gangrenosum, and peripheral gangrene. Jaundice can be present either as a sign of infection or as a result of MODS.

DIAGNOSIS

Shock is a clinical diagnosis that should be primarily based on a thorough history and physical examination (see Tables 85.1, 85.4, and 85.6). Important clues to consider in the history are recent trauma or bleeding, exposure to new medications or substances, preceding or concurrent symptoms of infection or fluid losses, the patient's comorbid conditions, and a brief review of systems. The physical examination should include rapid assessment of vital signs (including pulse oximetry), mental status/level of consciousness, extremity temperature, peripheral and central pulses, capillary refill, and presence of rashes or skin changes.

Increasingly, point-of-care ultrasound (POCUS) is being incorporated into the initial assessment of children with shock to assess intravascular volume status, likelihood of a positive hemodynamic response to fluid

Table 85.5 Considerations in Management of Hyperferritinemic Sepsis Beyond Usual Diagnostic and Therapeutic Measures Used in Sepsis Patients Without Hyperferritinemia

WHAT OCCULT INFECTION IS PRIMING AND WHAT CO-INFECTION IS PRESENT FOR THE HYPERFERRITINEMIC PROCESS?
Perform diagnostic workup for **viruses** (e.g., herpes simplex virus 1, HHV-6, HHV-8, Epstein-Barr virus, adenovirus, cytomegalovirus, parvovirus, Ebola, COVID-19, Dengue, hepatitis A, HIV, severe fever with thrombocytopenia syndrome virus, influenza, hemorrhagic fevers), **parasites** (e.g., toxoplasmosis, leishmaniasis, malaria, scrub typhus, babesiosis), **intracellular bacteria** (e.g., tuberculosis, atypical mycobacteria, mycoplasma, fusobacteria, babesiosis, ehrlichiosis), rickettsia, and **fungi** (e.g., histoplasmosis).
Begin empiric therapy and specific therapies according to context.
Give IVIG if no specific therapy is available to neutralize infection.
IS HEMOLYSIS AND FREE HEMOGLOBIN DRIVING THE HYPERFERRITINEMIC PROCESS?
Measure free hemoglobin and ferritin sequentially.
Minimize blood transfusions.
If unable to reverse hemolysis or hyperferritinemia, consider 5 days of plasma exchange to remove free hemoglobin and ferritin and to resolve inflammation.
IS AN ANTIINFLAMMATORY STRATEGY NEEDED TO SAFELY CONTROL INFLAMMASOME ACTIVATION?
If ferritin is >3,000 ng/mL in the high-resource PICU setting, or >500 ng/mL in the resource-poor PICU setting, then mortality risk is increased.
Methylprednisone, IVIG, and interleukin 1 receptor antagonist (anakinra) can be safely given to reduce mortality risk in these children.

HHV, human herpes virus; PICU; pediatric intensive care unit; IVIG, IV immunoglobulin. Modified from Carcillo JA, Kernan KK, Horvat CM, et al. Why and how is hyperferritinemic sepsis different from sepsis without hyperferritinemia? *Pediatr Crit Care Med.* 21(5):509-512, Table 1, p. 511.

therapy, and myocardial function. Cardiac and lung POCUS may also provide important diagnostic information about the etiology of shock, such as the presence of pericardial fluid to support tamponade, pneumothorax, or dilated right ventricle to support pulmonary embolus. The focused assessment with sonography for trauma (FAST) is commonly performed to screen for pericardial effusion and hemoperitoneum.

LABORATORY FINDINGS

Although the initial diagnosis of shock can and should be based on clinical data from the history and physical examination, the overall evaluation of shock should also include early laboratory testing to screen for hyperlactatemia (as a sign of increased anaerobic metabolism), acidemia, and electrolyte disturbances, including hypoglycemia and hypocalcemia. In children with septic shock, elevations in both venous and arterial blood lactate levels in the emergency department (ED) are associated with risk of organ dysfunction when measured in the ED and are associated with higher risk of death if elevated at the time of PICU admission. Although the optimal cutoff remains to be defined, arterial lactate ≥2 mmol/L is worrisome and associated with worse outcome. Laboratory evidence of concurrent MODS should also be sought, including a complete blood count, renal function tests, liver function tests, and coagulation profile (including fibrinogen and D-dimer or fibrin split products). Elevated neutrophil counts with increased immature forms (i.e., bands, myelocytes, promyelocytes) and elevated CRP and procalcitonin levels may be seen with infection. A blood gas analysis may be helpful to assess the degree of respiratory dysfunction, and an elevated venous to arterial P_{CO_2} gap ≥5 mm Hg (≥0.67 KPa) may signify an early shock state. For septic shock, at least one blood culture should be collected along with other cultures as supported by the history and physical. Ferritin levels should be determined in all patients with septic shock. In the presence of hyperferritinemia, laboratory studies for HLH and MAS should be obtained, including fibrinogen, triglycerides, CBC, soluble IL-2 receptor, natural killer (NK) cells, and specific genetic testing.

The hallmark of *uncompensated* shock is an imbalance between oxygen delivery (Do_2) and oxygen consumption (Vo_2). Oxygen delivery normally exceeds oxygen consumption by threefold. The oxygen extraction ratio is approximately 25%, thus producing a normal central venous oxygen saturation (Svo_2) of approximately 75%, most commonly measured from a catheter at the junction of the superior vena cava and right atrium. Svo_2 values <70% reflect an increased oxygen extraction ratio and document a decrease in oxygen delivery relative to consumption. This increase in tissue oxygen extraction is an attempt to maintain adequate oxygen delivery at the cellular level. This state is manifested clinically by increased lactic acid production (e.g., high anion gap, metabolic acidemia) caused by anaerobic metabolism and a compensatory increase in tissue oxygen extraction. Notably, in dissociative shock, hyperlactatemia is often accompanied by an elevated Svo_2 >80–85%, which reflects a state of impaired oxygen use despite adequate tissue perfusion. *Elevated blood lactate levels reflect poor tissue oxygen delivery noted in all forms of shock.*

TREATMENT

Almost all healthcare professionals that care for ill children will be faced with managing the clinical syndrome of shock, given that many childhood illnesses, such as gastroenteritis, infection, trauma, and toxic ingestions, can precipitate shock. Without timely medical intervention, the child in shock will inevitably follow a common pathway to MODS and death. Early recognition and resuscitation are therefore critical to limit morbidity and mortality associated with shock.

General Principles of Shock Management

Initial management begins with early recognition of the compensated or uncompensated shock state based on the history, physical examination, and laboratory assessments outlined earlier. Once recognized, immediate efforts to restore oxygen (and other nutrient) delivery by supporting the circulation and identifying and reversing the underlying etiology of shock are necessary (Fig. 85.2). Restoration of oxygen delivery includes ensuring airway patency and adequacy of breathing, providing supplemental oxygen if hypoxemia (Spo_2 <92–94%) is present, establishing vascular access, expanding the circulating blood volume, supporting the cardiac and vascular system with appropriate vasoactive agents when necessary, and frequently reassessing the patient's response to initial therapy. The management strategies discussed in the following sections apply to all shock types, with additional discussion at the end of the section for type-specific management recommendations.

Vascular access should be established within the first few minutes of shock recognition, ideally with at least two large-bore peripheral intravenous (IV) catheters. If peripheral IV access is not successful within 5 minutes, intraosseous (IO) access should be established until more definitive access is secured. Central venous access should be considered for patients with unstable peripheral IV access, persistence of shock despite 40-60 mL/kg fluid bolus therapy *(fluid-refractory shock),* or need for vasoactive medications or concentrated dextrose/electrolyte administration. In addition to optimizing safe administration of certain medications, central venous access will also enable measurement of Svo_2. Placement of an arterial catheter should be considered for patients with fluid-refractory shock who require active titration of vasoactive medications and/or those who may need serial laboratory tests, including frequent reassessment of blood lactate or electrolyte derangements. Notably, placement of a central venous or arterial catheter requires specialized skills that may not be immediately available, in which case continued resuscitation through peripheral IV or IO access, including initiation of vasoactive medications, is safe and appropriate.

Volume resuscitation with fluid bolus therapy in aliquots of 10-20 mL/kg pushed over 5-10 minutes is currently recommended for most types of shock and in most settings in children (see special considerations in septic shock later and Fig. 85.3). Several observational studies have demonstrated improved outcomes in children with shock with initial volume resuscitation titrated to improvements in hemodynamic targets, including decrease in HR; increase in BP; normalization of capillary refill, peripheral pulse strength, and extremity temperature;

Table 85.6 Physical Examination and Selected Laboratory Signs in Shock

Central nervous system	Acute delirium, restlessness, disorientation, confusion, and coma, which may be secondary to decreased cerebral perfusion pressure (mean arterial pressure minus intracranial pressure). Patients with chronic hypertension or increased intracranial pressure may be symptomatic at normal blood pressures. Cheyne-Stokes respirations may be seen with severe decompensated heart failure. Blindness can be a presenting complaint or complication.
Temperature	Hyperthermia results in excess tissue respiration and greater systemic oxygen delivery requirements. Hypothermia can occur when decreased systemic oxygen delivery or impaired cellular respiration decreases heat generation.
Skin	Cool distal extremities (combined low serum bicarbonate and high arterial lactate levels) aid in identifying patients with hypoperfusion. Pallor, cyanosis, sweating, and decreased capillary refill and pale, dusky, clammy, or mottled extremities indicate systemic hypoperfusion. Dry mucous membranes and decreased skin turgor indicate low vascular volume. Low toe temperature correlates with the severity of shock.
General cardiovascular	Neck vein distention (e.g., heart failure, pulmonary embolus, pericardial tamponade) or flattening (e.g., hypovolemia), tachycardia, and arrhythmias. Decreased coronary perfusion pressures can lead to ischemia, decreased ventricular compliance, and increased left ventricular diastolic pressure. A "mill wheel" heart murmur may be heard with an air embolus.
Heart rate	Usually elevated. However, paradoxical bradycardia can be seen in patients with preexisting cardiac disease and severe hemorrhage. Heart rate variability is associated with poor outcomes.
Systolic blood pressure	May actually increase slightly when cardiac contractility increases in early shock and then fall as shock advances.
Diastolic blood pressure	Correlates with arteriolar vasoconstriction and may rise early in shock and then fall when cardiovascular compensation fails.
Pulse pressure	Defined as systolic minus diastolic pressure and related to stroke volume and the rigidity of the aorta. Increases early in shock and decreases before systolic pressure decreases.
Pulsus paradoxus	An exaggerated change in systolic blood pressure with respiration (systolic blood pressure declines >10 mm Hg with inspiration) seen in asthma, cardiac tamponade, and air embolus.
Mean arterial blood pressure	Diastolic blood pressure + [pulse pressure/3]
Shock index	Heart rate/systolic blood pressure. Normal = 0.5-0.7. A persistent elevation of the shock index (>1.0) indicates impaired left ventricular function (as a result of blood loss or cardiac depression) and is associated with increased mortality.
Respiratory	Tachypnea, increased minute ventilation, increased dead space, bronchospasm, hypocapnia with progression to respiratory failure, acute lung injury, and adult respiratory distress syndrome.
Abdomen	Low-flow states may result in abdominal pain, ileus, gastrointestinal bleeding, pancreatitis, acalculous cholecystitis, mesenteric ischemia, and shock liver.
Renal	Because the kidney receives 20% of cardiac output, low cardiac output reduces the glomerular filtration rate and redistributes renal blood flow from the renal cortex toward the renal medulla, thereby leading to oliguria. Paradoxical polyuria in early sepsis may be confused with adequate hydration.
Metabolic	Respiratory alkalosis is the first acid-base abnormality, but metabolic acidosis rapidly occurs as shock progresses. Hyperglycemia, hypoglycemia, and hyperkalemia may develop. Hyperferritinemia suggests a poor prognosis.

From Angus DC. Approach to the patient with shock. In Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine,* 26th ed. Philadelphia: Elsevier; 2020:643, Table 98-1.

improved urine output; and fall in blood lactate by ≥10–20%. Fluid boluses totaling up to 60 mL/kg may be needed in the first hour of resuscitation, with volumes exceeding 200 mL/kg over several hours. Fluid should be administered via IV push or a rapid infuser system. IV push delivery may be facilitated by attaching a large syringe with a three-way stopcock to the IV tubing from the fluid bag, creating a "push-pull system" that allows the user to rapidly draw up fluid into the syringe and then administer to the patient without repeatedly disconnecting and reconnecting the syringe to the patient's IV. In patients >50 kg, a pressure bag or rapid infuser may be used to rapidly administer fluid through a large-gauge peripheral IV. Notably, in neonates, additional caution should be paid to fluid resuscitation, as tolerance may be limited by reduced myocardial ventricular compliance at baseline.

Importantly, not all children with shock will continue to improve with repeated volume resuscitation, particularly those with cardiogenic and dissociative shock, severe anemia, or malnutrition. Before repeating a fluid bolus, the clinician should determine if the patient responded in a hemodynamically desirable way after the prior fluid bolus and ensure that signs of fluid overload, such as rales, gallop rhythm, or hepatomegaly, have not developed. POCUS may also be helpful to identify ongoing hypovolemia and predict response to ongoing volume resuscitation. For children with evidence of fluid overload, adequate intravascular volume, or lack of hemodynamic improvement with prior fluid boluses, resuscitation should shift from volume resuscitation to vasoactive medications. Trials of earlier initiation of vasoactive support are ongoing to further clarify the optimal role of volume resuscitation in pediatric shock.

The optimal fluid type for initial shock resuscitation remains a matter of debate. Most studies have not demonstrated a clear benefit for use of colloids, such as 4–5% albumin, over crystalloids, though there may be a small clinical benefit for resuscitation with colloids in septic shock. There is also evidence supporting a risk of kidney injury and coagulopathy with the use of synthetic colloids, such as hydroxyethyl starch and gelatin, and their use is currently not recommended. Because crystalloids are inexpensive, easy to administer, and readily available, current guidelines generally recommend initial resuscitation begin with these fluids. Exceptions include children with hemorrhagic shock and dissociative shock resulting from severe anemia for whom early blood product transfusion is preferred.

Crystalloid volume resuscitation may include 0.9% normal saline or balanced/buffered fluids, such as lactated Ringer solution, Hartmann solution, and Plasma-Lyte. Saline consists of only sodium and chloride in a 1:1 ratio with a supraphysiologic chloride concentration, whereas balanced fluids have an anion buffer and electrolyte composition closer to human blood plasma, though formulations vary. As a result, high-volume resuscitation with 0.9% saline often induces a hyperchloremic metabolic acidemia. Although 0.9% remains the most commonly used crystalloid

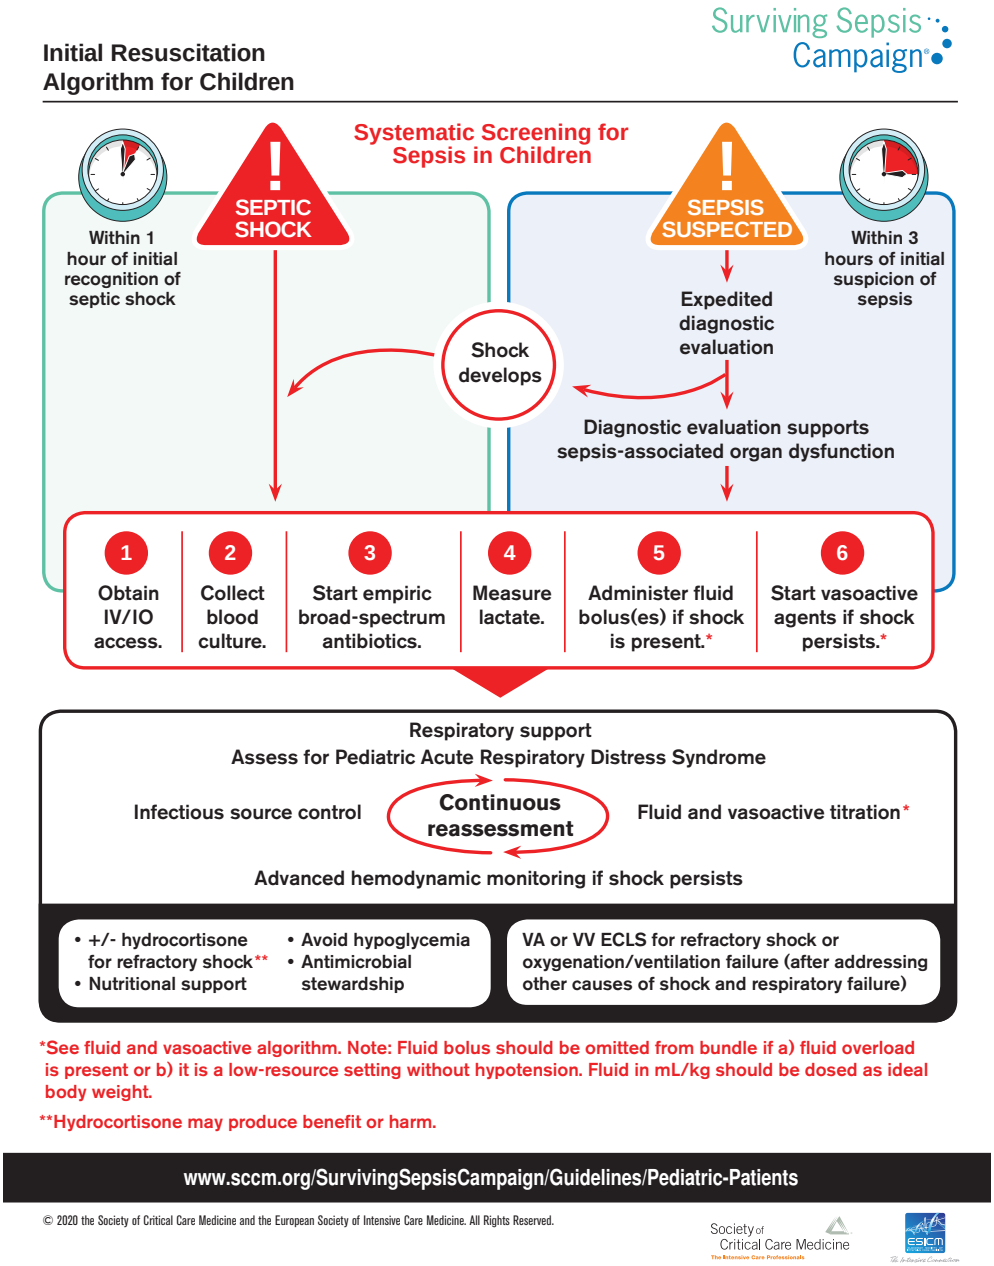

Fig. 85.2 Surviving Sepsis Campaign 2020 Initial Resuscitation Algorithm for Children. For children with clinical signs of shock, the following six key management steps should be completed within 1 hour of initial recognition of shock: (1) obtain intravenous/intraosseous access, (2) collect blood culture, (3) start empiric broad-spectrum antibiotics, (4) measure blood lactate, (5) administer crystalloid fluid therapy with volume and rate reflecting healthcare setting and titrated to patient response, and (6) initiate vasoactive medications if shock persists despite fluid and other therapy. VA, venoarterial; VV, venovenous; ECLS, extracorporeal life support. *(© 2020 the Society of Critical Care Medicine and the European Society of Intensive Care Medicine. All Rights Reserved. https://www.sccm.org/getattachment/SurvivingSepsisCampaign/Guidelines/Pediatric-Patients/Initial-Resuscitation-Algorithm-for-Children.pdf.aspx?lang=en-US.)*

for pediatric volume resuscitation, increasing data suggest that balanced/buffered fluids are associated with less acute kidney injury, inflammation, coagulopathy, endotheliopathy, and death. However, pediatric studies comparing balanced/buffered fluids with 0.9% saline have reported conflicting results, and adult interventional trials have not shown a consistent benefit for either crystalloid fluid type. Consequently, pending further data from ongoing studies, either 0.9% saline or balanced/buffered crystalloids are appropriate for initial volume resuscitation.

Resuscitation with blood products should be prioritized for children with hemorrhagic shock. The *Advanced Trauma Life Support* guidelines recommend resuscitation with red blood cells, plasma, and platelets in a ratio of 1:1:1 to limit coagulopathy and other risks associated with large-scale transfusion. For children with other forms of shock, the criteria to transfuse red blood cells are not clear, though it is reasonable to target hemoglobin levels >9 g/dL for children who remain hemodynamically unstable with low Svo_2 and/or high blood lactate despite other interventions. Notably, transfusion of plasma or platelets should be reserved to treat active bleeding or reduce risk of bleeding before an invasive procedure rather than used solely to correct laboratory abnormalities or as volume expanders.

Vasoactive medications should be initiated for children with fluid-refractory shock, with early consideration for inotropes, such as epinephrine, when myocardial dysfunction is present and vasopressors, such as norepinephrine, when vasoplegia is present (Table 85.7). For children with septic shock, two randomized trials have demonstrated that epinephrine as first-line vasoactive therapy is more effective at reducing mortality than dopamine. As such, epinephrine is the preferred first-line vasoactive therapy for fluid-refractory septic shock.

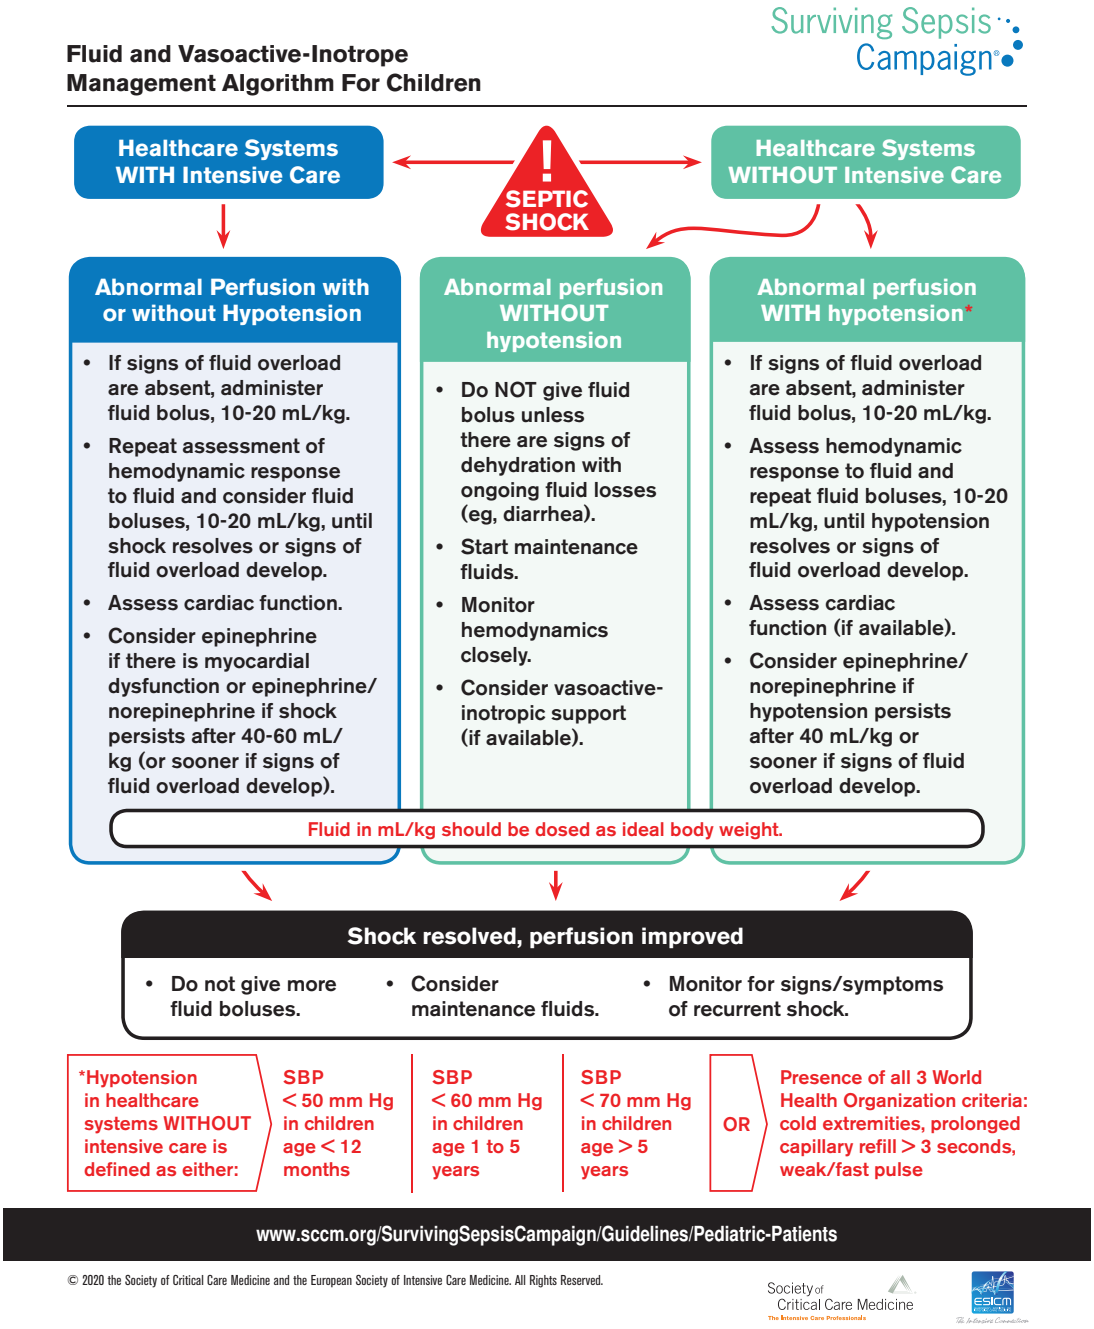

Fig. 85.3 Surviving Sepsis Campaign 2020 Fluid and Vasoactive-Inotrope Management Algorithm for Children. For children with septic shock treated in healthcare systems in which intensive care is accessible (either locally or via transport), fluid bolus therapy up to 40-60 mL/kg is recommended in the first hour of therapy until shock resolves or signs of fluid overload develop. For children with septic shock treated in healthcare systems in which intensive care is not available locally or via transport, fluid bolus therapy is not recommended unless hypotension is present. For all children, early assessment of cardiac function is recommended with consideration for initiation of epinephrine (or alternative inotrope) if myocardial dysfunction is evident. SBP, systolic blood pressure. (*© 2020 the Society of Critical Care Medicine and the European Society of Intensive Care Medicine. All Rights Reserved.* https://www.sccm.org/getattachment/SurvivingSepsisCampaign/Guidelines/Pediatric-Patients/Initial-Resuscitation-Algorithm-for-Children.pdf.aspx?lang=en-US.)

Epinephrine is also a potent inotrope and is the recommended initial vasoactive agent in children with cardiogenic shock. However, in children with a low-SVR state, as may be seen with distributive, septic, or neurogenic shock, norepinephrine should be preferentially prescribed as the first-line vasoactive therapy. Although vasoactive agents are ideally administered through a central venous line, these medications can be safely initiated through a peripheral IV or an IO in dilute concentrations while central venous access is obtained.

Electrolyte abnormalities, such as hypoglycemia and hypocalcemia, may precipitate or worsen shock. Blood glucose and ionized calcium can both be measured rapidly via bedside point-of-care testing, and if present, hypoglycemia and hypocalcemia should be corrected during the initial resuscitation. Other patterns of electrolyte abnormalities may indicate the presence of an underlying inborn error of metabolism, particularly in a neonate with shock. Any provider treating a patient with known or suspected inborn error of metabolism should consult immediately with a specialty center while resuscitating with volume and dextrose.

Airway management is an essential component of the initial management of shock. Early intervention to maintain an unobstructed

Table 85.7 Vasoactive Medications to Treat Shock

DRUG	EFFECT(S)	DOSING RANGE	COMMENT(S)
Epinephrine	↑ Heart rate and ↑ cardiac contractility Vasodilator at low doses, but potent vasoconstrictor at doses >0.1 mcg/kg/min	0.05-2.0 µg/kg/min	May ↓ renal perfusion at high doses ↑ Myocardial O_2 consumption Risk of arrhythmia at high doses
Norepinephrine	Potent vasoconstriction ↑ Cardiac contractility (but may be blunted by increased afterload)	0.05-2.0 µg/kg/min	↑ Blood pressure secondary to ↑ systemic vascular resistance ↑ Left ventricular afterload
Dopamine	↑ Cardiac contractility Significant peripheral vasoconstriction at >10 µg/kg/min	3-20 µg/kg/min	↑ Risk of arrhythmias at high doses
Dobutamine	↑ Cardiac contractility Peripheral vasodilator	3-10 µg/kg/min	—
Phenylephrine	Potent vasoconstriction No effect on cardiac contractility	0.25-2.0 µg/kg/min	Can cause sudden hypertension
Vasopressin	Potent vasoconstriction	0.5-20 milliunits/kg/min	Can cause sudden hypertension
Angiotensin II	Potent vasoconstrictor	Stepwise increase 5-10-25-40-80 ng/kg/min over 3 hr with titration down to 1.25-40 ng/kg/min after 3 hr	Can cause sudden hypertension, arterial ischemia
Methylene blue	Reduce responsiveness to cGMP-dependent (e.g., ischemia-reperfusion, NO mediated) vasodilators	Bolus 1-2 mg/kg, then consider continuous infusion 0.5-.01 mg/kg/hr	Causes blue/green discoloration of skin and urine
Milrinone	Increased cardiac contractility Improves cardiac diastolic function Peripheral vasodilation	0.25-1.0 µg/kg/min	Phosphodiesterase inhibitor—slows cyclic adenosine monophosphate breakdown
Prostaglandin E_1	Vasodilator Maintains an open ductus arteriosus in the newborn with ductal-dependent congenital heart disease	0.01-0.2 µg/kg/min	Can lead to hypotension Risk of apnea

airway may be needed in patients who are obtunded or have suffered a traumatic neck or chest injury. Supplemental oxygen should be provided to correct hypoxemia if Spo_2 is <92–94%. Although universal supplemental oxygen administration can, in theory, augment tissue oxygen delivery by increasing oxygen content of the blood, this approach is of little benefit if the oxyhemoglobin saturation is >92–94%, and some studies suggest harm from hyperoxia. However, universal administration of high fraction of inspired oxygen is likely to be beneficial for patients with severe anemia or dissociative shock. When oxygen is required, use of a 100% non-rebreather mask provides the highest amount of noninvasive supplemental oxygen delivery.

Indications for intubation and mechanical ventilation include acute hypoxemic or hypercarbic respiratory failure or persistence of circulatory failure, in which case a reduction in metabolic demand facilitated by sedation and ventilatory support can be helpful. Sedation and endotracheal intubation reduce the work of breathing, which can divert cardiac output away from the muscles of respiration and improve perfusion to other organs. However, extra caution needs to be taken during intubation and the transition from negative pressure to positive pressure ventilation. Positive pressure ventilation will decrease venous return in a patient who is already hypovolemic, which could precipitate cardiovascular collapse. It is therefore prudent to have fluid boluses readily available and vasoactive agents started or immediately ready to administer during this transition. Of the sedative agents available for intubation, ketamine is generally preferred because of its favorable hemodynamic effects that typically augment cardiac output and BP. As several studies have reported adverse outcomes after intubation with etomidate, pediatric septic shock guidelines recommend against using etomidate in these patients.

Specific Management Considerations by Shock Type

For children with **cardiogenic shock** due to congenital heart disease, cardiomyopathies, myocarditis, MIS-C, or other causes, decreased myocardial contractility must be reversed by early treatment with inotropes, such as epinephrine, dopamine, dobutamine, or milrinone. Gentle volume resuscitation to optimize preload may also be helpful, but excessive fluid administration can worsen volume overload and further compromise heart function. Despite adequate cardiac output with the support of inotropic agents, a high SVR with poor peripheral perfusion and acidosis may persist in cardiogenic shock. Therefore, if not already started, inodilators such as milrinone may improve systolic function and decrease SVR without causing a significant increase in HR. Furthermore, this agent has the added benefit of enhancing diastolic relaxation. Dobutamine or other vasodilating agents, such as nitroprusside, may also be considered in this setting (see Table 85.7).

In **obstructive shock**, action is often needed to relieve the point of mechanical obstruction. Examples include thoracentesis for tension pneumothorax, pericardiocentesis for cardiac tamponade, and administration of systemic fibrinolytic medications for pulmonary embolism. For neonates or young infants (typically <2-3 weeks of age) with shock caused by ductal-dependent congenital heart disease, a prostaglandin infusion should be started to maintain systemic cardiac output while preparing to transfer to a pediatric specialty center.

The management of **septic shock** should follow the recommendations of the 2020 Surviving Sepsis Campaign International Guidelines for the Management of Septic Shock and Sepsis-Associated Organ Dysfunction in Children (see Fig. 85.2 and Fig. 85.3). These guidelines recommend six initial management steps in the first hour after shock

recognition, including obtaining IV/IO access, collecting a blood culture, administering empiric broad-spectrum antibiotics, measuring lactate, providing volume resuscitation, and initiating vasoactive medication if shock persists despite fluid therapy. Early administration of antibiotics targeted to the most likely pathogens for each patient has been associated with reduced mortality and more rapid resolution of organ dysfunction.

Notably, the Surviving Sepsis Campaign suggests volume resuscitation with up to 40-60 mL/kg in bolus fluid (10-20 mL/kg per bolus) over the first hour, titrated to clinical markers of cardiac output and discontinued if signs of fluid overload develop, for children with septic shock treated in geographic regions that have access to intensive care (either locally or via transport) or in any setting when hypotension is present. However, in healthcare systems with no availability to access intensive care, fluid bolus therapy was associated with increased risk of mortality in the FEAST clinical trial when hypotension was not present, and thus fluid management should focus on starting maintenance fluids only in these settings (see Fig. 85.3).

Fluid-Refractory and Catecholamine-Resistant Shock

If shock persists despite volume resuscitation and vasoactive support with an initial catecholaminergic agent, such as epinephrine, the child has **fluid-refractory and catecholamine-resistant shock**. Such children have an increased risk for MODS and death, especially if requirement for vasoactive support is high, blood lactate exceeds 8 mmol/L (or is rising after 6 hours of resuscitation), and/or myocardial dysfunction is present. Several additional management considerations must be taken into account in this scenario, including evaluation for atypical and/or reversible etiologies, second-line vasoactive medications, stress-dose corticosteroids, and extracorporeal membrane oxygenation (ECMO).

Atypical and reversible etiologies that may contribute to refractory shock include hypothyroidism and intraabdominal hypertension/abdominal compartment syndrome. In addition, one must consider the presence of obstructive shock (tamponade, pneumothorax), an unrecognized closing ductus arteriosus, uncontrolled hemorrhage (which often requires surgical intervention), anaphylaxis, and need for removal of an infectious source (e.g., infected catheter, empyema, abdominal abscess).

Stress-dose corticosteroids are indicated for patients with septic shock who have absolute adrenal insufficiency, such as that caused by congenital adrenal hyperplasia, septic shock with purpura, prior steroid therapy for chronic illness, or hypopituitarism. Some children with septic shock may also develop *critical illness–related corticosteroid insufficiency* with an inadequate adrenal response to a severe stress. Stress doses of hydrocortisone (50-100 mg per m^2 per day) are recommended for those with risk factors for absolute adrenal insufficiency (e.g., septic shock with purpura, prior steroid therapy for chronic illness, known pituitary or adrenal abnormalities) and can be considered for children with fluid-refractory, catecholamine-resistant shock without a reversible etiology pending further data from ongoing clinical trials.

Second-line vasoactive therapy should be considered for patients in whom shock persists despite titration of the initial vasoactive agent. For patients with "warm" shock or evidence of low SVR initially treated with norepinephrine, the addition of vasopressin or epinephrine may be considered. Case reports, case series, and one trial indicate that administration of vasopressin is associated with an increase in mean arterial BP and urine output in children with fluid-refractory, catecholamine-resistant septic shock. However, in a multicenter trial of 65 children with vasodilatory shock, low-dose vasopressin did not decrease the time to hemodynamic stability off of vasoactive agents versus placebo (49.7 vs 47.1 hours), and there was a concerning trend toward increased mortality in the vasopressin group (30% vs 16%, $p = 0.24$). For patients with "cold" shock or evidence of myocardial dysfunction, priority should be given to improving cardiac contractility with inotropes. First-line therapy with epinephrine is recommended, with addition of dopamine, dobutamine, or norepinephrine as second-line agents, but these agents should be carefully titrated, as they may contribute to arrhythmias and increase myocardial oxygen demand. Initiation of inodilators, such as milrinone, can help to augment contractility, improve lusitropy (diastolic relaxation), and lower SVR but are generally longer-acting and should be carefully titrated to avoid worsening hypotension. Notably, it may be difficult to accurately differentiate between "warm" (low SVR) from "cold" (high SVR) shock using only clinical signs, such as extremity temperature, strength of peripheral pulses, and capillary refill time. Frequent reassessment and response to therapy are therefore paramount to ensure optimal titration of vasoactive therapies.

ECMO is a rescue option for patients suffering refractory septic shock, with reported survival rates of ~70% for newborns and ~50% for older children. One study suggests that central cannulation via sternotomy may achieve survival rates of 74% for refractory septic shock. In cardiogenic shock due to myocarditis treated with ECMO, survival rates of 70% have been reported. Although counterintuitive because of the need for systemic anticoagulation, ECMO has also been used successfully in hemorrhagic shock in a small series. In most cases of refractory shock, venoarterial ECMO is preferred over the venovenous route due to the presence of hemodynamic instability. A ventricular assist device may be considered as an alternative to ECMO in some children with cardiogenic shock.

Targets for Shock Reversal

Clinical signs of successful resuscitation include a decrease in HR and respiratory rate, increase in BP, improved urine output to >0.5 mL/kg/hr, normalization of mental status, decreased capillary refill time, warmth of distal extremities, and improved peripheral pulses. Serial laboratory measurements should aim for a rise in Svo_2 to >70% and a decreasing trend in blood lactate levels as evidence for increased tissue oxygen extraction and adequate oxygen delivery to meet cellular metabolic demand. In one observational study of septic shock in children, normalization of blood lactate to <2 mmol/L within 4 hours was associated with reduced organ dysfunction. Blood pH and base deficit may also be used as laboratory surrogates for improved tissue perfusion, but these may be affected by the degree of hyperchloremia after fluid resuscitation or by changes in ventilation.

Other parameters to monitor for improvement in shock include serial POCUS to assess volume status, cardiac output, and tissue perfusion; cutaneous near-infrared spectroscopy (NIRS) to measure regional tissue perfusion; and other devices that can estimate cardiac output based on the relationship among BP, stroke volume, arterial compliance, and SVR (e.g., pulse contour waveform analysis). If cardiac output is measured, aiming for a cardiac index between 3.3 and 6.0 L/min/m^2 is appropriate.

Though children can have isolated cardiovascular dysfunction with shock, many have additional associated organ dysfunctions or MODS. Ongoing support of noncardiovascular organ dysfunction is often required even after improvement or resolution of shock.

PROGNOSIS

In septic shock, mortality rates are as low as 3% in previously healthy children and 6–9% in children with chronic illness (compared with 25–30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and MODS remain one of the leading causes of nonaccidental death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy.

Chapter 86

Acute Care of Respiratory Distress and Failure

Alexandre T. Rotta, Martin C.J. Kneyber, and Ashok P. Sarnaik

The term *respiratory distress* is used to denote signs and symptoms of an abnormal respiratory pattern. A child with nasal flaring, tachypnea, chest wall retractions, stridor, grunting, dyspnea, or wheezing has respiratory distress. Taken together, the magnitude of these findings is used to judge clinical severity. Nasal flaring is nonspecific, but the other signs are useful in localizing the site of pathology (see Chapter 421). *Respiratory failure* is defined as the inability of the lungs to provide sufficient oxygen (hypoxic respiratory failure) or remove carbon dioxide (ventilatory failure) to meet metabolic demands. Therefore, whereas respiratory distress is determined by a clinical impression, respiratory failure is diagnosed when inadequate oxygenation or ventilation (or both) are present. Respiratory distress can occur in patients without respiratory disease, and respiratory failure can occur in patients without respiratory distress.

RESPIRATORY DISTRESS

A careful physical examination must be performed when evaluating a child in respiratory distress. **Nasal flaring**, although nonspecific, is an extremely important sign of distress in infants. It may indicate discomfort, pain, fatigue, acidosis, or breathing difficulty. The state of **responsiveness** is another crucial sign. Lethargy, disinterest in surroundings, and weak cry are suggestive of exhaustion, hypercarbia, and impending respiratory failure. Abnormalities of the rate and depth of **breathing** can occur with both pulmonary and nonpulmonary causes of respiratory distress. In diseases of decreased lung compliance, such as pneumonia and pulmonary edema, breathing is characteristically rapid and shallow (decreased tidal volume). In obstructive airway diseases, such as asthma and laryngotracheitis, breathing generally is deep with increased tidal volume, but less rapid. Rapid and deep breathing (tachypnea and hyperpnea) without other respiratory signs should raise suspicion of possible nonpulmonary or nonthoracic causes of respiratory distress, such as response to metabolic acidosis (e.g., diabetic ketoacidosis, renal tubular acidosis) or stimulation of the respiratory center (e.g., encephalitis, ingestion of central nervous system stimulants). Suprasternal, intercostal, and subcostal **retractions** are manifestations of increased inspiratory effort, weak chest wall, or both. Inspiratory **stridor** indicates airway obstruction above the thoracic inlet, whereas expiratory **wheezing** results from airway obstruction below the thoracic inlet. **Grunting** is most commonly heard in diseases with decreased functional residual capacity (e.g., pneumonia, pulmonary edema) or peripheral airway obstruction (e.g., bronchiolitis).

Respiratory Disease Manifesting as Respiratory Distress

Clinical examination is paramount in localizing the site of pathology and creating a differential diagnosis. Extrathoracic airway obstruction occurs anywhere above the thoracic inlet and is marked by inspiratory stridor, retractions, and prolongation of inspiration. In contrast, features of intrathoracic airway obstruction are prolongation of expiration and expiratory wheezing. Typical manifestations of alveolar interstitial pathology are rapid, shallow respirations, chest wall retractions, and grunting (Tables 86.1 and 86.2).

Respiratory Distress Without Respiratory Disease

Although respiratory distress most frequently results from diseases of lungs, airways, and chest wall, pathology in other organ systems can manifest as respiratory distress and lead to misdiagnosis and inappropriate management (Table 86.3). Respiratory distress resulting from heart failure or diabetic ketoacidosis may be misdiagnosed as asthma and improperly treated with albuterol, resulting in worsened hemodynamic state or ketoacidosis. Careful history and physical examination provide essential clues in avoiding misdiagnosis.

Cardiovascular Disease Manifesting as Respiratory Distress

A child with cardiovascular pathology may present with respiratory distress caused by either *decreased lung compliance* or *cardiogenic shock* (Table 86.4). Diseases that result in increased pulmonary arterial blood flow (e.g., left-to-right shunts) or increased pulmonary venous pressure (e.g., left ventricular dysfunction from hypertension or myocarditis, obstructed total anomalous pulmonary venous return) cause an increase in pulmonary capillary pressure and transudation of fluid into the pulmonary interstitium and alveoli. The increased pulmonary blood and water content lead to decreased lung compliance and result in rapid shallow breathing.

It is important to recognize that interstitial lung edema may not only manifest as alveolar fluid but as small airway obstruction as well. **Wheezing** as a sign of congestive cardiac disease is common in infants and young children and should be recognized. Patients with cardiac lesions that result in low cardiac output often present in shock. For example, obstructive lesions of the left side of the heart (e.g., critical coarctation of the aorta) and acquired or congenital cardiomyopathy result in decreased perfusion and metabolic acidosis, as well as respiratory distress because of chemoreceptor and baroreceptor stimulation. The likelihood of a particular cardiovascular illness manifesting as respiratory distress depends on age at presentation (Table 86.5).

Neurologic Disease Manifesting as Respiratory Distress

Central nervous system (CNS) dysfunction can lead to alterations in respiratory patterns and manifest as respiratory distress. Increased intracranial pressure (ICP) may manifest as respiratory distress. Early rise in ICP results in stimulation of respiratory centers, leading to increases in the rate **(tachypnea)** and depth **(hyperpnea)** of respiration. The resultant decrease in arterial blood partial pressure of carbon dioxide ($Paco_2$) and elevation of cerebrospinal fluid (CSF) pH leads to cerebral vasoconstriction and temporary amelioration of intracranial hypertension. Stereotypical respiratory patterns are associated

Table 86.1 Typical Localizing Signs for Pulmonary Pathology

SITE OF PATHOLOGY	RESPIRATORY RATE	RETRACTIONS	AUDIBLE MANIFESTATION
Extrathoracic airway	↑	↑↑↑↑	Stridor
Intrathoracic extrapulmonary	↑	↑↑	Wheezing
Intrathoracic intrapulmonary	↑↑	↑↑	Wheezing
Alveolar or interstitial	↑↑↑	↑↑↑	Grunting, crackles

with dysfunction at various levels of the brain. Cerebral hemisphere and midbrain lesions result in hyperpnea and tachypnea. In such situations, arterial blood gas (ABG) measurements typically show respiratory alkalosis without hypoxemia. Pathology affecting the pons and medulla manifests as irregular breathing patterns such as **apneustic breathing** (prolonged inspiration with brief expiratory periods), **Cheyne-Stokes breathing** (alternate periods of rapid and slow breathing), and irregular, ineffective breathing or apnea (Table 86.6). Along with respiratory changes, other manifestations of CNS dysfunction and increased ICP generally are present, such as focal neurologic signs, pupillary abnormalities, hypertension, and bradycardia (see Chapter 82). Occasionally, severe CNS dysfunction can result in **neurogenic pulmonary edema** and respiratory distress, which may follow excessive sympathetic discharge resulting in increased pulmonary venous hydrostatic pressure and increased pulmonary capillary permeability. **Central neurogenic hyperventilation** is characteristically observed in illnesses such as urea cycle defects and encephalitis. **Bradycardia** and **apnea** may be caused by CNS-depressant medications, poisoning, prolonged hypoxia, trauma, or infection (see Table 86.2).

Toxic Metabolic States Manifesting as Respiratory Distress

Direct stimulation of respiratory centers resulting in respiratory alkalosis is encountered in intoxication involving agents such as salicylates and theophylline. Similarly, intoxication with general CNS stimulants, such as cocaine and amphetamines, may result in increased respiration. Presence of endogenous (e.g., organic acids) or exogenous (e.g., methanol, ethylene glycol, salicylates) toxins causes metabolic acidosis and compensatory hyperventilation, which can manifest as respiratory distress. ABG measurements show decreased pH and compensatory hypocarbia with normal oxygenation. Conversely, metabolic disorders with hyperammonemia cause respiratory alkalosis (decreased $Paco_2$ with increased pH) as ammonia directly stimulates the respiratory centers. Cyanide poisoning and methemoglobinemia may also produce respiratory distress.

Other Nonpulmonary Entities Manifesting as Respiratory Distress

Sepsis and **septic shock** may cause respiratory distress from hypovolemic stimulation of baroreceptors, cytokine stimulation of respiratory centers, and lactic acidosis; they can also lead to **acute respiratory distress syndrome** (ARDS). Other indirect causes of ARDS include systemic inflammatory conditions, trauma, transfusion-related acute lung injury, and pancreatitis. Similarly, renal disease may manifest as respiratory distress by causing metabolic acidosis (e.g., renal tubular acidosis or renal failure) or hypertensive left ventricular failure and fluid overload.

RESPIRATORY FAILURE

Respiratory failure occurs when oxygenation and ventilation are insufficient to meet the metabolic demands of the body. Respiratory failure may result from an abnormality in (1) lung and airways, (2) chest wall and muscles of breathing, or (3) central and peripheral chemoreceptors. Clinical manifestations depend largely on the site of pathology. Although respiratory failure is traditionally defined as respiratory

Table 86.4 Cardiovascular Pathology Manifesting as Respiratory Distress

I. DECREASED LUNG COMPLIANCE

A. Left-to-right shunts

1. Ventricular septal defect, atrial septal defect, patent ductus arteriosus, atrioventricular canal, truncus arteriosus
2. Cerebral or hepatic arteriovenous fistula

B. Ventricular failure

1. Left heart obstructive lesions
   a. Aortic stenosis
   b. Coarctation of the aorta
   c. Interrupted aortic arch
   d. Mitral stenosis
   e. Hypoplastic left heart syndrome
2. Myocardial infarction
   a. Anomalous left coronary artery from the pulmonary artery (ALCAPA)
   b. Ventriculocoronary arterial connections (coronary sinusoids)
3. Hypertension
   a. Acute glomerulonephritis
4. Inflammatory/infectious
   a. Myocarditis
   b. Pericardial effusion
5. Idiopathic/genetic
   a. Dilated cardiomyopathy
   b. Hypertrophic obstructive cardiomyopathy
   c. Takotsubo syndrome

C. Pulmonary venous obstruction

2. Cor triatriatum

II. SHOCK RESULTING IN METABOLIC ACIDOSIS

A. Left heart obstructive lesions

B. Acute ventricular failure

1. Myocarditis, myocardial infarction

Table 86.5 Typical Chronology of Heart Disease Presentation in Children

AGE	MECHANISM	DISEASE
Newborn (1-10 days)	↑ Arteriovenous pressure difference	Arteriovenous malformation (brain, liver)
	Ductal closure	Single ventricle lesions or severe ventricular outflow obstruction
	Independent pulmonary and systemic blood flow	Transposition of the great arteries
	Pulmonary venous obstruction	Total anomalous pulmonary venous return (TAPVR)
Young infant (1-6 mo)	↓ Pulmonary vascular resistance	Left-to-right shunt lesions
	↓ Pulmonary artery pressure	Anomalous left coronary artery from the pulmonary artery (ALCAPA)
Any age	Heart rate disturbance	Tachyarrhythmias or bradyarrhythmias
	Infection	Myocarditis, endocarditis, pericarditis
	Abnormal cardiac myocytes	Cardiomyopathy
	Excess afterload	Hypertension

dysfunction resulting in arterial partial pressure of oxygen (Pa_{O_2}) <60 mm Hg when breathing ambient air and Pa_{CO_2} >50 mm Hg resulting in acidemia, the patient's general state, respiratory effort, and potential for impending exhaustion are more important indicators than ABG values.

Pathophysiology

Respiratory failure can be classified into *hypoxic* respiratory failure (failure of oxygenation) and *hypercarbic* respiratory failure (failure of ventilation). Systemic venous (pulmonary arterial) blood is arterialized through equilibration with alveolar gas in the pulmonary capillaries and is carried back to the heart by pulmonary veins. Arterial blood oxygen and carbon dioxide content are influenced by the composition of the inspired gas, effectiveness of alveolar ventilation, pulmonary capillary perfusion, and diffusion capacity of the alveolar capillary membrane. An abnormality in any of these steps can result in respiratory failure. **Hypoxic respiratory failure** results from intrapulmonary shunting and venous admixture or insufficient diffusion of oxygen from alveoli into pulmonary capillaries. This physiology can be caused by small airways obstruction, increased barriers to diffusion (e.g., interstitial edema, fibrosis), and conditions in which alveoli are collapsed or filled with fluid (e.g., pneumonia, atelectasis, pulmonary edema). In most cases, hypoxic respiratory failure is associated with decreased functional residual capacity and can be managed by lung volume recruitment with positive pressure ventilation. **Hypercarbic respiratory failure** is caused by decreased minute ventilation (i.e., tidal volume multiplied by respiratory rate). This can result from centrally mediated disorders of respiratory drive, increased dead space ventilation, or obstructive airway disease. *Hypoxic and hypercarbic respiratory failure may coexist as a combined failure of oxygenation and ventilation.*

Ventilation-Perfusion Mismatch

For exchange of O_2 and CO_2 to occur, alveolar gas must be exposed to blood transiting in close proximity through the pulmonary capillaries. Both ventilation and perfusion are lower in nondependent areas (upper lobes in upright position) of the lung and higher in dependent areas (lower lobes in upright position). The difference in perfusion ($\dot{Q}$) is greater than the difference in ventilation ($\dot{V}$). Perfusion in excess of ventilation results in incomplete arterialization of systemic venous (pulmonary arterial) blood and is referred to as **venous admixture**. Perfusion of unventilated areas is referred to as **intrapulmonary shunting**. Conversely, ventilation that is in excess of perfusion is wasted; that is, it does not contribute to gas exchange and is referred to as **dead space ventilation**. Dead space ventilation results in return of greater amounts of atmospheric gas (which has not participated in gas exchange and has negligible CO_2) back to the atmosphere during exhalation. The respiratory dead space is divided into the **anatomic dead space** and the **alveolar dead space**. The *anatomic dead space* includes the conducting airways from the nasopharynx to the terminal bronchioles, ends at the alveoli, and has no contact with the pulmonary capillary bed. The *alveolar dead space* refers to areas of the lung where alveoli are ventilated but not perfused. Under normal conditions, this usually occurs in West zone I, where alveolar pressure is greater than pulmonary capillary pressure, thus restricting blood flow. Under clinical conditions, this alveolar dead space may result from dynamic hyperinflation, high levels of positive end-expiratory pressure (PEEP), or large tidal volume in mechanically ventilated patients. Additionally, conditions that cause decreased pulmonary artery perfusion (e.g., pulmonary embolism, decreased cardiac output, hypovolemia) can result in alveolar dead space. The result is a decrease in mixed expired CO_2 (P_{ECO_2}) and an increase in the $Pa_{CO_2} - P_{ECO_2}$ gradient. Dead space as a fraction of tidal volume (V_D/V_T) is calculated as:

$$(Pa_{CO_2} - P_{ECO_2}) \div Pa_{CO_2}$$

Normal V_D/V_T is approximately 0.33. Venous admixture and intrapulmonary shunting predominantly affect oxygenation, resulting in an alveolar partial pressure of oxygen (P_{AO_2}) to Pa_{O_2} ($A\text{-}a_{O_2}$) gradient without elevation in Pa_{CO_2}. This occurs due to greater ventilation of perfused areas, which is sufficient to normalize Pa_{CO_2} but not Pa_{O_2} because of their respective dissociation curves. The relative straight-line

Table 86.6 Respiratory Patterns in Neurologic Disease

INJURY SITE	PATTERN*	COMMENTS
Normal		Variable V_T with normal respiratory pauses and sighs
Cortex		Hyperpnea and tachypnea
Midbrain		*Cheyne-Stokes breathing:* Gradually increasing and decreasing V_T
Pons		*Apneustic breathing:* Prolonged inspiration followed by prolonged expiration
Medulla and pons		*Biot breathing:* Rapid and irregular respirations with pauses

*Pattern tracings represent lung volume over time.
